When amputation is determined upon, in these and similar accidents, the next question is, when should the operation be executed? Shall it be performed immediately, or shall we wait until some time has elapsed, until, in short, the system has had an opportunity of recovering from the shock of the injury? To use the knife while the patient is in an exhausted, pallid, and perhaps almost pulseless condition, would only serve the more certainly and effectually to seal his fate; the additional shock to the constitution resulting from the loss of blood and nervous fluid could hardly fail to prove most disastrous. Hence the rule is to postpone a resort to the knife until there is satisfactory evidence of reaction; until, in a word, warmth and color return to the surface, the pulse beats vigorously at the wrist, and the sufferer regains, in some degree, his consciousness and courage. Now the use of chloroform is well borne, and the limb is removed with comparative impunity. On the other hand, care is taken not to wait until the part and system are assailed by inflammation, which, under such circumstances, often extends with frightful rapidity, placing the case, perhaps, literally beyond the resources of surgery in the course of a few hours. There is, therefore, a time when interference must be avoided, not less than when it must be courted. The limits of these two periods are not always well defined, and hence much must be left, in each individual case, to the judgment of the attendant.

An amputation, performed immediately after reaction has taken place, is usually designated by the prefix "primary," while the term "secondary" is used to denote the operation when it is executed after the limb has passed through the different stages of inflammation, an attempt having been made, perhaps well grounded, so far as the interpretation of the symptoms is concerned, to save the parts. Such a contingency must necessarily happen rather frequently, especially in civil practice; indeed, it is often altogether unavoidable on account of the obstacles interposed by the patient and his friends, not to say anything of the wavering and indecision of the professional attendant. But, although often unavoidable, such an occurrence is always much to be regretted; for if the chances of saving limb and life were bad in the first instance, they are now generally much worse; the system has been impaired by fever and perhaps hectic irritation, the secretions are seriously deranged, the patient has little appe-

tite and sleep, the blood is thin and watery, and the whole body is much emaciated. Life may possibly still be preserved, but the probability is that the operation will be attended with much risk, and that ultimate recovery is far off. Moreover, a much larger amount of limb may now have to be sacrificed; originally a foot might have sufficed, whereas now, in consequence of the ravages of the inflammation, the whole leg may require removal. There is, then, obviously an advantage in a primary over a secondary amputation, provided it is performed at the proper time, that is, after the establishment of reaction and before the occurrence of inflammation; and this circumstance is often eagerly embraced by the military surgeon, whose will is always law with his patients.

In addition to these divisions, some writers speak of what they term an "intermediary" amputation, performed either immediately, or soon, after the super-vention of inflammation, and consequently before the establishment of suppuration. The distinction was first made by Boucher, in the last century, in a memoir addressed to the French Academy, and was subsequently adopted by Guthrie, Alcock, and other military surgeons, in the early part of the present. Such an amputation is unquestionably the very worst that can be selected, inasmuch as it is performed at a period when the part and system, assailed by inflammation and fever, are ill able to bear up under its effects. Hence the mortality must necessarily be much greater than after either of the other procedures; and yet it is easy to perceive that cases might arise, both in private, hospital, and military practice, where it would be perfectly unavoidable. Accidents, as gunshot, railway, and other injuries, of the very worst character, must often occur under circumstances in which the patient is either neglected, or where it is impossible to remove the mutilated parts before the occurrence of inflammation and symptomatic disturbance. The moment the surgeon sees the case it is obvious at a glance that amputation is necessary; there is no other chance for the patient's life; nor is any time to be lost. Mortification is either impending, or has already taken place, and in a few hours the case may be wholly beyond the reach of the knife. Here there is no choice. Operative interference is compulsory and imperative. In estimating the mortality of primary and secondary amputations it is very important to exclude the intermediary, otherwise the calculations must lead to error.

2. *Mortification*.—Mortification, in whatever manner induced, necessarily imperils limb and life, and therefore often becomes a subject for amputation. Hence the question arises, under what circumstances is a resort to the operation advisable and proper? This question can only be answered satisfactorily by a consideration of the nature of the mortification. In the chapter on mortification there is an account of the several varieties of this affection, the causes under whose influence they take place, their symptoms, and the means required for their relief. By a reference to that portion of the work, it will be found that, as it respects the operation under notice, the great rule, recognized by nearly all practitioners at the present day, in acute gangrene, is, to wait for the formation of a line of demarcation between the dead and living parts, on the ground that it is not generally safe to interfere sooner, lest the disease should reappear upon the stump, and thus destroy the patient, or necessitate a repetition of the amputation. Of the propriety of this rule there can be no question, for there is no surgeon of experience who has not witnessed its beneficial effects in his own practice, as well as in that of his friends, and yet it is equally true that it may occasionally be violated with great advantage. But I would apply to these cases the term "exceptional," comprising under this head those attacks of mortification which are so apt to supervene upon inflammation from external injury, as wounds, fractures, and dislocations, which often spread with immense rapidity, hopelessly overwhelming, if they are not promptly arrested, both the part and system in a few hours. It will not do for the surgeon, in such an emergency, to fold his arms and become an idle spectator; he must have his eyes and wits about him, or his patient will be irretrievably lost; whatever is done must be done quickly. The wished-for line of demarcation will be looked for in vain; the gangrene will rapidly extend to the trunk, and death must soon close the scene. But in spontaneous

mortification, or in mortification from erysipelas, carbuncle, and analogous affections, the judicious surgeon waits for the arrest of the morbid action, his chief care being to bring about this event as speedily as possible by appropriate local and constitutional measures. His rule of action is the same in hospital gangrene; in both cases means are employed for supporting the system, or, what is equivalent to the same thing, for improving the condition of the fluids and solids, and the knife is used only when the line of circumvallation is fully established, not a minute before.

In senile, chronic, or dry gangrene, the result usually of ossification of the arteries and of their occlusion by fibrinous concretions, thus depriving the tissues of their due supply of blood, the rule has heretofore been to wait for the cessation of the mortification, experience having shown that, when this precaution is neglected, the disease will be certain to reappear in the stump. It is in view of this relapsing tendency in mortification that some surgeons, of great eminence and experience, have given it as their judgment that the case should always be left entirely to nature's efforts; in other words, that we should wait for spontaneous amputation, shaping the stump after the sloughs have been nearly completely detached, when, it is alleged, the part and system will be better prepared to withstand the shock of the knife. The propriety of such advice is sufficiently obvious when it is considered that this disease occurs nearly always in very old and infirm subjects, and that it is essentially dependent upon obstruction of the arteries leading to the affected structures. Such individuals, as I know from personal observation, are usually very feeble, and have, consequently, very little power of resisting the effects of shock or loss of blood. They often rapidly sink after the operation, even when there has been a distinct line of demarcation, or that the disease speedily reappears upon the stump, and soon destroys life secondarily. When we reflect how common these events are, would it not be wise, in these cases, to amputate early at a great distance from the disease, ere yet the vital powers have been seriously assailed by the morbid action; to remove, for instance, the thigh at its middle, for senile or chronic gangrene of the toes and foot? The only objection to such a procedure, it seems to me, would be where the occlusion of the main artery of the limb reaches above the knee. When no such disease exists, and the general health has not materially suffered, I should not hesitate to resort to the expedient, under the conviction that, however severe, it was perfectly justifiable in a class of cases so unpromising as this confessedly is.

3. *Morbid Growths*.—Amputation is sometimes required on account of morbid growths, or tumors, both benign and malignant. The removal of the forearm is perfectly proper for the cure of carcinoma of the hand, and of the arm at the shoulder for a similar affection of the humerus. No such operation is of course admissible if there is marked constitutional involvement, enlargement of the neighboring lymphatic ganglions, or decided tendency to ulceration; the propitious period has gone by, and interference would only hasten the fatal event. It is not so, however, as long as the general health remains good, and there is no evidence of general or local contamination; under such circumstances there is a strong probability that removal of the limb, although it may not prevent a recurrence of the disease, may yet considerably prolong the patient's life.

A tumor, wholly divested of malignancy, may, in consequence of acting obstructingly, cause so much functional and other disturbance as to demand removal of the limb upon which it is situated. The procedure will be particularly called for when the morbid growth is intimately connected with a bone, or deeply and inseparably involved in the soft parts, or prolonged into an important joint, compelling free exposure of its surfaces during the operation. A valuable rule in tumors is to excise the benign, and to get rid of the malignant by amputation.

4. *Aneurism*.—A neglected aneurism, seated in the extremities, and unamenable to ordinary treatment, occasionally calls for the removal of a limb; in former times, such operations were sufficiently frequent when the disease occupied the popliteal region, though at present they are seldom, if ever, required, except when morti-

fication sets in after ligation of the femoral artery, or from the injurious compression exerted by the tumor upon the leg.

5. *Affections of Bones and Joints.*—Various affections of the bones and joints, as caries, necrosis, morbid growths, aneurism, and ankylosis, may impose the necessity of amputation; and there is, according to my experience, no class of diseases in which the operation has been more frequently abused, or misapplied. There can be no question that many a limb, merely temporarily crippled by remediable disease, has been ruthlessly sacrificed to ignorance and a desire for eclat; carious joints, now that excision has been revived, can seldom demand so harsh a procedure, and, as to necrosis, pure and uncomplicated, it is difficult to conceive of a case justifying the use of the knife. It is only, or mainly, in white swelling, or scrofulous disease of the knee, ankle, and elbow, attended with hectic irritation, excessive pain, and exhausting diarrhoea, that the removal of a limb can be proper, and even then it should not be thought of if it be possible to exsect the affected structures without imperilling life by shock and loss of blood. In whatever manner the offending parts are disposed of, it is surprising to witness the great improvement which usually follows the operation; the profuse sweats and alvine discharges rapidly disappear, the appetite improves, the sleep becomes refreshing, and the patient soon regains his flesh and strength. Unfortunately, the operation is generally put off to an unreasonable period, so that, when it is at length performed, the sufferer too frequently sinks under its effects.

Of malignant growths of the bones almost the only one demanding amputation of the limbs is encephaloid; scirrhus, melanosis, and colloid are extremely infrequent in the osseous tissue, but whenever they occur, and their diagnosis can be determined, the same treatment must be applied to them as to medullary cancer; that is, early and thorough removal by the sacrifice of the suffering extremity, mere excision being always inadequate by reason of the involvement of the soft parts. Temporary relief only is aimed at; sooner or later the disease recurs, either at the cicatrice, or in some neighboring organ, and carries off the patient.

Fibrous, fibro-plastic, cartilaginous, and osseous growths, involving the bones, sometimes constitute a legitimate ground for amputation. An exostosis, of enormous size, and grotesque form, may render an extremity not only perfectly useless, but a source of the greatest inconvenience and even suffering. The so-called osteo-sarcomatous tumors are, perhaps, of all the morbid growths of the skeleton, the most common causes of amputation of the limbs. Aneurismal formations of the osseous tissue, met with chiefly in the head of the tibia, nearly always demand the same remedy.

Finally, amputation may be required on account of ankylosis of a joint, interfering with the comfort and usefulness of the extremity. Thus, in ankylosis of the knee, the leg may stand off at a right angle with the thigh, so as to interfere materially with the occupation of the individual, and induce a wish for an artificial limb, which, if well constructed, is generally worn with great satisfaction. Stiff and crooked fingers and toes are often the subjects of amputation.

6. *Ulcers.*—Amputation is sometimes performed on account of old and inveterate ulcers of the extremities; the operation, however, is less frequently resorted to now than formerly, and might, with proper management, be almost entirely dispensed with. Unless the sore is of a cancerous character, or caused by burns, scalds, and frost-bites, or complicated with serious lesion of the bones, excessive enlargement of the veins, or great hypertrophy of the integuments, there are few cases, it seems to me, that will not gradually yield to judicious treatment. Of the numerous ulcers of the extremities that have fallen under my observation, embracing, of course, many of the worst description, I have a distinct recollection only of three that required this harsh measure. Whether other practitioners have been equally fortunate I am not able to state; but, judging from the reports of cases in our periodicals, it is highly probable that the operation is still not unfrequently performed on this account.

7. *Malformations.*—There are certain malformations and deformities for the relief of which amputation may be demanded. An irremediable club-

cially if complicated with a painful bunion, an intractable ulcer, or excessive atrophy of the leg, would form a proper subject for such an operation; for there are few men who would not rather run the risk attending its performance than to be incessantly fretted and worried by such a disagreeable and useless companion. Supernumerary thumbs and fingers are disposed of in a similar manner; the operation is usually done within a few months after birth, and I have never known it to be followed by any bad consequences. Amputation is occasionally necessary on account of deformity caused by burns and scalds, or badly treated fractures and luxations.

8. *Tetanus*.—The propriety of amputating in tetanus has been so long doubted by many of the highest authorities in surgery that the question hardly merits serious consideration in a work of this kind. I have certainly not seen anything in my own practice tending to contradict an opinion now almost universally entertained by the profession in this and other countries. If such a measure is ever justifiable, it must be at the very commencement of the disease, before the supervention of the characteristic symptoms. I have seen a very considerable number of instances of acute traumatic tetanus, and, with one solitary exception, they have all proved fatal. This case occurred in a stout, well-fed countryman, aged fifty years, the fore and middle fingers of whose right hand had been badly mashed by the passage of the wheel of a wagon; symptoms of tetanus came on upwards of a month after the accident, and, although the disease had existed for five days when I amputated at the metacarpo-phalangeal articulation, yet complete recovery followed, not, however, without a slight continuance of the spasms for a short time after. I presume a practitioner would hesitate to cut off a large limb after the development of tetanus in any case; for, whatever notions we may entertain respecting the pathology of this affection, there can be no doubt that, once fully established, it must be looked upon as a constitutional disorder in the widest sense of that term.

SECT. III.—METHODS OF AMPUTATION.

Two principal methods are in vogue for performing amputation of the limbs, whether in their continuity or at the joints. These are the circular and the flap, both of which, but especially the former, are of ancient date, and therefore well grounded in the esteem of the profession. To these was added, early in the present century, the oval operation, which, although excellent in its way, has hitherto received but little attention; certainly less than it deserves. Very recently, an operation, termed the rectangular, was also proposed. It is not my object to enter into the history of these different methods, for to do so would carry me back into the regions of doubt and speculation; but it will be expected that I should offer some remarks concerning their respective advantages and disadvantages, and this I shall endeavor to do in as concise and impartial a manner as may be consistent with the great interest and importance of the subject.

1. *Circular Method*.—The circular operation, the most ancient of all, was originally performed in the most simple manner, the integuments, muscles, and bones being all divided upon the same level. The consequence of this procedure was that the bones, being inadequately covered by the soft parts, or, rather, not covered at all, invariably perished to the distance of several inches, thus sadly protracting the cure, besides subjecting the patient to much suffering and not a little risk in the interval. As surgeons became more enlightened, they endeavored to provide against this contingency by forcibly pulling back the muscles, by means of a peculiar contrivance called a retractor, before using the saw, which was then applied close to the surface of the tissues. At a later period still, and as a decided improvement upon the preceding methods, arose the plan of double incision, devised by Cheselden, better known for his success as a lithotomist than for his exploits as a general operator. It consisted, as, indeed, the name sufficiently indicates, of two stages, in the first of which the integuments were cut and drawn back, while in the second the muscles were divided higher up, the object being to afford more thorough protection to the bone. The opera-

tion of the English surgeon has undergone various modifications, some of which, having only served to render it more complex, have been justly discarded from practice. To this category belong the division of the muscles by two circular incisions, one higher up than the other, and the plan of scooping out the parts as the knife was being swept obliquely round them by cutting from below upwards and from without inwards towards the bone, which thus formed the apex of the hollow cone.

The circular operation, as now generally practised, consists, first, in dividing the common integuments, dissecting them from the parts beneath, to a variable extent, and then drawing them back, or even turning them up like the cuff of a coat; secondly, in cutting through the muscles on a level with the retracted skin, and, after detaching them for some distance from the bone, holding them also forcibly back; and, thirdly, in sawing off the bone as high up as possible without doing violence to the soft structures. In executing these several stages of the proceeding a long amputating knife, poised lightly between the thumb and fingers, is carried rapidly round the limb, the point being inserted into its anterior surface, external to the median line, and thence drawn towards the operator in such a manner that the heel of the instrument shall finish the incision. The wound thus made extends simply down to the aponeurosis, and care should be taken that it occupies the same level throughout, unless there be special reasons for carrying it higher or lower at one point than at another, rendered necessary, it may be, by the presence of a vicious cicatrice, ulceration, gangrene, or some morbid growth. The flap is then rapidly dissected up either with the same instrument, or a large scalpel, and held out of the way, its length being regulated by the thickness of the limb, about two inches being a good average. The amputating knife being now resumed, and held as before, is applied closely to the edge of the retracted integuments, and then drawn round the member so as to divide all the muscles down to the bone, as represented in fig. 160. This part of the operation is usually the work of a few seconds. The next step is to separate the muscles carefully from their connection to the bone, to the distance of at least an inch and a half, if not more, when, being pressed forcibly back by means of a retractor, the bone is sawed off close to their surface. The adjoining cuts, figs. 161 and 162, afford a good illustration of the appearances of the limb, both below and above the stump, after this operation.

In sawing the bone, whether in this or in the flap operation, it is an object of primary importance to inflict as little injury as possible upon the periosteum; for the less the integrity of this membrane is disturbed the less likelihood will there be of necrosis and other bad consequences. When the periosteum is very thick, as in the thigh-bone, it would be well, in view of this circumstance, to make a circular track in it for the saw, in order that there may be no risk of laceration. The manner of dividing the bone is a matter of some moment. In most of the amputations that I have witnessed the instrument was applied against the front of the bone, instead of being held perpendicularly so as to divide the bone from side to side, as it generally should be to avoid fracture, which is so liable to happen if proper care is not taken to support the limb in this stage of the procedure. Particular rules are usually laid down by authors for working the saw. Thus, it is generally stated that the heel alone of the instrument should be used until a track is made for it to move in; but I consider all such directions to be unnecessary, if not frivolous. If the saw is properly set it is of little consequence, according to my experience, what part is applied first or last, or whether it is moved rapidly or slowly, although, as a ma

Fig. 160.

Circular amputation shown in the leg, the integuments being turned back, and the muscles divided down to the bones.

choice, I should prefer to finish the operation as quickly as possible. When there are two bones of equal size to be cut, as in amputations of the forearm, they

Fig. 162.

Fig. 161. Appearance of the limb below the seat of the amputation, in the circular operation.

Fig. 162. Appearance of the stump in the circular amputation.

should be divided simultaneously; but if one is thicker than the other, as in the leg, the weaker must always be severed first, lest, if it should remain until the other is sawed through, it should be broken or splintered, and so impose the necessity of employing the nippers to smooth off its extremity.

When a limb is removed at a joint, the best plan, as a general rule, is to dispense with the use of the saw and pliers altogether, experience having shown that the preservation of the articular cartilages greatly favors the adhesive process, and thereby expedites the cure. Sawing off the ends of the bones exposes the parts to suppuration, erysipelas, caries, necrosis, and even to the danger of pyemia.

2. *Flap Method.*—Although the flap operation was described, and no doubt practised, by some of the earlier surgeons, yet it does not seem to have received any particular attention until towards the close of the seventeenth century, when Lowdham, of Oxford, England, published a short tract upon it, setting forth its advantages over the circular method. After this period, it was occasionally performed in different parts of Europe, especially in France and England, but it never fully acquired the confidence of the profession until the time of Mr. Liston, whose teachings and writings brought it into general notice.

There are several methods of forming the flaps, the choice of which must be regulated by the particular circumstances of each individual case. Thus, the operation may be performed by transfixion of the limb, and cutting from within outwards; by commencing at the surface, and carrying the knife inwards towards the bone; or, lastly, by making one of the flaps after the former fashion, and the other after the latter. In amputations of the thigh and arm, it is customary to make both flaps by transfixion, as the operation is thus greatly simplified and rendered more expeditious; but in the forearm, hand, fingers, leg, foot, and toes, they are formed either by cutting inwards, or one by cutting inwards and the other by cutting outwards. The number of flaps varies; in general there are two, but occasionally there is only one, and, on the other hand, there may be as many as three; accident, or the situation and structure of the limb, rendering one of these modes preferable to the other. Thus, in one instance, I amputated the thigh at its middle by a solitary flap, and succeeded in effecting an excellent cure. The military surgeon is often compelled to form his flaps as best he can, owing to the manner in which the soft parts are injured, and in civil practice the

icuity sometimes occurs in consequence of the effects of disease. Whatever be the nature of the case, the rule is never to include any unsound or any portion of bone that is fractured or divested of periosteum. In amputating the thigh and arm at their middle, the flaps are generally cut of the same length; but in most other situations one is usually made considerably longer than the other, depending upon the greater amount of muscular substance. The relative length must be regulated by the thickness of the limb, and the elasticity, laxity, and contractility of the soft parts. It is better, in every case, to have too much substance than too little, but the judicious surgeon will always regulate so to cut his flaps as to have just enough, and no more, to form a well-shaped and useful stump, redundancy being always unseemly, if not actually in the way of comfort and convenience. As a general rule, their length should be about three-fourths of the diameter of the limb, being invariably greater than in a similar operation upon the dead subject, to allow for contraction and relaxation. The form of the body of the flaps is commonly somewhat convex, and the extremity is more or less oblique, care being taken that they do not become too thin, narrow ends, and that there is always an abundance of integument which they are adjusted over the bone. When the muscular tissue is unobundant, as often happens in amputating through the calf of the leg, it is found it advisable to retrench it with the knife, in order to give the stump a more evenly shaped surface, as well as to place it in a better condition for bearing the weight of an artificial limb.

In performing the operation the same general rules are to be observed as in the circular method; hemorrhage is restrained by the same means, and the skin is drawn back by the hands of an assistant, who also retracts the flaps as one flap is made, and thus holds them out of the way of the knife and saw. Important vessels that may be bleeding are instantly compressed by the finger until they can be tied. Before applying the saw the knife is passed around the bone so as to divide every muscular fibre, and also, if possible, the periosteum. The most suitable instrument for removing the larger bones is a long amputating knife; for the smaller ones, an ordinary scalpel, bistoury, or catlin will answer best. Separation of the member having been effected, the vessels carefully secured, the next thing to be done is to cut off the nervous trunks a little above the level of the surface of the stump, and, as this operation is one of excessive pain, it should always be performed before the patient has fully recovered from the influence of chloroform. I need not insist upon the importance of thus dealing with the nerves involved in the flaps; the necessity of the procedure must be obvious upon the slightest reflection. When considered that they always become more or less enlarged and bulbous after amputations of this kind, it is easy to perceive what would be the consequence were they brought in contact, as some of them almost inevitably would be, with the extremity of the bone, before it has had time to become rounded off. In the circular amputation by the flap method as being finished unless provision has been made against such a contingency. The adjoining cuts, figs. 163 and 164, show the appearances of the stump and of the limb after its removal.

Oval Method.—In the oval method, as it is termed by Scoutetten, by whom it was first generalized, or the oblique process, as it has been called by others, the flap has somewhat of the shape of an ovoid, the small extremity of which is directed towards the bone or joint which is the seat of the amputation. The operation is a kind of intermediate position between the other two, resembling the circular process in the mode of incising the soft parts, and the flap in the form of the circular method. It is more especially adapted to amputations of the joints, particularly the smaller, as, for example, the metacarpo-phalangeal, but has also been applied to the joints of the hip and shoulder, especially by Guthrie, Larrey, and Scoutetten, who have devised plans which severally bear their names.

In the oval operation the flaps are formed by cutting from without inwards, or from within outwards, and the other by cutting in the opposite direction, or from within outwards. It is commenced by making two incisions, the first of which, after the letter V reversed, the angle of union falling at the

it is intended to saw the bone or effect disarticulation. These incisions are, of course, extended as far as the periosteum, when the knife, drawn closely round

Fig. 163.

Fig. 164.

Fig. 164. The corresponding stamp; intended to exhibit the comparatively small extent of wound that remains.

behind the bone, is carried downwards on a level with the termination of the two cuts already made, thus connecting them by one thrust, as the instrument sweeps through the intervening tissues. By adopting this plan of procedure the surgeon will have it in his power to leave the principal vessels and nerves until the operation is nearly completed, a circumstance which thus affords him a much better control over the hemorrhage.

The oval operation usually makes an excellent stump, there being always an abundance of material for covering the bone; it is generally a little more tedious than the flap amputation, but this should not be urged as an objection to it, as in all other respects the result is most satisfactory.

4. *Rectangular Flap.*—Mr. Teale, of Leeds, in 1855 modified the double flap operation by substituting a long and a short rectangular flap. The long flap should be made from the portion of the limb which does not contain important bloodvessels and nerves, these being included in the short one. Before proceeding to the operation, the lines of the incision should be traced with ink, in order

Fig. 165.

Teale's amputation, shown in the thigh, the lines indicating the size and form of the flaps.

to insure the proper dimensions of the large flap, which should be equal, in its length and breadth, to one-half the circumference of the limb at the point amputated. The short flap, which should be made last, must be one-fourth the length of the long one. The lines of incision and the length of the flaps will be more easily understood from the annexed cut, fig. 165 representing an amputation of the thigh. The parts having been dissected off, in close contact with the periosteum, the long flap will be found to be perfectly square, and to contain a sufficient amount of movable soft parts to form a complete cushion for the end of the bone, which must be sawn off perfectly straight, and must be free

the end of the bone, which must be sawn off perfectly straight, and must be free

from spicules, in order to prevent ulceration of the soft structures. The arteries having been taken up, the long flap is brought down over the end of the bone, and attached to the short one by several points of the interrupted suture. The short flap is also attached to the long flap laterally, as is also the reflected portion of the long flap to its unreflected portion. The appearances of the parts, when brought together, are shown in fig. 166.

Fig. 166.

Teale's operation, the flaps being drawn together.

Beside the sutures no other dressings are employed. The stump is placed on a pillow covered with a sheet of gutta-percha, and is protected by a wire cage from the pressure of the bedclothes. Should the wound gape during the process of union, a few adhesive strips may be applied, to give the flaps proper support.

Absolute rest is enjoined; and the stump should not be disturbed for several days, the discharges being removed from the parts and the gutta-percha cloth by a soft sponge.

There is no doubt that the rectangular operation makes an excellent stump, furnishing an abundant covering for the bone; but, although this is true, my opinion is that it does not possess any advantages whatever, in ordinary cases, over the common flap amputation, and hence I can perceive no reason for its general adoption. Unless great care is taken in forming the flaps, and in superintending the after-treatment, there will be danger of non-union, if not also of sloughing, from inadequate nervous and vascular supply.

Mr. Teale, in 1861, published the results of 103 cases of rectangular flap amputations, of which 84 were cured, and 19 died, or in the ratio of 1 in 5.4. Of the whole number 35 were of the thigh, and of these 11 died; 37 were of the leg with a mortality of 4; 14 of the arm with 4 deaths; and 17 of the forearm without any deaths. On comparing these results with those of other amputations, it will be seen that the mortality is very slightly in favor of the rectangular method. It should be added that all the operations were performed at the Leeds General Infirmary by Mr. Teale and his colleagues, Mr. Smith and Mr. Hey.

SECT. IV.—OPERATION AND AFTER-TREATMENT.

The position of the patient and the surgeon, the number and duties of the assistants, and the character of the instruments, must necessarily vary in different cases and under different circumstances, and can therefore be pointed out here only in a general manner.

Whenever it is practicable, the patient should be placed recumbent, as he will thus be much less liable to become faint, and at the same time bear the effects of chloroform much better than when he sits up. He may, however, put himself in the latter position without any inconvenience during the amputation of a finger or toe, or even of the arm or leg, if he is courageous, and willing to dispense with chloroform, or to take ether in its stead. The limb, well shaved, is generally held horizontally, away from the table, one assistant retracting the integuments, and another supporting the portion to be removed. A third assistant takes charge of the tourniquet, but before applying it care is taken to empty the superficial veins by raising the limb and pressing it from above downwards: or, instead of this, the extremity is tightly bandaged just before the operation. Such a precaution, however, is of material moment only when the patient is very feeble, and therefore ill able to bear the loss of blood. Chloroform having been administered, the instrument is firmly secured round the limb, the frame resting upon a

thick, narrow compress, lying directly over the main artery, and, when all pulsation is arrested, the operation is proceeded with in as rapid, orderly, and careful a manner as possible. When the amputation is performed high up near the trunk the tourniquet may advantageously be replaced by the compression of the hand of an assistant, who trusts either to his thumbs alone, or else makes the requisite pressure by means of the handle of a stout key, wrapped round with a piece of muslin. The same plan for restraining hemorrhage is adopted in amputating the hip and shoulder-joints. In separating a large limb, not less than five assistants are generally necessary; one for administering chloroform, a second to take charge of the tourniquet, a third to hold up the flaps, one to support the distal portion of the member, and a fifth to hand the instruments and sponges, and aid in securing the arteries. A smaller number will of course suffice when we remove a finger or other insignificant part.

The different methods of amputation are described in the preceding section. The one which I prefer is that by flap, though a most excellent stump may also be made by the circular operation. The rectangular method is well worthy of attention, as the arrangement of the long flap not only thoroughly protects the bone, but, what is of great consequence, admits of ready drainage. The oval operation is admirably adapted to amputations at the joints and to resections of the bones.

My reasons for preferring the flap to the circular operation, are, first, because it is more simple and easy of execution; secondly, because it makes, as a general rule, a much better covering for the bone; and, lastly, because the patient experiences much greater comfort in wearing an artificial substitute.

During the sitting of the commission appointed by Surgeon-General Hammond to report on the subject of artificial limbs, convened at New York, in 1862, upwards of a dozen manufacturers, then present, unanimously assured me that stumps made by the circular operation are, as a general rule, in every respect, inferior to such as are made by the flap method; that it is much more difficult to fit them with an artificial substitute; and that they are a great deal more liable to become chafed, irritated and ulcerated. The results of my own observations are precisely of the same character. I have been at much pains, by visiting some of our military hospitals, to inform myself personally of the comparative merits of the two operations, and, from all that I have witnessed, the preponderance is vast in favor of the flap method. Dr. R. J. Levis, surgeon in charge of the government hospital in this city for the cure of bad stumps, bears similar testimony.

Fig. 167.

Petit's tourniquet.

The principal instruments required for the operation are, for the larger limb a tourniquet, an amputating knife, a call, saw, and pliers, which are properly arranged upon a tray in the order in which they may be needed. For removing the fingers, hand, toes, and foot, an ordinary scalpel will commonly suffice. The tourniquet in general use is that of Petit, the construction and arrangement of which may be readily learned from the annexed sketch, fig. 167, a circumstance which, besides the fact that it is found in every cutler's shop, renders an formal description of it unnecessary.

The tourniquet of Petit was recently modified by Mr. Tiemann, of New York in such a manner as to concentrate much greater amount of pressure upon the artery, at the same time that it does not embarrass the venous circulation. The pad is placed either horizontally or

crosswise upon the vessel, and the strap, carried round the limb, is passed through the two side apertures in the metallic plate, after which the ends are drawn very tight, and fastened on the protruding hooks. The arrangement of the different pieces of the instrument is seen in fig. 168.

Fig. 168.

Tiemann's improved tourniquet.

Fig. 169 represents an arterial compressor which I devised in 1856, as a convenient substitute for the ordinary tourniquet, over which, I conceive, it possesses several decided advantages; first, in the facility of its application; secondly, in the amount of pressure which it is capable of exerting; thirdly, in its ready adaptation to limbs of different dimensions; fourthly, in the circumstance that it makes pressure only at two points, that is, over the artery, and at the spot

Fig. 169.

Author's artery compressor.

immediately opposite to the artery; and, lastly, the facility with which it may be slackened or removed at any stage of the operation. With a little modification, the instrument may readily be adapted to the femoral artery as it emerges from beneath Poupart's ligament, or even to the external iliac just above this ligament, in amputation at the hip-joint, and also to the axillary artery, in disarticulation of the shoulder-joint.

By a reference to the cut, it will be seen that the instrument is composed of two blades, differing in the degree of their curvatures, united by a screw, and regulated by a ratchet. Each short blade is provided with a pad, capable of being worked by a screw, and designed to rest upon the artery which it is intended to compress. By this arrangement two tourniquets are produced: a large one for the thigh, and a small one for the arm, or the thigh of a small subject.

The ordinary amputating knife, fig. 170, is from nine to twelve inches in length, by about five lines in width, with a moderately thick back, spear-pointed, and furnished with a stout, rough, ebony handle to prevent it from dropping out

Fig. 170.

Amputating knife.

the hand if it should become smeared with blood. The principal edge should extend the whole length of the blade, and be in the best possible condition for executing its important office, well tempered, and perfectly sharp. The edge upon the back should not be longer than an inch and a half. With such an instrument, properly managed, nearly all the amputations in the body may be

performed with great neatness and celerity. The catlin, shown in fig. 171, is a double-edged knife, used principally in removing the forearm and leg, and for

Fig. 171.

Catlin, or double-edged knife.

dividing the interosseous muscles and ligaments; I cannot see, however, that it possesses any special advantage, even in these cases, over the larger knife just described.

Every amputating case contains a large saw, resembling the common dovetail saw of the cabinet-maker. The adjoining sketch, fig. 172, represents the

Fig. 172.

Amputating saw.

form of the instrument which I am myself in the habit of using. The blade, which is very firm, is ten inches and a half in length at the cutting edge, by two inches and one eighth in breadth, exclusive of the back, which is very thick and convex, in order to afford the proper degree of strength which such an implement should always possess. The handle is rough, and sufficiently large to receive two fingers, while the thumb and forefinger are applied to its surfaces, parallel with the upper border, to keep it steady while engaged in the discharge of its duty. The teeth are rather large but sharp, and set crosswise on the edge, that the instrument may not hang or hitch as it works its way through the bone. The manner of using the saw has already been described.

A small saw, such as is represented in fig. 173, will be of great service in amputations of the hand and foot.

Fig. 173.

Small amputating saw.

Cutting-pliers, seen in fig. 174, of various sizes and forms, must be at hand and they should be short but rather slender in the blades, and very long and strong in the handle.

Fig. 174.

Bone nippers.

in the handle. Although I never use these instruments when it is possible to employ the saw, on account of their tendency to bruise the osseous tissue, they are of great convenience for removing sharp spicules, and cutting off c

tain pieces of the skeleton, as the phalanges of the toes and fingers, the ribs, and jaws.

The limb being removed, and the nerves, if necessary, retrenched, every bleeding artery is promptly secured, commencing with the main trunk and then tying up successively each smaller branch until the flow of blood is effectually arrested.

Not a little trouble is often experienced in checking the flow of blood from the veins, especially in amputations of the thigh and leg. When this is the case, the bleeding vessels may either be tied in the same manner as an artery, compressed by means of a long needle, as in ordinary acupuncture, or occluded with a very small pair of forceps, as proposed by Mr. G. H. Porter, of Dublin, the instrument being removed at the end of forty-eight hours. Great prejudice exists against ligating veins, but experience has shown that the fears that are entertained upon this subject are, if not entirely ill-founded, greatly exaggerated. The largest veins, as the internal jugular and femoral, have repeatedly been tied with impunity. I have myself never hesitated to adopt this treatment when occasion seemed to demand it; and in a paper in the *New York Medical Times* for March, 1864, Dr. S. W. Gross has related three cases of amputations of the thigh in which not a single untoward symptom followed the operation.

After-Treatment.—As it respects the permanent dressings after amputation, they should be of the lightest and most simple character. In the larger operations they should not, as a general rule, be applied under four or five hours, by which time the surfaces of the wound will usually be glazed with lymph, and all danger of hemorrhage be past. I can conceive of nothing more awkward for the surgeon or more disagreeable to the patient, than the necessity of undoing the dressings, some hours after the removal of a limb, for the purpose of searching for bleeding vessels. Such a procedure is sure to cause alarm and suffering; and, although it is always desirable to complete the dressings as early as possible in ordinary cases, yet after a large amputation, involving vast and numerous muscles liable to conceal arteries of considerable size, I regard it as a matter of great consequence not to hazard the necessity of their removal. During the period that intervenes between the operation and the permanent dressings, the limb should be placed in an easy, elevated position, and the flaps should either be loosely approximated with a few adhesive strips, or, what is better, left apart, and covered with light compresses wet with cold water, and frequently irrigated; not changed, unless soaked with blood, as this would only lead to exposure and irritation of the parts.

The rules here laid down are chiefly applicable to amputations in civil practice. In operations of this kind performed on the battle-field no such delay is of course admissible.

All bleeding and danger of bleeding having ceased, the flaps are carefully stitched in place, the ligatures are brought out at the nearest points, and the intervals between the sutures are covered with long and rather narrow strips of plaster, to admit of proper drainage. This should be still further favored, when the breach is very large and deep, by the insertion of a slender tent in the lower angle of the wound, and by strict attention to the position of the stump. To a want of these precautions are unquestionably to be ascribed some of the bad effects of these operations, as pyemia, profuse suppuration, and the death of the extremity of the bone. The wound being firmly closed at all points, the matter, of which there is nearly always more or less after all large amputations, accumulates in the depths of the stump, around the bone, and among the muscles, thus causing necrosis of the former, and affording the veins and lymphatics of the latter an opportunity of conveying the fluid into the system, and thereby inducing secondary abscesses. Now, all this risk may be effectually prevented by adopting the plan here suggested of keeping a long, slender, and well-oiled tent in the lower part of the wound for the first thirty-six or forty-eight hours; at the end of this time, it may be carefully removed, and any pus that may be present gently pressed out. A gum-elastic tube may now, if necessary, take the place of the tent, with a view to more ready and steady drainage; or, if the suppura-

tive crisis is passed, the foreign body may be dispensed with, and the case managed in the ordinary way.

The adhesive strips must, if possible, extend four or five inches beyond the upper extremity of each flap, especially in the larger amputations, so as to prevent the retraction of the integuments, and also for the purpose of quieting the muscles and bringing them well forward over the bone. I have been in the habit for many years of beginning the application of the roller at the part of the limb nearest to the trunk, carrying it firmly and equably downward to the very verge of the stump, which is then enveloped by a few crucial turns of the bandage, to give it greater support. No other dressing is necessary. The limb is now placed in an easy and slightly elevated position, over a sheet of oil cloth, and kept constantly wet with cold water, applied by means of a light porous napkin, renewed whenever it becomes bloody or offensive. If suppuration be threatened, or the cold is disagreeable and chilling in its effects, the most eligible substitute will be an emollient cataplasm or the warm water-dressing. Provision is of course made to protect the stump from the contact of the bedclothes. As soon as the operation is over, a full anodyne is ordered, for the twofold purpose of relieving pain and preventing spasm; and the dose is afterwards repeated from time to time as circumstances may seem to demand its exhibition. The diet should be light but rather nourishing than otherwise; and, with the exception of a mild aperient on the second day, no medicine whatever should be given unless it is absolutely necessary on account of the violence of the traumatic fever, or the danger of exhaustion from shock and hemorrhage. When the system is much depressed at the time of the operation, it will be well, as a general rule, to put the patient at once upon a generous diet, and perhaps even upon the use of milk punch. I am satisfied, from what I have seen of these cases, that the worst possible plan that can be pursued is starvation; this not only weakens the system still further but tends powerfully to the production of pyemia and typhoid fever.

The dressings may require removal within forty-eight hours after the operation, or not under three or four days, according to the condition of the parts. When the adhesive action is progressing favorably, the less interference there is the better; any discharge that may collect upon the surface of the stump may be easily soaked up with a soft sponge. If considerable swelling and pain take place, or profuse suppuration set in, the change cannot be effected too soon; and it need hardly be added that, while it is being made, the limb should be well supported by an assistant, at the same time that all pressure and unnecessary manipulation are avoided. Any tendency to bagging that may show itself is to be counteracted by the judicious application of the adhesive strips and bandage, aided, if need be, by declivity of the stump, so as to favor drainage, now of vital importance both to the part and system. The sutures should not be cut out too soon; as long as they are affording support they should be permitted to remain.

After the wound has healed, the stump should be protected for some time with a piece of soft flannel, to prevent the ill effects that might otherwise arise from atmospheric vicissitudes; and all pressure upon its surface should be carefully avoided until the parts have regained their natural sensibility.

Synchronous Amputations.—In cases of accident, as well as in certain diseases, but especially in the former, it occasionally becomes necessary to amputate two limbs simultaneously, or in immediate succession, the circumstances which call for the removal of the one demanding the separation of the other. This constitutes what is termed the synchronous double operation. It is founded upon the assumption that the recovery is more rapid when two limbs are cut off simultaneously than at two separate and distinct periods; that the loss of blood will be comparatively little more from two amputations thus performed than from one alone; that there will be, in the aggregate, much less pain, shock, and inconvenience; and, lastly, that the patient will thus escape the harassing anxiety of mind growing out of the knowledge that he will be obliged to submit to another operation. Synchronous double amputation has occasionally been performed in various parts of this country and Europe; but so far as my information extends it was first

adopted, as a rule of practice, by the surgeons of the Hôtel-Dieu, at Quebec, the first case having occurred, many years ago, in the hands of Dr. Morris, of that city. Within the last ten years the operation has also been performed by Dr. Carnochan, Dr. S. W. Gross, and a number of other surgeons. But the most remarkable instance of the kind of which I have any knowledge, occurred in 1847, at Schuylkill Haven, Pennsylvania, in the hands of Dr. John G. Koehler, who removed simultaneously, on account of a railroad injury, both legs and one arm from a lad, aged thirteen years, recovery taking place without the supervision of any serious symptoms. The limbs were frightfully crushed, and the operation was performed within a short time after the accident. The arm being removed first, the pulse immediately sank, but under the influence of stimulants it rose sufficiently in five minutes to justify amputation of both legs below the knee. So excessive had been the shock of the system that the boy hardly experienced any pain during the operation.

The synchronous double operation may be performed by two surgeons, or by one alone, the latter being perhaps the preferable method. In either event, it is a matter of paramount importance to protect the patient from the loss of blood, the slightest effusion of which might prove prejudicial to his safety. Dr. Carnochan cuts off both limbs before he ties any vessels, and this is undoubtedly the preferable plan if we can be certain of having perfect control over the hemorrhage, as we may be if we have proper assistants, and the removal is effected rapidly by the flap operation.

The prognosis of double synchronous amputations is, of course, for obvious reasons, more unfavorable in the lower extremities than in the upper. Experience shows that the operation, when performed for gunshot injuries through both legs, knees, and thighs, is nearly always fatal. Both feet, hands, arms, and forearms, on the contrary, may generally be removed with comparative impunity.

Reamputations.—Such operations may become necessary on account of a bad shape of the stump, as when it is too square or too conical, great retraction of the skin and muscles leading to protrusion of the bone, extensive necrosis, ulceration of the soft parts, and hypertrophy of the nerves, attended with neuralgia and exquisite morbid sensibility. The suffering that may be caused by some of these affections may not only greatly interfere with progression and the use of an artificial limb, but seriously impair the general health and render life perfectly miserable. I have seen cases where the extremity of the stump was so irritable as to be intolerant to the slightest touch, the patient screaming and jumping as if he had been electrified.

A second amputation should be performed upon the same principles as a first one. If the general health is much deranged, the knife should be withheld until it has been rectified, otherwise serious, if not fatal, consequences may ensue. Instead of amputation, resection may sometimes be advantageously performed, the offending parts being removed either with the scalpel, or the scalpel and pliers. Hemorrhage is carefully guarded against, as the slightest loss of blood may prove highly prejudicial.

SECT. V.—AFFECTIONS OF THE STUMP.

These affections are either of a primary or consecutive character, and both may be purely of a local, or of a local and constitutional origin. The primary consists of hemorrhage, spasm of the muscles, excessive pain, undue inflammation, osteomyelitis, and inordinate retraction of the soft parts, thereby permitting exposure of the bone. Among the secondary effects may be mentioned necrosis and exfoliation of the bone, degeneration of the nerves and neuralgic pain, aneurismal enlargement of the vessels, and contraction of the tendons in the neighborhood of the stump, by which the latter is drawn out of its proper position, and so made a source of inconvenience and discomfort.

1. PRIMARY AFFECTIONS.

a. *Hemorrhage* may come on soon after the dressing of the stump, or not until some time has elapsed; perhaps not for several days. It is usually occasioned by the want of a sufficient number of ligatures, in consequence of the retraction of some of the smaller arteries, thereby escaping the surgeon's attention while he is looking out for the principal and more accessible branches; or it may be that the vessel has been cut obliquely, and that it has not been tied high enough up; or, finally, that the arterial tunics are so much diseased as to give way under the pressure of the cord before the formation of an adequate internal clot, as when the bleeding supervenes several days after the operation. However induced, or whatever may be the circumstances which give rise to the hemorrhage, the proper remedy consists in exposing the open artery, and securing it with a ligature, either by separating the flaps, or, if adhesion is already far advanced, by dilating the canal along which the blood flows over a grooved director. The main artery of the limb is not tied unless it is found impossible, on account of disease, or some other cause, to effect the ligation at the stump.

Sometimes the hemorrhage is purely venous, the blood flowing away lazily in a dark purple stream, without any jet; and then it will generally be found to depend upon the want of accurate coaptation of the flaps, or some defective application in the bandage, making either too little or too much pressure; in the former case enabling the vessels to remain open and gaping, and in the latter interfering with the passage of their contents. Occasionally the blood oozes out at different points, as water oozes out of a sponge, and this may take place either from the soft parts, or from the Haversian canals of the bones, or from the medullary membrane and the marrow. Arrest of the bleeding is usually effected simply by compression of the stump, the compress and roller being made to bear steadily against the offending vessels, aided by elevation and cold applications; when this fails, the ligature may be required, or, what is preferable, because altogether free from the danger of phlebitis, constriction of the vein by inclusion in the surrounding tissues. For this purpose, after being carefully dissected from its attachments, it is transfixed by a curved needle, armed with a small double cord, and drawn through an opening made for it in one of the adjoining muscles. Both ends of the cord are then brought out at the nearest angle of the wound, and retained for twenty-four hours, or removed at once, if there is no probability that the vessel will lose its hold. When the vein has been cut off unusually high up, so as not to admit of this procedure, I never hesitate to tie it, even if it be one of large size, such, for instance, as the femoral, although the operation should always, if possible, be avoided for the reason just stated. When the blood proceeds from the Haversian canals it will generally be necessary to undo the flaps, and apply a compress directly to the surface of the bone, the wound being kept open until the flow is arrested. Caustic applications must not be used for fear of causing necrosis.

b. *Spasm* of the muscles, which is frequently a source of great distress, and which presents itself in the form of jerks or twitchings, usually sets in within a few hours after the operation, and is generally most severe in persons of a nervous, irritable temperament. No patient, however, is ever entirely exempt from it after amputation, and it is always sure to be materially aggravated on the occurrence of inflammation. In regard to treatment much is to be done in the way of prophylaxis; by the judicious use of the roller to give equable support to the muscles of the stump, together with elevation of the part to favor venous return, and also by the early exhibition of a full anodyne. The use of morphia, or of morphia and antimony, along with warm fomentations, will be required if the spasm is at all severe when no such precautionary measures have been adopted.

c. The degree and continuance of the *pain* which follows an amputation will be influenced very materially by the character of the case, the size of the limb, the presence or absence of complications, and, above all, by the temperament of the patient. Coming on usually as the system emerges from the influence of

chloroform, it is sometimes remarkably slight, while at other times it is so severe as to require large quantities of anodyne medicines for its subjugation. When the pain is complicated with spasmodic twitching of the stump, as it generally is during the first twenty-four hours, it must be promptly met with morphia and antimony. In order to render these two phenomena as light as possible, I have long been in the habit of administering a full anodyne about two hours before the operation, and have never been disappointed in my expectations.

d. The *inflammation* consequent upon an operation of this kind may be either of the ordinary character, or it may be erysipelatous, the determining circumstances not being always appreciable. In general, however, the danger of erysipelatous action will be considerable when there has been severe shock or excessive loss of blood, conjoined with previous bad health or habits of intemperance. It usually makes its appearance within the first forty-eight hours, and is characterized by the ordinary phenomena, such as a red dusky state of the skin, more or less throbbing, a sense of tension, and burning, smarting pain, with marked disorder of the general system. Whatever may be the degree or character of the inflammation, it is always hostile to the adhesive process; some parts may, it is true, unite in this way, but suppuration will be almost certain to follow, so as to lead to the necessity of healing the greater portion of the wound by granulation. In persons of a very dilapidated constitution the inflammation may pass into gangrene. I have found this termination most commonly in patients of a scrofulous habit of body and in those whose system has been contaminated by syphilis.

The treatment of this disease must be conducted upon general antiphlogistic principles. Special attention must be paid to the state of the system, and with this view it will generally be necessary to employ a mildly stimulating course, consisting of quinine and milk punch, with blue mass and ipecacuanha to evacuate the bowels and correct the secretions. Morphia is given in liberal doses to allay pain and procure sleep. The best local remedies are the dilute tincture of iodine, with fomentations, or cataplasms, medicated with solutions of acetate of lead and opium. Leeches will generally prove prejudicial. Sometimes the disease is promptly arrested by the application of a large blister. Inordinate tension and confined fluids are relieved by puncture and incision. If mortification is threatened, the parts are freely touched with nitrate of silver, sulphate of copper, or dilute acid nitrate of mercury, and enveloped in a fermenting poultice. The chlorides are used for allaying fetor, and the syringe for washing away secretions from beneath the flaps.

e. Bad effects occasionally follow amputation in consequence of the development of *osteomyelitis*. In the Crimean war this affection was of such frequent occurrence that the question was seriously debated by a number of surgeons whether it would not be best to abandon amputation altogether in the continuity of the larger bones, and resort to disarticulation as a substitute. The disease is also sufficiently common in hospital and private practice, especially in railway and other severe accidents, attended with violent concussion of the osseous tissues. The probability is that it is occasionally caused by injury inflicted in sawing the bone. However induced, it generally sets in within a short period after the operation, so that by the time the dressings are removed, as they usually are on the third, fourth, or fifth day, it is found to have already made considerable progress, the marrow being of a brownish, blackish, or greenish appearance, of a soft, putrilaginous consistence, excessively fetid, and partially detached from the bone, which is itself either dead, or in a dying state, and more or less denuded of periosteum. The disease is generally attended with considerable pain, although in some of the cases that I have seen there was almost an entire absence of local suffering; it is not unfrequently coincident with pyemia and erysipelas. Hence the prognosis is often exceedingly unfavorable.

The treatment of osteomyelitis must be antiphlogistic, modified by the peculiarity of the constitutional symptoms. Great attention must be paid to cleanliness; the dressings must be frequently changed, and free use must be made of the chlorides. The judicious application of nitrate of silver to the affected

structures might possibly assist in circumscribing and ultimately arresting morbid action. If the bone die, no attempt should be made to remove it the part and system have sufficiently recovered from the effects of the disease bear the shock of the operation.

f. Finally, amputation is occasionally followed by inordinate *retraction* of muscles, so as to uncover the bone, and perhaps lead to the necessity of removal. The accident is most liable to happen after amputation of the thigh in consequence of the action of the numerous, large, and strong muscles in that situation, and cannot always be prevented even when more than ordinary care is taken in forming the stump. The occurrence is always to be deprecated as much as it not only interferes with the union of the flaps, but is very a cause the death of the bone. The remedy consists in bandaging the limb from above downwards, preceded by the application of long adhesive strips in placing the parts in the best condition for relaxing the affected muscles. If these means are unavailing, we may, provided the bone remains sound, cut some of the muscles of the stump subcutaneously, and then draw them for either with or without incision of the integuments, as the case may see demand. If the bone, however, is diseased, the best plan will be to saw higher up; but such an operation is often more hazardous than the original and should, therefore, always, if possible, be avoided.

2. SECONDARY AFFECTIONS.

The most common, as well as the most serious, secondary effects of amputation are, as was previously stated, necrosis, neuralgia, synovial bursae, varicose enlargement of the arteries, and permanent shortening of the tendons in the vicinity of the stump.

a. Disease of the bone, eventuating in a loss of its vitality, may be induced in various ways; in general, it is caused by injury inflicted upon it during operation, consisting either in the laceration and separation of the periosteum in the excessive jarring of its substance, or in the violence inflicted upon the nutrient artery, thereby cutting off its wonted supply of blood. Uncovering the bone, in consequence of too great a brevity of flap, and the accumulation around its extremity of pus, are also very apt to produce it. Sometimes it arises from the intensity of the inflammatory action. The loss of vitality is indicated by the peculiar whitish, greenish, or pale yellowish aspect of the bone, the absence of bloody points upon its surface, and a characteristic hollow noise struck with the handle of the knife. The marrow and its enveloping membrane retain their vitality for a short time after the osseous part has died, an event most likely to happen when the bone is necrosed only in a part of its circumference. I believe it will be found that necrosis, as a result of amputation, is more liable to occur in the thigh-bone than in any other piece of the skeleton, depending probably upon some peculiarity of its organization. The tibia is also occasionally affected, and a similar occurrence is sometimes met with in the humerus. The dead bone comes off in the form, first, of an exfoliation, consisting of a part of its outer compact substance; or, secondly, of an osseous ring, with long, narrow, sharp, spicules; or, finally, of a complete cylinder or tube, as when it involves several inches of the entire circumference of the bone. The more common appearances of the necrosed bone are exhibited in fig. 175.

Fig. 175.

Necrosis of the bone after amputation.

The management of these cases must be left very much to the operation of time, especially when the bone has been exposed high up, and when, in order to reach it, extensive dissection would be required. If, on the other hand, the necrosis is limited, an attempt may be made to get rid of it with the cutting-forceps, or trephine. Too much caution, however, should not be used in such an operation, trifling as it appears.

I have seen death produced by it in two cases, and similar instances have been witnessed by others. It would seem, when a bone is thus affected, as if the system were more than usually intolerant of instrumental interference and loss of blood; the parts are generally excessively irritable, and the constitution rarely fails to sympathize with them in the most lively manner. Besides, the operation is necessarily attended with some degree of hemorrhage, and I am not certain that a patient may not be destroyed in this way alone, especially if he is very feeble and irritable at the time.

Instances occur in which the sequester is firmly, and even obstinately, imprisoned by the remains of the living bone, or, more properly speaking, by the new matter that is thrown out upon its surface, thus occasioning great difficulty in regard to its removal. Dr. Markoe, of New York, had the kindness, a few years ago, to communicate to me the particulars of a case, wherein the sequester, consisting of an inner shell of the femur, was retained for many months by a spur of new osseous substance extending through an opening in its sides, in such a manner as to nail the dead and living parts together, but at the same time allowing the former to be moved freely backwards and forwards upon the latter. It was not until after several attempts had been made at extraction, attended with much pain and constitutional suffering, that riddance was finally effected by means of the chisel and forceps.

b. Another disagreeable, frequently, indeed, a most distressing effect of this operation, is *neuralgia*, coming on at a variable period after its performance, and often continuing, despite the most judicious and persevering efforts at relief, to molest the patient during the remainder of his life. Supervening generally without any assignable cause, it is most common in nervous, irritable persons, subject to the disease in other parts of the body. Females are more prone to it than men, and in them the attack frequently coincides with the eruption of the menses. Sometimes the disease is periodical, especially in residents in malarious regions, the paroxysms coming and going very much as in intermittent fever. Most commonly, however, the pain is irregular, one portion of the day being as liable to bring it on as another. It is generally of a darting, shooting nature, or dull, heavy, and aching, and is invariably aggravated by damp states of the atmosphere, fatigue, and disorder of the digestive apparatus.

In the more violent forms of this affection the immediate cause of the suffering is a bulbous enlargement of the nerves ramifying through the stump, as in fig. 176. This degeneration takes place, to a greater or less extent, after nearly every amputation, and is therefore to be considered as a disease only when it exists in excess. Under such circumstances the tumor, which sometimes attains the size of a hickory nut, or even of a pullet's egg, is of a firm, dense consistence, and is composed of a strong fibrous stroma, inlaid with hypertrophied and curiously interlaced nervous trunks and filaments. It is, in fact, a true neuroma. The accompanying pain is exquisite, and the part is so sensitive as to be intolerant of the slightest touch; the general health is much affected, and the patient is remarkably susceptible of atmospheric vicissitudes, every change in the weather from warm to cold and dry to wet being followed by an increase of suffering. The malady is of a much more serious character than the other, and requires proportionately stronger measures. In general, nothing short of removal will avail; by excision, if the tumor be single and easily accessible, by amputation, if it be multiple and deep seated.

For the milder varieties of neuralgia the ordinary remedies will sometimes

Fig. 176.

Neuromata of a stump, after amputation of the arm. A large mass at a; opposite b, the tumors are more defined.

suffice, as in neuralgia in other parts of the body, especially quinine, or, if the patient is anemic, quinine and iron, combined, in either case, with strychnia and arsenious acid, belladonna, stramonium, or aconite; the effects of the articles being studiously watched, lest an overdose be given, and life placed in jeopardy. Sometimes marked benefit accrues from the exhibition of colchicum and morphia, administered in full doses at bedtime, as one drachm of the wine to a grain of the salt. These medicines are particularly valuable in subjects of a rheumatic state of the system. Locally, iodine, blisters, issues, and other counter-irritants are used, along with anodyne embrocations. The stump is well protected from cold, friction, and pressure.

c. A *bursa* sometimes forms upon the stump, generally immediately over the end of the bone, in consequence of the long-continued pressure of an ill-constructed and ill-adapted artificial leg. The tumor, in time, becomes exquisitely tender and painful, compelling the patient to seek relief. The seat and character of the disease are usually pointed out by the discoloration and swelling of the part, which often fluctuates on pressure. The history of the case, aided by the exploring needle, will readily serve to distinguish it from abscess, the only lesion with which it is likely to be confounded. The proper remedy is excision in the severer grades of the affection, and in the milder a more careful adaptation of the artificial to the natural limb.

d. Varicose enlargement of the *arteries* of the stump is extremely rare, only a few instances of it being upon record. Unless the disease is unusually extensive, which, however, it is not likely to be, nothing need be done for its relief, as it does not generally act even as an inconvenience.

e. Permanent shortening of the *tendons* in the immediate vicinity of the stump is sometimes a source of great discomfort, as well as of serious interference with the usefulness of the limb. The accident is most liable to happen in the tendons of the hamstring muscles after amputation of the leg, and in the tendo Achillis after removal of the foot by Chopart's method. Much may be done, in both cases, in the way of prevention by attention to position during the after-treatment; it is, in fact, the neglect of this precaution that usually occasions the difficulty. When the occurrence is unavoidable, or is already fully established when first brought under the notice of the surgeon, rectification is attempted, generally with a fair prospect of success, by the subcutaneous section of the shortened tendons, and the subsequent use of an extending apparatus, constructed on the principle of the double inclined plane, with such modifications as may be required to adapt it to each particular case.

SECT. VI.—CONSTITUTIONAL EFFECTS OF AMPUTATIONS.

The most common constitutional occurrences after amputations, especially of the larger limbs, are excessive prostration, traumatic fever, pyemia, congestion of the lungs, tetanus, retention of urine, and, as a secondary consequence, hectic irritation.

a. The *shock*, consequent upon amputation, is frequently extremely severe, and may be due, either partly or exclusively, to mere depression of the nervous system, caused by the extent, violence, and duration of the operation, to loss of blood, or to the effects of anæsthetic agents, or to all these circumstances combined. More or less nervous depression will almost necessarily occur during such an operation, however slight, but it generally passes off without any particular treatment, simply under the influence of repose, exposure to the air, and a drink of cold water. In the more severe forms of the affection, however, it may endanger life by its long-continuance or excess, and then demands prompt attention. The most appropriate remedies are lowering of the head, so as to facilitate the flow of blood to the brain; the administration of brandy and ammonia, by the mouth, if the patient can swallow, or by the rectum, if the power of deglutition is lost; a full dose of morphia; and sinapisms to the spine, extremities, and precordial region.

b. *Traumatic fever* generally sets in within from six to twelve hours after the

operation, and will be violent or otherwise according to circumstances, of which the most important are, the extent of the previous shock and loss of blood, and the temperament, habits, and state of health of the patient. It is characterized by heat and dryness of the skin, flushed countenance, suffusion of the eyes, headache, restlessness, excessive thirst, rapid respiration, and a frequent, hard, and irritable state of the pulse, attended, when there has been much hemorrhage, by a peculiar jarring impulse. These symptoms, in the milder cases, will often speedily subside spontaneously, but under opposite circumstances they will require attention, and, if the surgeon is not fully on his guard, he will be very apt to do a great deal more than is either necessary or proper. The fact is, this is not unfrequently the critical point in such cases; if we do too much, the patient is irretrievably gone, the consequence being death either from exhaustion, pyemia, erysipelas, or a low state of fever, which nothing can cure. Hence the greatest caution is to be observed; the symptoms must be watched, and the utmost care must be taken that they do not deceive us by their violence, which is often feigned rather than real, and therefore extremely apt to entrap the unwary and inexperienced. In general, it will suffice to administer a mild aperient, as a little Epsom salts, or a Seidlitz powder, to sponge the surface frequently with tepid water, and to give cooling, acidulated drinks, which are always very grateful in these cases. If the fever threatens to be obstinate, a little antimony is prescribed, either alone or in union with morphia, to promote perspiration, allay the heart's action, and induce sleep. The lancet is scrupulously withheld, unless the symptoms are of extraordinary urgency, and the patient is very plethoric, without having been weakened by shock and loss of blood. Then a vein in the arm may be opened, and the effect of the stream carefully watched, the bleeding being arrested as soon as the pulse evinces signs of flagging.

Very often after amputations of the larger limbs, especially those performed for compound fractures and dislocations, gunshot wounds, and railway accidents, a low form of fever ensues, the system reacting badly, the countenance looking pale and haggard, the skin being icterode, cold, and doughy, and the pulse shattered, with great depression of spirits, and an utter indifference on the part of the patient as to his fate. It is difficult to say what is the real condition of the system under such circumstances, but, if we may be allowed to indulge in conjecture, we may suppose that the disorder is mainly due to the loss of blood and nervous fluid consequent upon the excessive shock to the system at the time of the accident, heightened, perhaps, by the effect of the operation. However this may be, the system being depressed and withered, the issue is usually most disastrous, very few persons recovering, no matter what course may be adopted for their relief. Our chief reliance must obviously be upon stimulants, as brandy, quinine, ammonia, and nutritious food, with opium to allay pain and procure sleep.

c. Amputations, especially those of the thigh, are often followed by *retention of urine*, caused apparently by partial paralysis of the bladder, or, rather, as it seems to me, by a want of proper volition, the bladder retaining its power, but the patient being unable to call it into action. It usually supervenes within the first twenty-four hours after the operation, and seldom lasts less than two or three days, when it gradually passes off. From what I have seen of this affection, in this class of cases, I am not disposed to ascribe to it, as some have done, an inflammatory origin; that such a condition occasionally exists is certain, but, in general, I am sure it does not. Knowing how frequent retention of urine is after this and other capital operations, the attendant should be diligently on the watch for it, and promptly use the catheter, if it should arise.

d. A not unfrequent event after amputation is *pyemia*. Experience shows that it is most to be dreaded in cases preceded by excessive shock of the system; hence it is very common after gunshot, railroad, and steamboat accidents, attended with extensive laceration of the soft parts, and after compound fractures and dislocations. From an interesting paper "On the Causes of Death after Amputation," by Mr. Thomas Bryant, of London, it appears that of 300 cases of this

operation collected from Guy's Hospital, pyemia occasioned death in 42 per cent. of all the fatal cases, and in 10 per cent. of the entire number, the affection having been most frequent after amputation of expediency, and least so after secondary amputation. The attack generally comes on within the first six or seven days, being ushered in by violent rigors alternating with flushes of heat, and followed by a bad state of the stump with aching pains in the limbs and joints, excessive thirst, restlessness, and a tendency to delirium even early in the disease. When the joints are involved there is commonly an erysipelatous blush upon the overlying skin, with great tenderness on pressure and exquisite pain on motion. The case generally proves fatal in less than a week from its commencement, and examination after death usually reveals the existence of small and ill-defined abscesses in some of the internal organs, particularly in the lungs, liver, and spleen.

The treatment is by stimulants and tonics, as brandy and milk, quinine, and opium, given in large quantity to support the rapidly sinking powers of nature. Mercury, in the form of calomel, is sometimes useful, and may be administered in doses of three grains every four or six hours, with a view to rapid but gentle ptyalism. The bowels are moved by enemas, all active purgation being inadmissible. Locally, the ordinary remedies are employed, generally only such as are of a soothing character.

e. Congestion of the lungs, if not actual inflammation of these organs, is another effect of this operation, occurring either alone, or in conjunction with pyemia, erysipelas, or an adynamic state of the system. It generally comes on in a slow, insidious manner, and is therefore apt to make serious, if not fatal, inroads before its true nature is even suspected, none of the characteristic signs of pneumonic disease being present. The only way in which it is usually detected is by auscultation and percussion, or by the changes perceptible in the respiratory movements and the sounds of the chest. These changes are generally most conspicuous in the lower and posterior portions of the lungs, where the greatest amount of blood, in debilitated states of the system, is, in obedience to the laws of gravity, most liable to accumulate, and, consequently, to produce the greatest degree of mischief. In most of the cases of pulmonary congestion that I have met with after amputation of the larger limbs, there was either an entire absence of pain and cough, or these symptoms were so trivial as, of themselves, to attract hardly any attention. The patient is able to lie upon his back or on either side, and it is not often that the respiration is materially hurried or embarrassed.

Cupping and blistering are the most reliable local remedies, and the system must be supported with stimulants and tonics, aided by morphia and minute doses of tartrate of antimony and potassa. The prognosis is generally unfavorable, especially if the disease has made considerable progress and the patient is much exhausted.

f. The occurrence of tetanus after amputation is uncommon, especially in the more temperate regions of this and other countries. Mr. Curling, in his work on this disease, gives a table of 128 cases of traumatic tetanus, three of which only were caused by amputation. The affection is much more frequent in military than in civil practice, and is most liable to be produced in persons of a nervous, irritable temperament, in consequence of exposure to direct currents of cold air. A few years ago I lost a man on the third day after an amputation of the thigh solely from this cause; he had been moved, during my absence from the hospital, to an open door, so as to allow the wind to blow upon him in a full stream. I am familiar with the history of other cases that have been induced in a similar manner; and I refer to the fact in order to attract special attention to it. The treatment of this disease being discussed elsewhere, it is unnecessary to refer to it here.

g. Hectic irritation is observed only, or chiefly, as a secondary effect of amputation, being caused either by profuse suppuration, or by a poisoned state of the blood and solids, from shock, hemorrhage, or the absorption of pus. The symp-

toms are characteristic, and the treatment consists of such means as are calculated to sustain the flagging powers of the system, especially quinine and iron, with aromatic sulphuric acid, milk punch, and nutritious food.

SECT. VII.—ARTIFICIAL LIMBS.

The stump, after the cicatrization of the wound, gradually undergoes, as might be expected, important changes in its several structures, so as to adapt it the better for the various hardships which it is destined to experience in the daily routine of a business life, and especially for the support of an artificial limb. The muscles, deprived of the power of motion, soon become pale and wasted, and are eventually transformed into hard, dense, cellulo-fibrous bands, entirely destitute of their primitive properties. The bloodvessels are obliterated as high up as their first large collateral branches, and converted into solid, rigid cords; the extremities of the nerves are expanded into large bulbous masses, of an elongated, cylindrical shape, exhibiting more of a fibrous than of a nervous structure; and the ends of the bones are rounded off, and covered in by a thin shell of osseous matter, which thus effectually closes the medullary canal, as seen in fig. 177. The cellulo-adipose substance gradually disappears, and the skin, unless habitually subjected to pressure, is rendered abnormally thin and sensitive. These changes are, of course, the work of time, and hence they are always more conspicuous in proportion to the age of the stump.

The period at which the stump may be in a condition for the reception and support of an artificial limb must necessarily vary according to circumstances; if the operation has been well done, and the cicatrization has gone on favorably, the substitute may be used as early as the sixth or eighth week, though in general it will be better to wait some time longer, inasmuch as too early a recourse to it will be likely to render the parts sore and sensitive, if not the seat of ulceration and severe pain. So much, indeed, is the patient's comfort influenced by attention to this point that it is hardly possible to be too cautious respecting it. The stump should be tightly bandaged for several weeks previous to the application of the artificial limb, to promote absorption of redundant material, and thus impart to it somewhat of a conical shape. Washing it well several times a day with a strong solution of tannin and alum will have the effect of hardening the integuments, so as to moderate their sensibility and prevent excoriation.

Great improvement has of late years been effected in the construction and adaptation of artificial limbs, and there is reason to believe that the inconvenience and suffering occasioned by their use are more frequently attributable to the misconduct of the surgeon than to the want of skill on the part of the manufacturer of the substitute. It has only been within a comparatively recent period that operators have hit upon the correct principles of making good and serviceable stumps. Allanson, nearly three-quarters of a century ago, understood the subject much better than it has been understood since, if we except the last fifteen or twenty years. He strongly insisted upon a long and well-shaped stump, and exerted himself with great ability, but in vain, to induce the profession generally to follow his example. The happy changes lately introduced into this department of operative surgery are, I believe, mainly due to the manufacturers of artificial limbs, who, with an ingenuity and perseverance worthy of so good a cause, have reduced the whole process to one of principles founded upon the study of anatomy and mechanical philosophy. It would be difficult to conceive of any apparatus more beautiful in its construction, or more admirably adapted to the

Fig. 177.

Appearance of the bony stump after amputation.

end proposed, than the artificial substitutes of Mr. Palmer, of this city, who obtained the prize medal at the great exhibition in London in 1851. Combining lightness with strength, and neatness with symmetry, they are worn with great comfort and satisfaction, and are apparently as perfect as any piece of human mechanism of the kind can well be made. The joints, constructed on the principle of the ball and socket articulation, are situated at the proper points, and their surfaces move upon each other with great accuracy and facility, through the intervention of cords, wires, springs, and levers, the whole arrangement being a close imitation of the natural muscles and tendons, if not in shape, at least in position and function. The socket is made with special care, neatly fitting the stump in every portion of its extent, and is well padded to prevent friction and excoriation, the pressure being diffused over the entire circumference of the stump, while the extremity of the latter is perfectly free in the interior of the former. The annexed cut, fig. 178, affords a good illustration of this apparatus.

Fig. 178.

To enable the patient to wear his artificial limb with comfort and convenience, it is necessary that he should have a good long stump, well covered, perfectly even, and of proper shape, being neither too square and fleshy, on the one hand, nor too thin and conical, on the other. A short, thick, ill-formed stump is a great evil, from which the patient can promise himself no good; on the contrary, it can hardly fail to be a constant source of annoyance and pain, becoming sore and excoriated under the slightest exercise. The duty of the surgeon, therefore, is one of great responsibility, and cannot be discharged without properly weighing, in every instance, the probable consequences of the operation. When he has his choice, his invariable aim should be to make a long stump, so as to

afford an abundant leverage and support for the artificial contrivance. In the leg and thigh its length should not, if possible, be less than nine or ten inches; hence the place of election, for the former, should be only about from three inches to three inches and a half above the ankle, and for the latter about the same distance above the knee. It is not always, however, by any means in the power of the surgeon to select the point where he might otherwise cut off the limb, and he must then be contented in leaving as much substance as he can. If the leg is amputated very high up, the weight of the body may be supported upon the knee, especially if the patient's social position is such as to prevent him from wearing an expensive substitute, and this will be the more necessary because it is often very difficult, if not impossible, to preserve the straightness and flexibility of the joint in the event of a very short stump, on account of its incessant tendency to retraction and ankylosis. It is for this reason that some surgeons have advised amputation of the thigh just above the knee, when accident or disease interferes with the formation of a suitable stump below; but, if we consider the difference in the danger of the two operations, we should hesitate before we give our sanction to such counsel, not forgetting that the risk increases with every inch the nearer we approach the trunk. In amputation of the thigh, the principal pressure of the artificial limb upon the stump is concentrated near the body, but care is taken not to apply any direct pressure to the perineum, lest it should produce excoriation.

In amputations in children, the development of the limb is always partially arrested, so that, by the time the individual attains his full stature, it will be several inches shorter, as well as thinner, than its fellow of the opposite side. Now, surgeons in applying this knowledge to amputations of the inferior extremity, have advised that it should never be cut off below the knee, but at the lower third of the thigh, on the ground that, if this precaution be neglected, one knee will ultimately be elevated a considerable distance above the other, thereby imparting to the gait a peculiar grotesque appearance. Experience, however

has shown that amputation of the leg, even if the stump is only a few inches in length, instead of being an objection, is a decided advantage, the limb thus affording a much longer leverage than when it is cut off through the thigh, for the adaptation of the artificial substitute, the knee-joint of which can always be made to correspond, in situation, with that of the sound limb. Moreover, by adopting this procedure, the weight of the body, provided the stump is not too long, is supported upon the knee; another most important desideratum under such circumstances.

Ingenuous and excellent artificial limbs, apparently not at all inferior to those of Palmer, have been devised by Bly, Hudson, Jewett, Selpho, and others, and are extensively used by our mutilated soldiers. The contrivance of Dr. Bly, besides combining lightness with elegance, dura-

Fig. 179.

Fig. 180.

bility, and strength, admits of lateral motion at the ankle, in imitation of the natural joint, and is, in all respects, constructed upon strictly anatomical principles.

The annexed drawing, fig. 179, conveys a good idea of the artificial limb usually worn by the laboring classes after the loss of a leg or thigh. It may be made very light, and, when the stump is of proper length, affords an admirable substitute, the person being able to walk nearly with the same facility as in the natural state.

Various attempts have been made to construct artificial hands and arms. Mr. Palmer, after many trials, has devised a limb, fig. 180, which, in point of neatness and adaptability, leaves hardly anything to be desired upon the subject.

SECT. VIII.—MORTALITY AFTER AMPUTATIONS.

The mortality from amputations is so much influenced by extraneous and intrinsic circumstances, and requires such a vast amount of statistical material for comparison and contrast, that it is extremely difficult, if not impossible, in the existing state of the science, to arrive at any satisfactory conclusions respecting it. It has long been known that the danger of the operation is always greater in proportion to its proximity to the trunk and the size of the limb. Hence, amputation of the leg is less hazardous than amputation of the thigh, and of the thigh in its continuity than of the thigh at the hip-joint. The mortality of the operation is also greater, as a general rule, in hospital than in private practice, in military than in civil practice, and in private practice in cities than in the country. Amputations on account of railway accidents are extremely dangerous, and are liable to be followed by the worst consequences, even in subjects perfectly healthy at the time of the accident, owing to the excessive tendency to mortification and pyæmia.

The circumstances which mainly influence the mortality after amputation may

conveniently be arranged into four classes, the first of which refers to the age, previous health, and social position of the patient; the second to the causes necessitating the operation; the third to the nature, seat, and extent of the operation; and the last to the after-treatment.

1. It will readily be granted that the condition of the *patient* at the time of the accident rendering amputation necessary must exert an important influence upon his fate. If he is old, broken in constitution, or in a state of poverty, so as to preclude the possibility of receiving proper attention after the operation has been performed, the chances are that he will die, either from shock, erysipelas, pyemia, or congestion of the lungs. The previous state of his health exerts no little influence upon the recovery; not, perhaps, however, to the extent that is generally imagined. A person who is in bad health at the time he is severely injured cannot be expected to bear the shock of an amputation with the same impunity as one whose health is good. The system, exhausted by previous suffering, is ill qualified in such a case to react favorably after the nervous depression consequent upon the operation.

Age also exerts a considerable influence over recovery. Children, as a general rule, bear amputation better than adults and elderly persons, being less subject to attacks of erysipelas and pyemia, and making a more rapid recovery. The parts, too, unite more frequently by the first intention. At the Hôpital des Enfants in Paris, Guersant, who annually performs from fifteen to twenty operations of this kind, including all the larger limbs, and also occasionally the hip and shoulder joints, does not lose more than one out of about nine cases. He ascribes his extraordinary success mainly to two circumstances; first, a thorough preparation of the system, and, secondly, the use of an abundance of good, wholesome, and nutritious food immediately after the operation, on the well-known principle that children do not tolerate abstinence nearly as well as adults. It should be added that nearly all the cases in this Institution demanding amputation are of a scrofulous nature.

The social position, or the habits and occupation of the patient, must materially influence the result of an amputation. The poor man cannot command the same care and attention as the rich; he often suffers for want of proper food and nursing, and even medicine, at a time, perhaps, when he is most in need of them, and there is no doubt that many patients perish from this cause alone that might otherwise be saved. Intemperance in eating and drinking, and unwholesome occupations must necessarily produce a prejudicial effect upon the result.

2. The influence of the *causes* necessitating amputation has long been a subject of remark on the part of practitioners, both in private and public. Thus, it is an established fact that a person who undergoes amputation of one of the larger limbs on account of a severe injury, as a compound fracture, or a lacerated and contused wound, is much more likely to perish from its effects than one who loses a limb on account of chronic disease. The system, in the former case, deeply depressed by the shock of the accident, often reacts very slowly and imperfectly, and is therefore ill prepared for the approaching ordeal of another violent commotion, the effect of which is felt by every organ and tissue of the body. In disease, on the contrary, the constitution, although perhaps extensively implicated, has become inured to suffering, and, unless too much prostrated, will generally be immensely benefited by the removal of the offending parts. The chief exception to this rule is in malignant affections, in which, in consequence of the vitiated state of the solids and fluids, amputation is often followed, and that very rapidly, by the worst results.

3. In considering the probable result of a case of amputation, we must not forget to take into view the nature, seat, and extent of the *operation*. Experience has proved that, in civil practice, primary amputation is, other things being equal, a decidedly more dangerous procedure than secondary. The very fact that such an operation is required shows that the accident for which it is performed must have been a severe one, involving, perhaps, the most dreadful lesions of the bones, muscles, joints, and bloodvessels, with frightful depression of the nervous system. Now, it is surely impossible that a patient thus circumstanced

should be in a favorable condition to submit to another violent shock, such as must necessarily attend the removal of the affected limb, within a short time after reaction has been established. The statistics, both of private and hospital practice, in America and Europe, are decisive upon this subject, proving beyond the possibility of doubt, the greater mortality after primary than secondary amputations. Thus, of 48 primary amputations of the thigh, leg, and arm, performed in the London hospitals from June, 1855, to June, 1856, inclusive, 26 terminated fatally, or upwards of one-half, while in 156 secondary ones the number of deaths was only 35, or in the ratio of about 1 to $4\frac{1}{2}$.

In military practice, on the contrary, the results of amputations are reversed, the primary being incomparably more favorable than the secondary. This has been the result of the experience of surgeons in all ages and in all countries since the invention of gunpowder. Larrey and Guthrie saved three-fourths of their cases after primary operations, and the returns of the British surgeons in the Crimea are of a similar character, although the rate of mortality here was considerably higher, owing to the fact that most of the wounds were inflicted with the conical ball; whereas, in the campaigns of Bonaparte, and in the Peninsular war, they were made with the round ball, the effects of which are, as a general rule, much less destructive than those of the former. The observations of European surgeons in regard to the superiority of primary over secondary amputations have been abundantly verified by the surgeons during the present war on both sides of the line.

The differences between the results of primary and secondary amputations in civil and military practice, are no doubt due to the circumstances under which they are performed and the causes which lead to their necessity. In the first place, there is generally less shock in injuries received on the field of battle than in those received in civil life. Secondly, the soldier usually submits to the removal of his limb with greater *sang-froid* than the civilian, and often glories in his loss, believing that the world will regard it as an evidence of his prowess and patriotism; whereas, the latter finds in his misfortune nothing but regret and private calamity. Thirdly, the operation is commonly more promptly performed in military than in civil practice, delay, in the latter case, being frequently occasioned by the doubts of the surgeon and the interference of the patient and of his friends; and, lastly, a soldier has not much chance of recovery from an amputation, when, an attempt being made to save his limb, he is subjected to rough and tedious transportation, and is afterwards obliged, when the operation has been performed, to breathe the contaminated atmosphere of a crowded hospital, tenanted by persons borne down by similar accidents. Under such circumstances the mortality from erysipelas, pyemia, and typhoid fever will, other things being equal, be much greater than in private practice. Faure, from these and other causes, lost 270 out of 300 secondary amputations consequent upon injuries received in battle.

The size and situation of the wound exert an important influence upon the recovery. Here again the statistics furnished by various authorities are most eloquent and decisive. They have conclusively established the fact, now regarded as a great general law, that the larger the wound is and the nearer it is to the trunk, the greater is the danger to life. Thus, Malgaigne, in his statistics of amputations of all kinds in the hospitals of Paris, found that the mortality after removal of the great toe was in the ratio of one to six, whereas that of one of the smaller toes was only as one to twenty-six. In amputations of the foot the proportion of deaths was about twenty-five per cent., of the leg fifty-six per cent., and of the thigh sixty-two per cent. These results have been abundantly verified by the statistics of other institutions, as well as by those of military and private experience, and they are full of interest, as establishing a law, which should never, if possible, be violated.

The causes which induce this difference in the larger and smaller amputations are chiefly shock, hemorrhage, pulmonary congestion, pyemia, erysipelas, profuse suppuration, and gangrene of the stump. Tetanus, too, is more frequent after the former than the latter, although the mortality from this affection is not great

under any circumstances, especially in the more temperate regions of this and other countries. It is certainly not difficult to understand the reason why the removal of a large limb should be attended with so much more risk than that of a small one. In the former case, the patient has to contend not only with the shock of the accident necessitating amputation, which is often of itself almost sufficient to destroy him, but as soon as reaction is established he is subjected to another source of depression, perhaps almost equally great, from the operation, frequently involving copious hemorrhage, and liable to be followed by profuse suppuration and high febrile excitement, all tending to depress and exhaust the vital powers. In the latter, on the contrary, there is little or no shock, either from the accident or the operation; the loss of blood is inconsiderable; and the inflammatory effects, local and constitutional, are comparatively trivial. In short, there is no disorganization of the blood as there is in the former, and hence no predisposition to pyemia, or purulent infection, and pulmonary congestion, which are a source of so much mortality after the large amputations performed for severe injuries.

The result of an amputation may be materially affected by the situation at which the bone is divided. Experience has shown that, in the femur, tibia, and humerus, more particularly, the danger is much greater when the bone is sawn through its shaft than when it is cut off at its articular extremity, owing to the injury inflicted upon the endosteum, and the consequent liability of this membrane to diffuse suppuration, and other bad effects.

4. Finally, it needs no labored argument to prove that the mortality from amputation must be materially affected by the nature of the *after-treatment*. That many persons perish after such an operation from sheer neglect, bad nursing, or bad surgical management, is a fact too well known to require comment. This is true both of private and of hospital practice, but the remark applies with increased force when it is made with reference to military practice, which, however well the surgical staff of an army may be organized, must often, from the very necessity of the circumstances in which the operations are performed, and the difficulty of conducting the after-treatment in a proper and satisfactory manner, be followed by the most disastrous results, many lives being lost that might, under more auspicious circumstances, as to locality, comfort, and convenience, be saved. The state of the atmosphere, as it respects purity and temperature, the prevalence of epidemic diseases, mental depression, want of proper diet, severe depletion, and inattention to the dressings, all exert a more or less powerful influence upon the issue of such an operation. The crowded wards of hospitals in large cities, incessantly pervaded by foul air, are notoriously prejudicial to recovery after amputations; gangrene, exhausting suppuration, erysipelas, and pyemia are the common lot of such patients, and the consequence is that many of them perish. Hence it is that private practice, especially that of the country, always shows a much more favorable result than that of large public institutions, or that of large towns and cities. During epidemic diseases, the percentage of deaths from amputations always exhibits a great increase; for it is then that patients are particularly prone to erysipelas, pyemia, and congestive pneumonia. Starvation and depletion are a serious source of mortality after this operation, establishing, as it does, a tendency to purulent infection and to a typhoid state of the system, from which often no stimulants, however powerful and well-directed, can afterwards rouse it. I regard such treatment after amputation of a large limb, as, indeed, after every other capital operation, as a great evil, and one which, in my judgment, demands thorough reform on the part of our civil and military practitioners. Finally, I may mention, as another source of mortality, want of attention to the dressings, which, if allowed to remain on too long, not only taint the surrounding atmosphere, but favor the absorption of pus, much to the detriment both of the part and system.

I subjoin the following summary of the *statistics* of amputations performed at the Pennsylvania, New York, and Massachusetts Hospitals, because it seems to place the whole subject of the mortality after these operations in a clear and satisfactory light. It is founded upon the reports of Dr. Norris, Dr. Lente, and

Dr. Hayward, and embraces the results of 546 cases, of which 198 proved fatal. The thigh was amputated in 164 cases, of which 68 died, or 41.4 per cent.; the leg in 194 cases, of which 68, or 35 per cent., perished; the arm in 94, of which 20 died, or 21.2 per cent.; and the forearm in 85, with a mortality of 11, or 12.9 per cent.

Of 133 primary amputations of the lower extremity in its continuity 69 died, or 51.9 per cent.; while of 111 secondary amputations only 44 were lost, or 39.6 per cent. Of 117 operations performed for disease 28 died, that is, 19.5 per cent. These cases include several double operations of the legs, a majority of which recovered. Of four amputations at the hip-joint all proved fatal. Of 10 amputations at the knee 5 were lost. Five of the ten were primary, one secondary, and three for disease; of the first two died, of the second one, of the third two. The shoulder-joint was the seat of operation in 25 cases, of which 12 were fatal, or 48 per cent.

In regard to the ages of the patients operated upon in the three hospitals, the mortality in all, under 20 years, was 20 per cent.; between 20 and 30, 29 per cent.; between 30 and 40, 40 per cent.; between 40 and 50, 40 per cent.; and over 50, 33.3 per cent.; the number of cases, however, being only 12, and therefore too small to justify any general deduction as to the rate of mortality.

The most valuable statistical tables of amputations, both primary and secondary, that have yet been furnished are those of Mr. James R. Lane, of London. They embrace an aggregate of 5851 cases, derived from various sources, civil and military, private and hospital, European and American, and may, therefore, be regarded as exhibiting a very fair view of the mortality after these operations in different parts of the world.

		2067	819		1451	540		587	259	

The results of these tables thus show, in their aggregate relations, a mortality of 33.25 per cent., or one death in every three persons subjected to operation. Of the 546 cases in the three American hospitals, 190 died, giving a mortality of 36.2 per cent.

CHAPTER XVIII.

EXCISION OF BONES AND JOINTS.

THE term excision serves to denote the removal of a bone, whether in its continuity or at its extremity, whether it be limited to a portion of its extent or embrace its totality. When only the head of a bone is concerned in the operation, the word decapitation is occasionally used, and, as meaning the same thing, some authors have adopted the name of exsection, while others, especially the French and German surgeons, employ that of resection. Excision differs from amputation in this, that, while in the latter the bone is removed along with the soft parts which surround it, in the former the bone alone is cut away, the integuments, muscles, and other tissues being retained, in order that they may contribute to the future usefulness of the limb; or, in other and more comprehensive language, while in the one case all the structures are destroyed, in the other as many of them as possible are preserved. Hence this department of surgery has very appropriately been denominated conservative surgery, and it is most gratifying to know that it constitutes one of the leading characteristics of the healing art of the present day. It is not to be expected that excision of the bones and joints will ever entirely supersede the necessity of amputation, for as long as the various tissues of the body are subject to disease and accident, so long will they require removal by the knife, in order to prevent the extension of their effects; but that the frequency of the operation will eventually be greatly diminished, the experience of the last twenty years abundantly attests. Conservative surgery is still in its infancy, and it is needless to conceal the fact that it will take a long time to determine its legitimate limits.

Although incidental mention of excision of the bones occurs in the writings of some of the earlier surgeons, yet it is probable that, if such an operation was ever performed by them, it was in great measure, if not entirely, limited to the removal of the protruding ends of fractured bones. However this may be, it is certain that there is no well authenticated case of excision of the heads of any of the bones until 1762, when Mr. Filkin, of Northwich, removed those of the knee-joint. Soon after this a similar service was performed for the superior extremity of the humerus by Vigaroux, David, and White. In 1781, Mr. Park, of Liverpool, repeated Filkin's operation, and, from the gratifying success attending it, he was led to propose its extension to all the principal articulations, much to the surprise of most of his contemporaries, who looked upon the measure as harsh and reckless. The consequence was that the proceeding met with much opposition, and it might even have been entirely lost sight of if it had not been for the boldness and skill of Moreau, the elder, of Bar-sur-Ornain, who, towards the close of the last century, exsected, in rapid succession, the articular extremities of the shoulder, knee, and elbow. The success of the French surgeon was followed up by that of his son and successor, who obtained great celebrity for his operations upon the joints, attracting patients from all parts of France, and who, at various intervals, embodied the results of his observation and experience in separate monographs addressed to the Academy of Surgery at Paris and other learned societies. In the early part of the present century excision of the joints received a powerful and salutary impulse from the French army sur-

geons, particularly Larrey, Percy, Willaume, and Bottin, who repeatedly performed extirpation of the heads of the bones, especially those of the shoulder, on account of gunshot injury. The operation, indeed, was performed, at one time, upon a large scale, and many limbs, as well as lives, were doubtless saved by it. Notwithstanding this, however, the procedure was generally regarded with suspicion in Great Britain, where, although it originated there, it made no real progress until about thirty-five years ago, when, chiefly through the example of Mr. Liston and Mr. Syme, it began to attract the universal attention of medical men. During the last few years the operation has been performed in numerous instances, by surgeons of the highest eminence, upon nearly all the principal articulations, and the results have been such as to warrant the belief that this department of the healing art is destined rapidly to undergo a most salutary change. In this country excision of the joints was, until recently, greatly neglected, both in hospital and private practice; this, however, is no longer the case, for, since the breaking out of the present civil war, the intelligence, zeal, and skill of the surgeon have nowhere been displayed to greater advantage in this branch of practice than among us. All innovations require time for their adoption, and what De Condillac said of another subject is equally true of this. “*Il est rare que l’on arrive tout-à-coup à l’évidence : dans toutes les sciences et dans tous les arts, on a commencé par une espèce de talonnement.*”

Excision of the bones in their continuity has been practised, for various purposes, for a long time, and modern surgery is indebted to it for many of its most brilliant exploits. It is in this department, more particularly, that American operators have displayed their greatest skill. Commencing with excision of the inferior jaw by Dr. Deadrick, of Tennessee, in 1810, we may with just pride point to the operations of Mott upon the clavicle, of Mussey, McClellan, and Gilbert upon the scapula, of Butt and Carnochan upon the ulna, and of the latter upon the radius, not to mention numerous minor cases, which, although less known, have reflected the highest credit upon the scientific character of the profession, and conferred the greatest benefit upon a class of sufferers who would otherwise have been doomed to loss of limb and life.

The principal circumstances necessitating excision are, disease of the bones and joints, as caries and necrosis, gunshot, railway, and other injuries, and various kinds of deformity. The existence of malignant disease in or around an articulation contra-indicates its performance. Excision has often been advantageously practised in ununited fractures of the bones. It may also be resorted to for the relief of deformity dependent upon ankylosis, but in such an event it can hardly be employed with safety unless the affected joint has been completely annihilated by osseous matter. If any portion of the natural structure remains, the operation will be attended with great risk both to limb and life from pyemia and erysipelas.

The most common cause for which excision is employed is caries, usually called white swelling, of the bones, especially of their articular extremities, and the operation, if properly executed, is generally followed by the most gratifying results, not only as it respects the life of the patient, but the usefulness of the limb. The operation is particularly adapted to chronic cases, in which the morbid action is in great degree arrested, and the system has become inured to suffering. Under opposite circumstances, it is liable to lead to the most disastrous effects, and should, therefore, if possible, be avoided.

In compound fractures and dislocations excision has been practised almost from time immemorial, and frequently with the most satisfactory results. In the latter of these accidents in particular, whether involving the large or small articulations, experience has shown that it is generally more safe, both as it respects life and limb, to resect the ends of the protruded bones than to restore them in the usual manner. In the ordinary reduction, the synovial membranes and cartilages are usually rapidly destroyed; profuse suppuration takes place, and the patient gradually sinks under hectic irritation; or, if after having struggled through the general danger, he at length escapes with his life, he is very

liable to lose his limb, or, at all events, to have a permanently stiff, deformed, useless joint.

Statistics of excision for gunshot injuries will be given in a future chapter. Here I shall only observe that the experience of the present war has demonstrated that the only large joints to which the procedure is at all applicable are the shoulder and elbow. Performed upon the hip, knee, ankle, and wrist, it is either promptly fatal, or so unsatisfactory as to require subsequent amputation.

Instruments.—Various instruments are required for the ready and successful performance of this operation, and it is always desirable to have rather too many than too few, so that every emergency may be promptly met as it arises. Incisions through the skin and muscles are made with ordinary scalpels, but in detaching the bones from the soft parts and dividing the ligaments, stout, pointed knives, with broad, steel handles, convex and semi-sharp at the end, will be necessary. Excision of the bone is effected with a hand-saw, a pair of pliers, or the gouge and chisel, according to the structure, size, and situation of the affected piece. The saw, which may be a common amputating one, should be from six to ten inches in length by from three to twelve lines in width, its teeth being sharp and widely set, and its handle long and thick. A saw, lately introduced by Mr. Butcher, of Dublin, and bearing his name, will be found very useful, especially when there is but little space, or when it is necessary to divide

Fig. 181.

Butcher's saw.

bone obliquely. It has, as will be perceived by a reference to the engraving, a very narrow blade, the angle of which can be changed at pleasure. In addition

Fig. 182.

Hey's saw.

to these instruments, it will be well to have upon the tray a Hey's saw, fig. 182, and also a very narrow concave saw, fig. 183, with a blunt end, in the event

Fig. 183.

Curved saw for small bones.

its being necessary to divide the bone from behind forwards. As to the common hand-saw, fig. 184, even in its most approved forms, it may be well dispensed with

its use is generally only productive of delay, vexation, and disappointment. Bone forceps or pliers, figs. 185-6-7, usually known as Liston's, although long ago described and delineated by Scultetus, should be at hand, of various shapes and sizes, as they may frequently be employed with great advantage in places where it is impossible to introduce and work the saw. The surgeon should also be provided with several gouges and chisels, a strong mallet, trephines, scrapers, and a large elevator, together with a thick leather strap or leaden spatula for protecting the soft parts during the division of the bone, suitable instruments for holding the flaps apart, and a syringe for washing out the wound or clearing away sawdust and the debris of diseased bone and cartilage.

From this catalogue of instruments I have purposely excluded the tourniquet, which is not only unnecessary, but absolutely hurtful in excision of the bones and joints. If proper care is used, the surgeon will seldom lay open any of the more important arteries, none certainly which may not be readily secured by the ligature; there is, there-

Chain saw.

Fig. 185.

Fig. 186.

Fig. 187.

Bone forceps.

fore, no need of such a contrivance, as it would only serve to dam up the blood in the larger veins, and thus cause injurious waste.

Position of the Patient.—The position of the patient, the surgeon, and the assistants, as well as the number of the latter, varies in different cases and under different circumstances, and does not admit of any precise rules. Generally speaking, the recumbent posture will be the most suitable, especially if chloroform is given and the operation is at all likely to prove tedious. In cases of any magnitude, as in exsection of the knee-joint, the number of assistants should not be less than five or six; one administering the anæsthetic, two holding the limb, one handing instruments and tying arteries, and another having charge of the sponges.

As it respects the operation itself, it may conveniently be considered as consisting of three stages, the division of the soft parts, the excision of the bone, and the dressing of the wound.

Incisions.—In planning the incisions, care must of course be taken not to in-

terfere with any structures, the division of which might compromise in any way the result of the operation. The sheaths of the tendons are to be especially avoided. To lay them open would be to invite inflammation and plastic deposit, which could not fail to impair their usefulness. The nervous trunks are turned aside, out of harm's way, and the larger vessels, both arterial and venous, are studiously protected from injury.

The number and direction of the incisions will necessarily vary in different cases. Sometimes a single longitudinal cut will be sufficient, even in such a joint as that of the shoulder; in general, however, they should be so arranged as to enable us to form a good-sized flap, either of a semi-lunar, horseshoe, or square shape, as this will afford more ready access to the affected bone, as well as greater facility for sawing it. Incisions made after the manner of some of those depicted in the chapter on minor surgery will afford the surgeon an opportunity of adapting his operations to any case that will be likely to come under his observation.

The elliptical incision may be adopted, if it be necessary to remove any integument on account of disease. Whatever plan may be pursued, the great rule is to sacrifice as little soft substance as possible. Even when the flap is very large and unseemly, it must not be retrenched, experience having proved that it will always contract down to the proper dimensions during the progress of the cure. In separating the bone from its muscular and ligamentous connections, the knife must be kept as close as possible to its surface; any deviation from this rule will be likely to be followed by the division of structures which should not be meddled with, especially important bloodvessels.

Removal of the Bone.—Insulation of the bone having been effected, it is next to be pushed through the wound, and excised, the parts around being carefully protected from injury by a piece of leather, or a metallic spatula placed underneath. Whenever it is feasible, I prefer sawing off the bone to cutting it away with the pliers, as the surface thus made is more smooth, as well as less bruised, and, consequently, more liable to heal well. In operating upon the smaller bones, as those of the carpus and tarsus, we are generally obliged to make free use of the gouge and chisel. In whatever manner the excision may be accomplished, the invariable rule is to cut through the healthy structure; and this is applicable even when the bone is merely denuded of its periosteum, observation having shown that, when the osseous tissue is divested of its natural covering, it is either already dead, or will soon die. In excision of the long bones, the condition of the medullary canal and its contents should always be carefully scrutinized, with a view of ascertaining whether the part should be still further retrenched or not. Imperfect excision is worse than useless, as no thorough cure can take place after it without another operation. Finally, when two bones require to be removed, as, for example, in excision of the tibia and fibula, they should be sawn off upon the same level, otherwise the limb will be apt to be forced to one side, and so be rendered comparatively worthless.

In excision of the joints, care must be taken not to leave any of the capsular ligament, experience having shown that the danger from inflammation is materially increased when this precaution is neglected. In operating upon the bones in their continuity, the most important rule, besides taking away all that is dead or diseased, is not to disturb the periosteum, lest the part that is thus denuded should perish, and so necessitate farther interference. In many cases, indeed, this membrane, if allowed to remain, will afford essential aid in the formation of new bone.

Dressing.—Bleeding having been arrested, the wound is washed out with cool water thrown in with a large syringe, in order to get rid of the sawdust, which, if allowed to remain, never fails to act as a foreign substance, liable to provoke suppuration and erysipelas, if not worse consequences. Any sinuses that may exist are also pared or laid open. The edges of the wound are then approximated by the interrupted suture and adhesive plaster, aided, if necessary, by a compress and bandage. The most dependent portion of the wound, however, should always be kept patent by means of a small tent or tube, to admit of the necessary drainage. If this precaution be neglected, the result will be that the

secretions, which are always more or less profuse after such an operation, will accumulate in the wound, thus not only impeding the cure, but often inducing necrosis of the bones, and affording an opportunity for the easy entrance of pus into the system.

Before the patient is returned to bed, the limb should be placed in the position in which it is to rest during the after-treatment, and kept perfectly quiet by means of appropriate apparatus. In excision of the inferior extremity osseous union is usually desired, as the limb would hardly be useful without it, and hence it will not be proper, as a general rule, to make passive motion. In the upper extremity, however, this rule is not applicable; here motion is both sought for and attained at all hazard, an anchylosed wrist, elbow, or shoulder being of little value.

The great sources of *danger* after excision of bones and joints, are excessive suppuration, pyemia, and erysipelas. These accidents are to be carefully guarded against by the ordinary means, and treated upon general principles in the event of their occurrence. If the convalescence is unusually protracted, and especially if the wound is slow in healing, if sinuses form, or if there is much discharge of an unhealthy character, there will be reason to suspect that the bones have again become diseased, and that further interference will be required before a cure can finally be effected.

Statistics.—The statistics of excision of the bones and joints have been placed in a very prominent and satisfactory point of view by the researches of Dr. Richard M. Hodges, of Boston, and Dr. Oscar Heyfelder, of St. Petersburg, in two excellent and exhaustive monographs, published in 1861. The subjoined tables, compiled by the latter of these writers, comprise the aggregate results of 2,241 cases, of which 1,280 relate to the bones, and 961 to the joints.

Excision of Bones.

	Cases.	Recoveries.	Deaths.	Failures.	Percentage Deaths
Extremities	605	471	60	74	9.91
Face	559	379	174	6	31.12
Trunk	116	82	32	2	27.58
	1280	932	266	82	35.04

Excision of Joints.

	Cases.	Recoveries.	Deaths.	Failures.	Percentage Deaths.
Wrist	49	35	9	5	18.36
Elbow	286	205	32	49	11.18
Shoulder	196	131	30	8	15.30
Ankle	174	149	16	9	9.19
Knee	213	129	64	20	30.04
Hip	70	35	35	—	50.
	961	684	186	91	36.78

It will thus be perceived that in excision of the joints the smallest mortality is afforded by the ankle, and the largest by the hip. In regard to excision of the bones, the greatest percentage of fatal cases is furnished by the face. The mortality after all amputations, according to Mr. James R. Lane, calculated from a total of nearly 6,000 cases, is as high as 33.25 per cent., or one in every three of the patients submitted to the operation.

CHAPTER XIX.

ANÆSTHETICS.

THE prevention of pain in surgical operations has been an object of anxious solicitude with practitioners from time immemorial, and it is therefore not surprising that various attempts should have been made, at different periods, with a view of meeting this important end. No practical benefits, however, resulted from these trials until 1846, when Dr. Morton, of Boston, after numerous experiments with sulphuric ether, ascertained that it might be inhaled, not only with entire impunity, but with the most perfect certainty of preventing suffering in every operation, however severe or protracted. The anæsthetic properties of chloroform were discovered by Dr. Simpson, of Edinburgh, in 1847. Various other articles, as chloride of hydrocarbon, nitrate of ethyl, aldehyde, benzin, the Dutch liquid—a compound of chlorine and olefiant gas—bisulphuret of carbon, amylene, and kerosoline, possess anæsthetic virtues, but it is questionable whether any of them are sufficiently innocuous to justify their exhibition.

The relative value of ether and chloroform, as anæsthetic remedies, is still a mooted point. I have, myself, always preferred chloroform, believing it to possess decided advantages over ether, although its administration unquestionably requires greater care and attention. Among the more important of these advantages are, first, the more rapid manifestation of the anæsthetic action of the remedy, the system becoming affected much sooner, as a general rule, than it does by ether; secondly, a smaller amount of laryngeal and bronchial irritation; thirdly, the more easy maintenance of the anæsthetic influence, after the system has once been fairly affected; and, lastly, the less liability to cause vomiting and other unpleasant consequences. The very odor of ether is to many persons excessively offensive, and there are very few in whom the inhalation does not produce more or less cough and vomiting. On the other hand, it certainly requires less caution in its administration, and thus far it has furnished but few deaths, whereas the mortality from chloroform is already very considerable. Dr. Maddin, of Nashville, who has carefully investigated the subject, finds that most of the fatal cases of anæsthesia have occurred in minor surgery, or in operations of a comparatively trifling nature, and in which, consequently, the remedy might probably have been entirely dispensed with. For a number of these cases the dentist is accountable, nearly all the earlier and not a few also of the later having happened during the extraction of teeth, mostly from the want of precaution in not sufficiently depressing the head.

It is remarkable that most of the fatal cases have occurred in private practice, or in small institutions, a circumstance which would seem to show that there had been some fault in the mode of administration of the remedy. At Guy's Hospital, London, chloroform had been used in upwards of 12,000 cases before there was any serious accident; and in the war in the Crimea, according to the testimony of Flourens, it was administered more than 25,000 times without a single death. It has been asserted by the opponents of chloroform that the rate of mortality in the great operations of surgery has been essentially increased since the introduction of that article into practice, and Mr. Arnott, of London, has taken pains to collect elaborate statistics with a view of establishing the fact upon an irrefragable basis. On the other hand, the statistics of Dr. Simpson, the discoverer of the anæsthetic properties of chloroform, go to show that the

number of deaths is not only not increased, but absolutely diminished. Perhaps the truth lies between these two statements. Dr. Macleod, in his *Notes on the Surgery of the War in the Crimea*, published in 1858, declares it as his conscientious belief that the use of chloroform in the British army saved many lives, and that numerous operations were performed by its assistance which could not otherwise have been attempted. It is not improbable that, if there has really been an increase in the mortality after operations since the introduction of anæsthetics, it has been owing, not to the pernicious effects of the remedy, but to the fact that surgeons have been emboldened to undertake operations in cases which were formerly regarded as unfit for the employment of the knife, and, above all, to the circumstance that of late years there has been a fearful increase of railway and other terrible accidents, many of which are necessarily fatal, no matter to what treatment they may be subjected.

Dr. Henry W. Davis, of Illinois, in a paper in the *Chicago Medical Examiner* for 1862, declares that chloroform, judiciously administered, so far from being a depressant, in severe shock from gunshot injury, is a powerful stimulant, rapidly raising the pulse, and soon followed by healthy reaction. He states that he could cite numerous instances, presenting every degree of severity, but all attended with extreme prostration, in which the exhibition of this agent produced the most happy effects, and he adds that no amount of exhaustion, however intense, would induce him to withhold it, provided the lesion is recent. The experience of Dr. Davis has been confirmed by other observers, and I have myself seen a number of cases illustrative of the truth of his statements.

Although I have now given chloroform in several thousands of cases, for the most trivial as well as the most severe and protracted operations, no death has occurred in my hands, and in the only two instances in which I felt any serious alarm the danger was occasioned, not by any fault of the article itself, but by its injudicious administration.

I ascribe my good luck in the use of this remedy to the great caution with which, except in the above cases, it has generally been given in my practice, and to the great care which I have always taken in selecting a pure article. During my residence at Louisville, Dr. D. D. Thomson for many years superintended the inhalation in almost every important operation that I performed, either in private or public, and, when he was not present, I either gave it myself or confided the task to a trustworthy assistant.

The mortality from anæsthetics has been placed in a very satisfactory light by Dr. Charles Kidd. In a paper in the *London Medical Times and Gazette* for May, 1860, he states that, up to that period, about 125 cases of death from chloroform had occurred in Europe, 25 from ether, and several from amylene. Of 121 deaths from chloroform, 54 happened immediately before the operations; 42 during the operations; and 25 after the operations. The statistics of Dr. Kidd show that the mortality from chloroform has hitherto been more than twice as large in males as in females, and that the danger from the inhalation of this substance, as had been previously ascertained by Dr. Maddin, is much greater in trivial than in large, tedious operations, the latter establishing apparently a chloroform tolerance. Of the number of deaths from chloroform and other anæsthetics in this country, we have no accurate data, but it has been much less than in Europe. As an offset to the above fatal cases, it may be stated that chloroform, the use of which is unquestionably more dangerous than that of ether, has now been administered in hundreds of thousands of operations with perfect safety.

Anæsthetics not only prevent pain and mental suffering, but by placing the patient in a passive condition give the surgeon a control over him which he could not possibly obtain in any other manner. Deprived of sensibility and consciousness, the former is virtually dead to all external impressions, and the latter is therefore enabled to conduct his dissections and other manual processes with as much ease and deliberation as if he were operating upon the cadaver. The advantages thus gained are absolutely incalculable, and he who would fully appreciate them must be able to put himself in the twofold situation of patient and surgeon, and then, in imagination, contrast their condition with

that of the patient and surgeon of former times, before the discovery of anæsthetics, when the one was writhing in pain and agony during a tedious dissection, and the other had his progress incessantly interrupted by the cries and struggles of the sufferer.

The exhibition of anæsthetics is important not merely as a preventive of pain, but also as a means which enables us to investigate our cases more thoroughly prior to an operation. Sounding for stone in the bladder, formerly a source of so much suffering, may now be performed without the slightest uneasiness, and the same is true of stricture of the urethra, diseased bones, affections of the anus and rectum, and various other lesions. The use of anæsthetics affords immense advantages in the examination of dislocations and fractures, enabling us to handle the parts more satisfactorily than formerly, and therefore often leading to a much more certain diagnosis.

There are some occasions in which the use of anæsthetics is usually regarded as inadmissible; thus, in hare-lip, excision of the tongue, and removal of the jaw, the patient, as a general rule, should be under the influence of these remedies only at the beginning of the operation; after the dissection has been fairly commenced, he should be sufficiently conscious to enable him to co-operate with the surgeon, otherwise the blood, passing down into the windpipe, might cause severe cough and other inconvenience, seriously embarrassing the procedure. The same remark applies to excision of the tonsils, although I have frequently removed these organs while the patient was so far under the influence of chloroform as to render him incapable of offering any resistance. Extirpation of the jaws I have repeatedly performed under similar circumstances, passing through the different stages of the operation while the person was in a state of perfect unconsciousness. Even the more delicate operations upon the eye, as the establishment of an artificial pupil, and the extraction of cataract, may be safely performed with the aid of anæsthetics; as it respects the latter, however, it should not be forgotten that the vomiting which occasionally attends their use might destroy the organ.

An advantage which has often been claimed for anæsthetics is that there is apt to be less hemorrhage during operations; I am, however, in doubt whether this is true, and, even if it were, any good that might thus accrue would be more than counterbalanced by the liability to secondary bleeding, caused apparently by a partial loss of tone in the smaller vessels, interfering with the formation of protective clots. Possibly the blood itself may be more or less at fault.

Chloroform, a terchloride of formyl, is a clear, colorless liquid, very volatile, of an agreeable, aromatic odor, of a pungent, saccharine taste, very dense, of the specific gravity of 1.500 at 60° of Fahrenheit, almost insoluble in water, non-inflammable, and perfectly neutral, neither reddening nor bleaching litmus paper. It is a compound of three atoms of carbon, one of hydrogen, and three of chlorine. Various impurities are liable to be mixed up with it, especially the chlorinated pyrogenous oils, ether, and alcohol. The presence of oils is readily detected by pure, strong sulphuric acid, to which they impart a change of color, varying from yellowish to reddish brown, according to the quantity of the extraneous substances. A still more simple test consists in pouring the suspected fluid upon the hand, where, rapidly evaporating, it deposits its oily impurities, which are easily recognizable by their offensive smell. Dropped upon white paper, pure chloroform speedily disappears without leaving any stain. The existence of alcohol is detected by dropping a small quantity of chloroform into distilled water; if pure, it will retain its transparency at the bottom of the glass, if not, each globule will acquire a milky appearance. The presence of ether may be detected by a lighted taper, or the inflammable character of the fluid. It is practically important to know that chloroform deteriorates by exposure to heat and to a strong light. The most reliable article is prepared with methylated spirit.

Mode of Administration.—There are five principal circumstances which should be closely attended to during the exhibition of chloroform, and if this be done, it will be difficult, unless the article is bad, or the patient has some idiosyncrasy, to

produce any unpleasant effects with it. These are recumbency, an empty state of the stomach, a free play of the diaphragm, an abundance of atmospheric air, and a gradual administration.

1st. During etherization the patient may sit up with impunity, but this is not the case during the inhalation of chloroform, owing, apparently to the greater relaxation of the muscles, and, consequently, to the increased difficulty in maintaining the circulation of the brain through the influence of the heart's action. Not only should the body be recumbent, but care should be taken to depress the head and shoulders, bringing them nearly to a level with the trunk. Lying upon the side, when this is practicable, is perhaps the safest posture of all, as the breathing will then be less likely to be interfered with by the falling back of the tongue.

2d. An empty state of the stomach is desirable for two reasons; first, because if chloroform be given soon after a hearty meal it will almost be certain to induce vomiting; and, secondly, because a crowded condition of the organ interferes materially with the movements of the diaphragm. Food must not be taken for at least four hours before the exhibition; but, on the other hand, the interval should not be too protracted, lest serious exhaustion result from the want of the necessary stimulus.

3d. Care must be taken, before the inhalation is commenced, that the patient's clothes are sufficiently loose to prevent constriction of the chest and abdomen. Any compression from this source would necessarily impede the action of the diaphragm, and might thus become a cause of mischief.

4th. The importance of having an abundance of atmospheric air during the inhalation of an article so potent as chloroform is self-evident; in etherization this is of comparatively little consequence, but in the exhibition of chloroform for surgical and obstetrical purposes, it is absolutely indispensable to the safety of the patient.

5th. The inhalation must be effected gradually, not hurriedly, time being allowed to the system to accommodate itself to the influence of the remedy, thus avoiding the shock which might otherwise result to the heart and brain. From three to eight minutes should usually be spent in producing the full effects of the anæsthetic.

When the patient is very feeble, or pale and timid, it will be advisable to give him, immediately before the operation, from half an ounce to an ounce of brandy; and the dose may afterwards be repeated, if the effect is obliged to be maintained for an unusual length of time, sufficient consciousness being permitted for the performance of deglutition.

The best mode of administering chloroform is to pour the fluid upon a napkin or handkerchief, previously folded into a kind of cup-shaped hollow, and held securely in the hand. Or, instead of this, a small, hollow sponge may be used. As to the various inhalers that have been devised for the purpose, they are all objectionable on account of their inconvenience and the difficulty of obtaining a sufficiency of atmospheric air. The patient having taken his place upon the table, and emptied his lungs by a deep and protracted expiration, the napkin, impregnated with a drachm of chloroform, is held over the mouth and nose, at a distance of about two inches, being gradually brought nearer and nearer until it is within half an inch, beyond which it should not be carried, the chest being at the same time regularly and powerfully distended. The pungent effect of the liquid upon the skin should be prevented by anointing the face with some protective unguent, otherwise vesication might arise. All unnecessary conversation is avoided, lest the attention of the patient should thereby be unduly distracted. The assistant having charge of the administration gives it his earnest and undivided care; wetting the napkin from time to time with the fluid, and seeing that the patient gets an abundance of air, his vigilance increasing as the effects of the medicine become more and more apparent. As soon as the sensibility is completely abolished, the operation is commenced, a return to consciousness being prevented by holding the napkin, wet with a small quantity of the vapor, occasionally before the nose, and thus the impression is maintained, steadily and cautiously, not only until the

knife has fully accomplished its object, but until the principal arteries have been secured, and, in some cases, even until the dressings have been applied.

As soon as the inhalation has been fairly entered upon, an attendant should sedulously watch the pulse, respiration, and countenance. Should any sudden change be noticed in their condition, the administration must instantly be discontinued, or, if persisted in, conjoined with a more liberal supply of atmospheric air. It is not necessary that a finger should be constantly kept upon the pulse, for the color of the face and the nature of the breathing will always sufficiently indicate the effects which the anæsthetic is exerting upon the system, and thus afford abundant opportunity for preventing any unpleasant occurrence.

The *quantity* of chloroform required during an operation, and the time during which its effects may be safely maintained, must, of course, vary according to the exigencies of each particular case. In general, from half an ounce to an ounce may be regarded as a fair average, but very frequently it takes three, four, or even five times that amount, depending upon the severity and duration of the operation, and the susceptibility of the individual. In some instances almost an incredibly small portion answers the purpose. Children usually require comparatively little; and it is well known that women are, as a general rule, more susceptible to its influence than men. Persons exhausted by hemorrhage are very easily affected by it, owing to the rapidity of its absorption, and hence it should always be administered to them with unusual care. In obstetric practice, the effects of chloroform may be maintained, with impunity, for many hours together, and the same remark is true of severe and tedious surgical operations. Thus, in an attempt to reduce a chronic dislocation of the shoulder-joint, I kept the patient steadily under the influence of the remedy for two hours, during which not less than twenty ounces were used.

Age is no bar to the use of anæsthetics. I have given chloroform repeatedly to very young children, and, in several instances, with excellent effect, even to infants under two months. In fact, the more tender the age is the more easy is the induction of insensibility. Old persons also bear the inhalation well. Last winter I gave it to a lady of ninety-two, supposed to be laboring under a fracture of the neck of the thigh-bone. The effect was most delightful. Certain diseases are usually regarded as contra-indicating the employment of anæsthetics, particularly organic lesions of the heart and brain; but, for my own part, I have never allowed any affection whatever to stand in my way, and I can really, upon general physiological principles, see no reason why it should, since, by tranquillizing the system, these agents effectually prevent the mental and bodily perturbation so liable to attend operations performed without their aid. In giving chloroform to infants and very young children, only a few drops should be poured upon the napkin at a time, and care should be taken to hold the cloth at a considerable distance from the mouth and nose, so that the fluid may enter the lungs well diluted with atmospheric air.

Effects.—The effects of chloroform upon the system may, for practical purposes, be divided into two stages, namely, that of excitement, and that of insensibility. The first begins soon after the commencement of the inhalation, and is characterized by various cries and struggles, as if the patient, feeling alarmed, were anxious to escape from the table. The face becomes flushed, the eye has a wild and staring expression, the pulse is preternaturally frequent, and the mind is incoherent; as the effects increase, the brain falls into a species of exhilaration closely akin to that of intoxication. It is now that the individual usually exhibits his peculiarities of temperament and habit. Thus, if he is of a boisterous disposition, he will be very apt to be noisy, to swear, or to fight, and to make the most violent efforts to disengage himself from the assistants. One man will laugh and joke; another will weep, or moan and sigh; the sportsman will fancy himself occupied in the pleasures of the chase; the wily craftsman in driving a good bargain; the lawyer in addressing a jury; the preacher in exhorting his congregation, and the physician in prescribing for his patient. The mind is in a dreamy, perverted condition, and whatever is most predominant at the time in thought and feeling is sure to exhibit itself in expression.

This excitement varies much both in degree and duration; in many cases it is very slight and transient, while in some it is even entirely wanting, the patient being perfectly tranquil throughout. When considerable, it is very liable to be reproduced, to a greater or less extent, as the effects of the remedy wear off, so that the individual will perhaps be quite as boisterous after the inhalation is over as he was soon after its commencement. In very nervous, excitable persons the intoxication may last for several hours, although this is uncommon.

In the second stage, which succeeds imperceptibly to the first, the individual gradually lapses into a state of entire unconsciousness, the muscles, thoroughly relaxed, are no longer under the control of the will, the limbs retaining any position in which they may be placed; the eyelids are closed and the balls turned up, the pupils being contracted, and insensible to light; the respiration is calm and easy; and the pulse is soft and undisturbed, or, if at all changed, it is rather below than above the normal frequency. Feeling and intellection are suspended, and everything indicates that the patient is in a quiet and pleasant sleep, wholly unconscious of surrounding objects, and therefore completely insensible to pain. If this state be carried a little farther, coma will arise; the patient will snore as if he were apoplectic, the pulse and respiration will diminish in force and frequency, and the pupil will become notably dilated. As yet, all is safe, but a few more whiffs, and an important link in the chain of life may give way, and the patient be sent into eternity. In the administration of chloroform we should always strive to prevent coma. The most unexceptionable form of anæsthetization unquestionably is that in which there is a perfect suspension of sensibility without the complete abolition of consciousness; but it need hardly be added that it is, practically, extremely difficult to produce such a nice result in any case. In general, the patient, on recovering from the effects of the remedy, has no distinct recollection of anything that passed while he was under its influence.

The effects of chloroform seldom completely disappear under several hours. After the more characteristic symptoms have gone off, the mind will still be somewhat bewildered, the muscles relaxed, and the feelings perverted. In some cases, especially in children, the patient, after having passed through a most severe operation, will fall into a tranquil sleep, and perhaps not wake up fully for an hour or two. In other cases, again, the effects will go off very rapidly, and the individual will not only be roused to a state of consciousness, but to severe pain. If the vapor has been inhaled largely, there will frequently be some degree of nausea or even vomiting, either during the operation, or at its close, upon the return of consciousness. Emesis is most frequent in children and in persons of a nervous, irritable temperament. Headache, although not common, is occasionally met with, and sometimes lasts for a number of hours. It is most liable to come on if the chloroform is impure.

It has not fallen to my lot to witness any permanent ill effects from the exhibition of chloroform, such as partial paralysis, loss of sensation, or perversion of taste and smell; and a similar declaration has been recorded by the late Dr. Snow, of London, in his work on Anæsthetics, published in 1858.

Although chloroform is one of the greatest boons which a kind and beneficent Providence has bestowed upon man for the prevention and alleviation of pain, yet, like every other remedy, it is capable, when abused, or injudiciously administered, of producing the most deadly effects. These effects are those of a narcotic poison; and as they may follow, in persons of unusual susceptibility, the inhalation of the smallest quantity of the liquid, it is of the utmost importance that they should never, for a moment, be lost sight of in the use of the article. An over-dose may destroy life almost instantaneously, or death may occur at a variable period after the exhibition; sometimes after partial reaction has taken place. The phenomena indicative of danger are, stertorous respiration, a small and feeble pulse, lividity of the features, dilatation of the pupils, relaxation of the sphincters, and rapid diminution of the temperature of the body. It seems probable, although the question does not admit of positive adjudication, that these effects are mainly, if not wholly, due to the action of the carbonic acid gas contained in the chloroform primarily upon the blood and nervous centres, and

secondarily upon the respiratory organs, thereby disqualifying them for the performance of their functions, death being caused by asphyxia. What corroborates this view of the subject is the fact that the danger from the inhalation of chloroform is generally in proportion to the impurity of the article, or the quantity of its pyrogenous oils, and the want of a sufficiency of atmospheric air during the administration of the remedy.

The *treatment* for the relief of the poisoning consequent upon an over-dose of chloroform must be prompt and efficient; for everything depends upon the presence of mind of the surgeon and the rapidity and energy with which he applies his remedies. The first thing to be done is to desist from the further administration of the remedy; the second, to draw the tongue out of the mouth with a tenaculum, so as to lift it away from the glottis; the third, to cause a full access of cold air, by throwing open the doors and windows of the apartment, and making free use of the fan; the fourth, to dash cold water upon the body, or, still better, to pour it from a height of several feet; the fifth, to institute artificial respiration, by introducing a tube into the windpipe and percussing the body, or blowing air into the mouth; the sixth, to stimulate the surface, especially over the spine and heart, with hot mustard water, or dilute spirits of hartsborn; the seventh, to administer an injection of turpentine; and the last, to apply galvanic electricity, passed through needles inserted into different parts of the body. As soon as the patient is able to swallow, free use is made of brandy and ammonia. These means should be employed with great diligence and regularity until it is perfectly evident that life is irrecoverably extinct.

For the minor effects of chloroform very little is necessary, beyond a discontinuance of the inhalation, sprinkling the face and chest with cold water, allowing a free access of cold air, and holding a smelling bottle near the nose, but not to it. If vomiting occur, the patient must immediately be turned upon his side—not on his abdomen, lest the action of the diaphragm be impeded—with the head inclining downwards, otherwise the contents of the stomach, as they are lazily ejected from the œsophagus and fauces, might easily descend into the larynx, and thus induce suffocation. When the gastric distress is obstinate or protracted, the best remedy will be a dose of morphia and brandy.

In women, the unconsciousness, consequent upon the exhibition of chloroform, sometimes continues so long as to cause serious alarm for the safety of the patient. Such apprehension, however, is generally groundless, experience having shown that, when this state lasts beyond half an hour, it is due to hysteria, and not to the effects of the anæsthetic.

Anæsthetics should never be administered to females except in the presence of witnesses. The cases of the two dentists, the one of this city and the other of Montreal, which lately created so much excitement both in and out of the profession, should serve to admonish us that no man's character, however pure or exalted, may altogether escape censure, if, indeed, ruin. The remarkable instance which, a few years ago, occurred at the Philadelphia Hospital, of a woman who, while under the influence of anæsthesia, went through all the movements of the sexual congress, and analogous examples reported in the medical journals, clearly show how strongly the imagination of the patient may be impressed in this way, while thus affected, and how vividly the idea may remain after the ordinary effects of the remedy have passed off. A case that occurred, some years ago, at Louisville, might have been followed by a vexatious and disgraceful law suit, had it not fortunately been witnessed by several medical gentlemen. A practitioner should take care of his character not less than of the life of his patient.

Inhalation of Ether.—The inhalation of ether is best effected by means of a large hollow sponge held closely over the nose and mouth, although a folded napkin will be found to answer the purpose sufficiently well. No special attention need be paid to the admission of atmospheric air, as this fluid possesses none of the poisonous qualities of chloroform and other kindred articles. Not less than half an ounce should be poured upon the sponge at a time, and the administration should be diligently maintained until a full anæsthetic effect is produced,

which usually requires a considerably longer period than in the case of chloroform. At first a short cough is generally provoked, but this soon subsides, and the system gradually lapses into a calm, quiet condition, attended with muscular relaxation, closure of the eyelids, and mental unconsciousness, followed, in many cases, by stertorous respiration.

The quantity of ether consumed in an ordinary operation is seldom less than from four to eight ounces, while in the more protracted cases twice or even thrice that amount may be necessary. Sickness and vomiting are common effects of the use of this agent, and there is also not unfrequently a great deal of headache after the patient has recovered from his unconsciousness, sometimes lasting upwards of twenty-four hours. Moreover, the breath usually retains for a long time—occasionally, indeed, for several days—the disagreeable odor of the anæsthetic.

In administering chloroform the patient always lies down; in etherization, on the contrary, he may sit up, or recline, as may be most convenient to the operator, no injury resulting even from the protracted maintenance of the erect position. The inhalation too may be carried on more rapidly, and, as already stated, without any special reference to the admixture of atmospheric air, a sufficiency always entering through the sponge. Any bad effects that may arise from etherization should be treated upon the same general principles as those produced by an overdose of chloroform. The cold douche in particular will be of much service in recalling the patient to consciousness. All the different varieties of ether possess anæsthetic properties; but the one universally preferred is the sulphuric, thoroughly washed, and divested of impurities. It is the article which Dr. Morton originally introduced to the notice of the profession under the name of letheon, or pain-destroyer, and which is now so much employed in surgical and midwifery practice in this country.

Some practitioners prefer a mixture of ether and chloroform to either of these articles alone, considering it as equally efficacious, and at the same time more safe. I have myself frequently employed them in this way, and regard the combination as unobjectionable in every respect. The ordinary proportion is three parts of sulphuric ether to one of chloroform; but the quantity of either agent may be increased or diminished, according to the exigencies of the case, or the whim, fancy, or caprice of the surgeon. A mixture, composed of equal parts of chloroform and alcohol, was recommended by Dr. Snow, and is generally regarded as a very safe and efficient anæsthetic. In administering it to very young children, it may be diluted with rectified spirits, although, if proper care is taken, this is not at all essential, either to safety or convenience.

Local Anæsthesia.—Various plans have been tried for the purpose of inducing local anæsthesia, but the results have not been such as to hold out much encouragement for their practical application. When we consider the absorbent powers of the skin, it might reasonably be supposed that the endermic use of the more potent anodynes, as opium and its different preparations, aconite, belladonna, hyoseyamus, and other kindred articles, might be employed beneficially in this wise, but experience has proved that any effect of this kind that they may possess is exceedingly transient and altogether incapable of serving as a preventive of pain during the application of the knife. The employment of ice, or of the frigorific mixture, recommended by Mr. James Arnott, of London, is hardly entitled to more confidence; my experience with it is, it is true, very limited, but I have seen enough of it to satisfy me that its value has been greatly overrated by its advocates, and that it can never, except, perhaps, in the most trivial cases of injury and disease, be carried to a sufficient extent to prevent pain in surgical operations. I tried it on one occasion upon an old lady during the removal of the mammary gland; and, although the skin and subcutaneous cellular tissue were partially congealed, the ice in the latter producing a crackling noise, yet she suffered most severely, especially during the dissection of the deeper structures, where the effects of the freezing mixture had evidently not penetrated. No one can deny that, in this instance, the remedy had not been carried to a sufficient extent, and yet it certainly exercised but a very feeble influence

as an anæsthetic. Besides, the application is not without risk, as the part, if not carefully watched, may be frost-bitten, and thus experience unpleasant secondary effects.

Mr. Arnott's freezing mixture consists of two parts of ice and one of common salt, the former being previously reduced to a fine powder in a canvas bag, pounded with a flat-iron. The latter should also be pulverized. The two articles are then thoroughly and quickly mixed, either with a knife, or by stirring them together in a gutta-percha or other non-conducting vessel. The mixture is now inclosed in thin gauze netting, and as soon as the action of the salt upon the ice is rendered apparent by the dripping of the brine, it is placed upon the part to be benumbed, which is held in a horizontal position during the application. The netting should occasionally be raised to watch and equalize the effect of the remedy. About a quarter of a pound of ice and half that quantity of salt suffice for an ordinary application.

The first effect of the remedy is to chill the part, but this rapidly disappears, and is succeeded by pallor of the surface and a sense of numbness. Very soon the skin is found to be notably shrunken, and to assume a deadly, tallow-like appearance, at the same time that it is rendered somewhat stiff and perfectly insensible. If the application be continued longer, the subcutaneous cellular and fatty tissues become partially congealed, as is proved by the fact that they feel hard and crackle slightly under the finger. When the application is properly made, that is, gradually and cautiously, the netting being occasionally raised for the purpose of inspection, it is perfectly harmless and almost unattended with suffering. It is only when it is continued too long that it is likely to be productive of mischief. Ordinarily from fifteen minutes to half an hour will be required to secure the desired anæsthetic effect.

PART SECOND.

SPECIAL SURGERY; OR, DISEASES AND INJURIES OF PARTICULAR ORGANS, TEXTURES, AND REGIONS.

CHAPTER I.

DISEASES AND INJURIES OF THE SKIN AND CELLULO-ADIPOSE TISSUE.

SECT. I.—ERYSIPELAS.

ERYSIPELAS is so frequent and formidable an occurrence that every practitioner should be perfectly familiar with its nature and symptoms. Produced by various causes, both local and constitutional, it may exist as a primary affection, or show itself as a complication of other lesions, modifying their character, interfering with their evolution, and even, at times, entirely supplanting them. Observed from time immemorial, it is distinctly mentioned by Hippocrates, and has been a subject of particular investigation in the present century, as is evinced by the numerous papers and monographs that have been published respecting it during the last fifty years. The names and titles alone of these productions would fill many pages.

Erysipelas, at one time supposed to be peculiar to the skin and cellular tissue, is liable to attack various other structures, particularly the mucous and serous. By dermatologists it is usually ranked among the exanthematous diseases, on account of the discoloration which forms so striking a feature in its symptomatology. The term by which it is commonly designated is a Greek compound, signifying a tendency to spread.

The disease is generally arranged under different heads; according to the symptoms which attend it, or the parts of the body which it implicates. Thus, there may be erysipelas of the head, face, trunk, genital organs, and extremities. The most common, as well as the most proper, division, however, is into simple, phlegmonous, and œdematous. To this some authors have added a fourth, namely, the gangrenous. To such an arrangement no valid objection can be made, provided it be borne in mind that it is altogether artificial, and that it is intended to denote merely a difference in the degree, but not in the kind, of the morbid action. There is reason to believe that this distinction has not been sufficiently heeded in practice. Erysipelas is said to be idiopathic or traumatic, according as it depends upon some constitutional vice, or upon external injury.

The malady occurs at all periods of life, and in both sexes, but in what ratio has not been ascertained. The idiopathic variety is perhaps most common in women, the traumatic in men, owing to the greater liability of the latter to all kinds of injury.

There are no facts to show that *temperament* exerts any influence in the production of this disease. Bilious, or bilio-sanguineous, and nervous, irritable persons are said to be most prone to it; but in what proportion, or for what reason, remains to be determined. The malady is more frequent, at least in America, in the latter part of autumn, in winter, and early in the spring than at

any other season of the year, not a day of which, however, is anywhere exempt from its invasion in either of its two forms. Locality, doubtless, exerts an important influence in its causation; it is well known that it is particularly liable to occur in the narrow, crowded, and filthy streets of large cities, in the confined and ill-ventilated wards of hospitals, and in marshy, malarious districts. The effect of occupation in producing erysipelas has not been determined; but there is no question that cooks, blacksmiths, foundrymen, and persons habitually exposed to dry heat are particularly obnoxious to its attacks.

No *region* of the body is exempt from this affection, though some are more liable to it than others. The idiopathic form is most frequent in the face, scalp, neck, and trunk, while the traumatic appears to be most common in the extremities, particularly the inferior. It has been observed by most writers that the eyelids, nose, and forehead are especially prone to be attacked; a fact for which it is impossible, in the existing state of the science, to assign any satisfactory reason. Old, decrepit subjects, and persons worn out by intemperance and disease, often suffer from erysipelas of the scrotum, vulva, feet, and legs. In infants a very common seat of the disease is the lower part of the abdomen, around the umbilicus. Injuries of the scalp, tendons, and aponeuroses frequently give rise to erysipelas, and are liable, in consequence, to be followed, in many cases, by the worst results.

Erysipelas occasionally assumes an *epidemic* type. Hippocrates had already observed this fact. During the middle ages a gangrenous erysipelas repeatedly ravaged France, where, from its excessive violence, the disease was called the plague of fire. Erysipelas has frequently prevailed as an endemic in camps, barracks, hospitals, and prisons. In modern times it has been observed in both of these forms in various localities. Dr. Gregory expresses the belief that there is not a single hospital in London which has not, occasionally, been visited by the endemic variety of the disease. At St. George's Hospital, in that city, he has repeatedly seen erysipelas so prevalent that all important surgical operations were obliged to be postponed for fear of the supervention of the malady. The inmates of the Hôtel-Dieu, of Paris, are frequently assailed in this way, and the mortality thence arising is said to be quite great. Calmiel states that there are periods when erysipelas prevails so extensively in the lunatic asylums of the French metropolis that the physicians of those institutions are compelled to suspend all treatment by counter-irritants, as blisters, setons, issues, and moxas, on account of its great liability to be followed by an outbreak of this affection. Velpeau describes an epidemic erysipelas which prevailed at La Pitié in 1831. In 1844, '5, and '6, the disease was so common in the Louisville Hospital, and also throughout the city of Louisville, that I was obliged, on numerous occasions, to postpone the performance of all operations in which delay was admissible, for fear of giving rise to it. Such was the tendency, at that period, to its occurrence, that the most trivial incision, puncture, or scratch was almost sure to be followed by an attack. For a long time we were obliged, in consequence of this proclivity, to refrain from the use of blisters, leeches, venesection, setons, and issues. Chancres, buboes, and common ulcers were often invaded in a similar manner. But the epidemic was not confined to that city; it prevailed more or less extensively in different sections of the Union, and carried off an immense number of all classes of people. In many localities there was a marked connection between the affection and puerperal peritonitis, the latter of which proved very fatal.

The question as to the *contagiousness* of this disease is not fully settled. Much may be said both against and in favor of such a view. My own opinion, founded upon considerable experience, is that the affection, at times, possesses such a character. It is very well known that it is inoculable. Thus, a sponge impregnated with the matter of an erysipelatous sore will very readily communicate the disease to an ulcer or an abraded surface in a sound person, and the same thing is true of poultices, salves, and other dressings. Facts which show that the nurses and friends of individuals affected with erysipelas often contract the disease are of frequent occurrence. In this way whole families are sometimes cut

down. A gentleman, in 1852, lost his only son by this disease. A cousin and a female acquaintance who attended on him soon became ill with it, and both died; it then spread to other members of the family, and produced most serious ravages before it was finally arrested. In 1846, when erysipelas reigned as an epidemic in Kentucky, a man was received into the Louisville Hospital with an ulcerated bubo, and about the same time a woman, who had been his mistress, was also admitted with the prevailing distemper. In consequence of an inability to obtain a female nurse, the man was permitted to attend upon her in that capacity. He soon cohabited with her; in a few days he became excessively ill, the sore in the groin assumed an erysipelatous aspect, and in less than a week from the time of his admission he died from the effects of the malady. In the wards of hospitals erysipelas often spreads from one person to another; and in private practice the disease, there is reason to believe, is occasionally carried by the physician from one house to another. In this way it is no doubt sometimes communicated by the accoucheur to parturient females.

Causes.—The causes of erysipelas are too numerous and diversified to admit of any very definite specification. As a general rule, it may be assumed that whatever has a tendency to disorder the digestive, hepatic, or, in short, any other important function, is capable of producing the disease. So true is this that there is seldom, if ever, a case of the complaint in which such derangement does not play a more or less conspicuous part. The fact is important, as leading to valuable therapeutic considerations. Certain articles of diet either predispose to or induce the malady. Thus, there are some persons who can never eat shell-fish or particular kinds of fruits, as strawberries, nuts, and similar substances, without suffering an attack. The retention of vitiated secretions and undigested food in the alimentary canal often leads to similar results. Derangement of the uterine function, suppression of the cutaneous perspiration, great mental excitement, the habitual use of ardent spirits, loss of sleep, hard study, inordinate sexual indulgence, and, in short, whatever else has a tendency to weaken the corporeal faculties, may be enumerated as so many causes of the disease. A vitiated state of the atmosphere, such as is witnessed in hospitals and other charities, often powerfully predisposes to its attacks and its continuance. Some of the worst cases of this disease I have ever seen came on during the progress of albuminuria.

Erysipelas frequently supervenes upon wounds, both accidental and artificial, interfering with the healing process, and, at times, seriously compromising both the part and system. The period at which this occurs varies from twenty-four hours to several days, according to the nature and extent of the lesion, the presence or absence of complications, the habits of the patient, the condition of the system, and the state of the atmosphere. Lacerated, punctured, gunshot, and poisoned wounds are much more liable to be assailed in this manner than incised wounds, though the latter are by no means exempt from it, especially if they involve the scalp, hands, or feet, or if they affect old, intemperate, or debilitated individuals.

When the disease is epidemic, it often shows itself within a very short time after the receipt of an injury, however slight or insignificant. Under such circumstances, indeed, I have, as already stated, known it to follow upon the most trifling wound, scratch, or puncture, as a leech-bite, venesection, vaccination, or the application of a blister. Fractures, dislocations, sprains, contusions, and various other injuries not unfrequently give rise to it. Ulcers, whether common or specific, are often invaded by it, especially when the patients are of a broken constitution. Lying-in females are, in certain conditions of the atmosphere, particularly prone to suffer from erysipelas of the uterus and pelvic veins.

Finally, erysipelas frequently ingrafts itself upon other diseases. During the winter of 1857, when the malady was endemic in this city, a number of instances occurred where it supervened upon measles, scarlatina, and typhoid fever. During an outbreak of endemic erysipelas in Louisville, in 1844, '5, '6, every case of disease that was admitted into the public hospital of that city received its peculiar impress, and wore for a time its peculiar livery. When the affection was raging at its fullest height in the institution, many of the patients who were con-

valescening from other maladies were suddenly seized with diarrhœa, pneumonia, and bronchitis, over which the usual remedies exercised no control, and which generally proved fatal in a few days.

When erysipelas supervenes upon wounds, its approach is usually denoted by an arrest of the adhesive process, by a tensive, burning sensation in the affected part, by a discharge of thin, sanious matter, or an entire suspension of secretion, and by an œdematous appearance of the surrounding structures. Finally, the characteristic blush occurs, and, gradually diffusing itself, often spreads over a considerable extent of surface.

When erysipelas seizes upon ulcers, as it may at any time, whether they are benign or malignant, simple or specific, the local symptoms closely resemble those which characterize the complaint when it follows upon wounds and contusions. The granulations, if any exist, assume a pale, glossy, unhealthy aspect, the pus is replaced by a thin, ichorous fluid, the part is rendered uncommonly painful, and the edges of the sore, along with the adjacent surface, exhibit a reddish, œdematous appearance. In chancres and dissection wounds the presence of the malady is indicated by reddish, tender lines, formed by superficial lymphatic vessels, generally extending as high up as the neighboring ganglions, which, in turn, become swollen and exquisitely painful. The morbid action may, in both cases, be simple or phlegmonous, and is almost always dependent upon derangement of the digestive organs, or the suppression of some habitual discharge.

Erysipelas, consequent upon wounds, contusions, fractures, and dislocations, generally displays itself within the first forty-eight hours after the receipt of the injury, and often spreads very rapidly over a large extent of surface, as the greater portion of a limb, one side of the trunk, or the whole scalp and face. The accident is particularly liable to supervene upon the more severe forms of these lesions, and is always to be viewed with distrust, as it not unfrequently compromises the patient's recovery. Erysipelas of the scalp, caused by wounds and fractures of the skull, generally appears from the second to the third day, and often proves dangerous by its extension to the brain and its envelops, through the intervascular communications between the pericranium and the dura mater. Such cases always demand the greatest vigilance on the part of the practitioner.

Varieties.—Erysipelas occurs under several varieties of form, as the simple, phlegmonous, and œdematous, each of which merits brief attention. To this division may be added erratic erysipelas, so called from its disposition to wander from one part to another.

The term *simple* is employed to designate that form of the disease which is confined exclusively to the skin. It manifests itself in a bright, vivid, almost scarlet discoloration of the surface, a pungent, smarting, or burning pain, and a sense of stiffness, with, perhaps, here and there a little vesicle, not larger than the head of a pin, and filled with a serous fluid. The swelling is very slight, and, unless the extent of disease is considerable, there is no particular constitutional disturbance. The attack is usually of short duration, and the subsidence of the local disease is always followed by a furfuraceous desquamation of the epidermis.

Phlegmonous erysipelas is a much more serious lesion than the simple, all the symptoms existing in a higher degree, and the disease often terminating in extensive suppuration, abscess, and even gangrene. The discoloration varies from scarlet to deep purple; there is extensive swelling; vesication soon arises; and the pain is of a violent, burning, tensive, and throbbing character, the part feeling heavy, stiff, numb, and as if it were on fire. The inflammation extends deeply into the different tissues, affecting skin, cellular substance, muscle, and, in short, everything that comes in its way. As it progresses, suppuration takes place, leading to the formation of extensive abscesses, and the destruction of large portions of the cellular and adipose tissues. If the morbid action is very intense, mortification will be apt to arise, its approach being indicated by the development of large blebs, filled with bloody or muddy serum, and by a dark, livid, brownish, or ash-colored appearance of the skin. The constitution sympathizes early and deeply, the symptoms being at first of a sthenic character, but soon becoming typhoid.

The *œdematous* variety depends entirely upon accidental causes, its name

being derived from the circumstance of the parts being infiltrated with serosity, and, consequently, pitting under pressure. It is most commonly met with in the eyelids, scrotum, prepuce, vulva, and inferior extremities, in persons who are debilitated by previous disease, or who naturally possess a feeble constitution. The swelling is often considerable, but the discoloration and pain are comparatively trivial. The diseased surface has a glossy, distended appearance, and retains the mark of the finger for some time after it has been withdrawn. The inflammation is attended by constitutional disorder, generally of a typhoid character, and is apt to terminate in mortification rather than in abscess, though the latter is often present in the more severe cases.

Erratic erysipelas is characterized, as the name imports, by a disposition to extend from one point to another; it is most commonly met with on the face and forehead, from which it frequently spreads, on the one hand, to the hairy scalp, and, on the other, to the neck and ears. I recollect a case of this form of erysipelas, which, commencing on the left nates, finally extended over the whole trunk. The disease is generally superficial, and is characterized by an erythematous appearance of the surface, with pungent pain but little swelling.

If a *dissection* be made of a limb in a state of erysipelas, it will exhibit various appearances, according to the amount of the diseased action. In the milder grades, there will merely be some degree of induration of the skin, unusual distension of the vessels, and slight effusion of serum, or of serum and lymph, in the subjacent cellular substance. In the phlegmonous variety, there is generally extensive infiltration of the ordinary inflammatory products; the lymph has a spoiled and unnatural appearance, looking like lard or a mixture of flour and water; abscesses exist in various situations; the cellular tissue is converted into grayish, or ash-colored sloughs; and the muscles are extensively separated from each other. In a case which occurred in the Louisville Hospital in 1846, during the prevalence of epidemic erysipelas, the abscess reached from the hip to the ankle, extensively detaching the muscles from each other and from the bones, which might have been lifted almost bodily from the diseased mass, so completely were they severed from their connections. Pure blood is sometimes extravasated in considerable quantity; and the matter, which varies much in its color and consistence, is often excessively offensive. Metastatic abscesses are occasionally found in the internal viscera, and effusions in the serous cavities.

An epidemic erysipelas, of a very singular character, prevailed in various sections of this country, from 1842 to 1847, its first appearance having been noticed in Vermont and New Hampshire. It had previously shown itself in Canada, and soon after it broke out in the southwestern States, where, as well as in other parts, it proved exceedingly fatal. In Louisville, where I then resided, it prevailed for several years, and afforded me an excellent opportunity of studying its character. It usually began in the throat and fauces, or simultaneously in these parts and upon the cranio-facial region, in the form of a deep red, glossy, œdematous swelling, which gradually extended until it involved the whole of the neighboring structures, the countenance being generally distorted in the most hideous manner, so that the patient could hardly be recognized even by his most intimate acquaintances. The tongue, uvula, and tonsils were enormously swollen, deglutition and breathing were extremely difficult, and death was often produced by suffocation. Delirium and excessive prostration were early and prominent symptoms, and many of the cases perished within the first five days. The disease remained generally confined to the parts originally affected. If the patient survived any time, profuse suppuration, and sometimes even extensive sloughing, occurred; abscesses formed in various regions of the body; and, after much suffering, the patient either recovered, or died from exhaustion. In some of the persons whom I attended there was extensive ulceration of the tonsils and arches of the palate; and, in several, complete destruction of the parotid gland of one side. In one case, almost the whole of the occipital bone was stripped of pericranium. Dissection disclosed deep engorgement of the lungs, accompanied, in many cases, by inflammation of the bronchial tubes, and even of the pulmonary parenchyma, and by effusion of serum, or of serum and pus, in the pleura

and arachnoid sac. The abdominal and pelvic viscera were generally sound, except in lying-in females, who usually exhibited high evidence of peritonitis, metritis, and phlebitis. In one instance, which occurred quite early in the epidemic, the immediate cause of death was a large metastatic abscess in the left lung, the erysipelas being seated in the corresponding leg.

The disease which I have thus briefly described was generally known in the West under the name of "black-tongue," "swelled head," or "erysipelalous fever." It seldom attacked any one under fifteen years, but from that period up it was indiscriminate in its selection of subjects. Females seemed to suffer quite as frequently as men. The poor and the intemperate were its most common victims.

Constitutional Symptoms.—Whatever form it may assume, erysipelas is usually preceded by symptoms denotive of general indisposition, such as a feeling of *malaise*, or discomfort, creeping, chilly sensations, lassitude, pain in the head and limbs, impaired appetite, and an indisposition to exertion. After continuing in this state for a period varying from twenty-four to thirty-six hours, the disease declares itself in a more open manner. The patient is now suddenly seized with shivering, or violent rigors, followed by, or alternating with, excessive heat, and accompanied by severe cephalalgia, nausea, intense thirst, restlessness, and a great sense of muscular prostration. The tongue is dry and coated, the skin hot, the pulse strong and frequent, the urine high-colored and scanty. As the disease progresses, the system becomes more and more exhausted, the mind wanders, and the case soon assumes a typhoid character. Or, typhoid symptoms may be present almost from the very commencement, especially if the patient is old, or depressed by previous suffering. In the milder forms of erysipelas, there is often very little, if any, constitutional disturbance.

If blood be drawn during the progress of the disease, it will generally be found to exhibit a sizzly appearance. Sometimes it is deeply buffed and even cupped. What internal, or intrinsic changes, the mass of blood undergoes in this affection has not been satisfactorily determined.

Diagnosis.—Erysipelas is generally so well marked as to render it impossible to confound it with any other disease. The only form which is liable to cause error of diagnosis is the simple, which may be mistaken for erythema, which it certainly very much resembles. The signs of discrimination are, the peculiar character of the pain, which is sharp, pungent, and smarting in erysipelas, and almost absent in erythema; the deeper redness in the former than in the latter, and the tendency also to the evolution of vesicles, which does not exist in erythema.

Pathology.—The pathology of erysipelas has been a fruitful subject of discussion almost from time immemorial, and yet, notwithstanding all that has been said and written about it, it is still involved in impenetrable obscurity. How it is induced, what is its seat, or where it originates, are points concerning which we are wholly ignorant. We only know that it has a peculiar predilection for the dermoid and cellular tissues, and that it is usually, if not invariably, connected with disorder of the general system, affecting, probably, both solids and fluids. So thoroughly am I convinced of the latter fact, that I do not believe it would be possible for erysipelas ever to appear in a perfectly sound individual. If this be true, as I think multiplied and carefully conducted observation authorizes me to affirm, then derangement of the general health, especially as displayed in a vitiated condition of the digestive organs, must be regarded as a most important element in the pathology of this affection, and one which must exert a marked influence upon our curative agents. The opportunities constantly afforded the surgeon, in cases of accidents and operations, of testing this point, peculiarly qualify him for pronouncing upon the question. I am not now, of course, speaking of epidemic erysipelas, to which every one is more or less liable, but of the ordinary form, the development of which, as is well known, is so much influenced by intrinsic and extraneous circumstances, as the health and habits of the patient, his residence, the nature of his diet, and the state of his mind. When a person is intemperate, breathes a foul air, eats bad food, or has a troubled

mind, the most trivial injury, as the merest prick of the finger, is often followed by a fatal attack of the disease, whereas another, although severely hurt but enjoying better health, will, perhaps, escape entirely, or suffer only in a slight degree. The surgeon, aware of this circumstance, constantly acts upon it in practice, making it a rule never to perform any serious operation until he has put his patient in a proper condition for it by the rectification of his secretions and the improvement of his general health.

Erysipelas has sometimes been regarded as consisting essentially in a bad form of capillary phlebitis, it being alleged that the smaller veins are generally found to be involved in the disease, as is shown by the inflamed condition of their coats, and the existence, in their interior, of various kinds of substances, as lymph, pus, and coagulated blood. Such changes undoubtedly occur, to a greater or less extent, in all severe cases of the malady; but they occur, not as a cause, but as a consequence of the morbid action. Other pathologists, again, consider erysipelas as being essentially an affection of the lymphatics, or of these vessels and of the veins. Finally, there is another class who look upon it as being altogether, from first to last, a blood disease, or, in other words, a species of toxemia. All these views, however, amount to nothing but conjecture, their truth or falsity remaining to be established.

Prognosis.—The prognosis of erysipelas is influenced by the character, extent, and seat of the morbid action, by the age and habits of the patient, and by the absence or presence of complications. Phlegmonous erysipelas, other things being equal, is generally more dangerous than the simple or œdematous, as it is more liable to end in extensive suppuration, gangrene, and metastatic abscesses. A simple erysipelas, however, if of great extent, is hardly less dangerous to life than a phlegmonous one, the shock to the nervous system being nearly as severe as in a superficial but extensive burn, which often kills on this account. The disease is particularly to be dreaded when it attacks the scalp, from its liability to extend to the brain. Infants, young children, old persons, and the habitually intemperate bear up badly under it. Erysipelas occurring during the progress of other affections, as measles, scarlatina, and typhoid fever, is generally fraught with danger. An epidemic erysipelas is always more destructive than a sporadic one, as it is sure, under such circumstances, to impress itself with peculiar force upon the constitution. Traumatic erysipelas often proves fatal in a surprisingly short time. In the summer of 1856, I attended a young butcher, who died in less than three days from a violent attack of this disease of the hand and arm, brought on by a punctured wound inflicted by a hook used for hanging up meat.

Treatment.—As erysipelas is capable of being developed by such a variety of circumstances, it necessarily demands a corresponding variety of treatment. Experience long ago showed that remedies which afford relief in one case are productive of no benefit in another, and hence it is all important, in every instance, that our curative measures should be based, if possible, upon a correct appreciation of the nature of the exciting causes. If the practitioner should attempt to combat it upon any other principle, he will find himself sadly mistaken.

The treatment of this disease may conveniently be divided into general and local, each embracing a great variety of means, which it will be necessary to pass briefly in review. The most important constitutional remedies are blood-letting, emetics, purgatives, diaphoretics, mercurials, anodynes, and stimulants.

General *bloodletting* is rarely necessary; in fact, in most cases it proves mischievous, by augmenting the debility of the system, already, perhaps, greatly depressed by the violence of the morbid action. The circumstances which, in my judgment, render a resort to the lancet proper in this complaint are, first, a strong, full, and frequent pulse; secondly, a robust and vigorous state of the system; thirdly, excessive pain and tension of the parts; and, lastly, the involvement, threatened or actual, of important internal organs, as the brain, lungs, and throat. The amount of blood to be abstracted must depend upon the effects which the operation exerts upon the system. One moderately copious bleeding, performed early in the disease, will usually be sufficient, and will answer a much better purpose than two or three small ones. It should be borne in mind that

venesection should never be carried as far in epidemic as in sporadic erysipelas, and in old, sickly, or intemperate persons, as in the young, robust, and plethoric. In the epidemic erysipelas which prevailed so extensively a few years ago in various sections of the United States, the abstraction of blood was generally borne very badly, and many lives were lost by its injudicious employment. In the Louisville Hospital not a single patient recovered that was bled for this disease. In erysipelas supervening upon capital operations and severe accidents, as compound fractures and dislocations, wounds, and contusions, proper allowance must be made for the effects of shock and loss of blood, and the resulting suppurative discharges. Children affected with erysipelas rarely, if ever, require bleeding in any form.

Great contrariety of opinion has prevailed among writers respecting the employment of *emetics* in this disorder, some having pointedly condemned them, while others have expressed themselves most warmly in their favor. In the hands of Desault and his disciples the greatest benefit seems to have attended their exhibition. The probability is that here, as elsewhere, in similar cases, the truth lies between the two extremes; for it can hardly be supposed that a class of remedies of such acknowledged potency in many cutaneous affections should be altogether useless in erysipelas. The cases in which, according to my observation, emetics are mainly indicated are those in which there is marked biliary derangement, along with nausea, loathing of food, headache, pain in the back and limbs, great restlessness, and dryness of the surface. These symptoms, so distressing to the poor sufferer, are often promptly relieved by full emesis, excited by ipecacuanha and tartrate of antimony and potassa, ipecacuanha alone, or salt and mustard, and encouraged by the free use of tepid drinks. In protracted cases, and in the erratic form of the malady, attended with derangement of the digestive organs, gentle emetics often operate like a charm in breaking up the chain of morbid action.

Great stress has always been placed upon the administration of *purgatives* in the treatment of erysipelas. When it is remembered that this disease is often directly dependent upon an overloaded state of the bowels, the presence of irritating ingesta, and the suppression of the secretions of the digestive organs, it is not difficult to discover a reason for this practice. Indeed, it would be hard to find a case in which it would be altogether safe to dispense with them. I have myself always derived the most signal benefit from them, especially in the earlier stages of the complaint, although there is no period in which they can perhaps be entirely omitted. The articles upon which I mainly rely are calomel, rhubarb, and compound extract of colocynth, variously combined, and given in sufficient quantity to produce two or three free and consistent motions. Sometimes the addition of a little tartar emetic or ipecacuanha proves beneficial, especially when there is an arid state of the skin and mouth; while occasionally they may be advantageously replaced by others, as castor oil and spirits of turpentine, oil alone, senna, or Epsom salts. When there are nausea and headache, with a highly coated tongue, the best cathartic, in general, is calomel and ipecacuanha, in the proportion of about fifteen grains of the former to two grains of the latter, followed, if necessary, in six or eight hours, by a stimulating enema, or a dose of sulphate of magnesia. When the bowels have been once thoroughly evacuated, a moderate passage should daily be induced by some mild laxative, as blue mass and rhubarb, Seidlitz powder, or colocynth and hyoscyamus.

Diaphoretics constitute a valuable class of remedial agents in the treatment of this affection, and can seldom be entirely dispensed with, as there are few cases in which the cutaneous function is not more or less interrupted, perverted, or suspended. After proper depletion by the lancet and purgatives, or, at all events, thorough evacuation of the bowels, and the restoration of the secretions of the digestive organs, the administration of medicines calculated to act upon the skin often proves eminently serviceable. Among the best of this group of articles are Dover's powder and the salts of antimony and morphia, aided by tepid sponging, or, when the patient's strength admits of it, the warm bath. In children and debilitated persons, the spirit of Mindererus and wine of ipecacuanha

may be advantageously resorted to. Aconite, in doses of three drops of the tincture, every two, three, or four hours, generally answers an excellent purpose, especially when there is a hot and arid condition of the surface, and inordinate excitement of the heart. The same is true of veratrum.

There are few cases of erysipelas, even of the milder grades, in which the use of *anodynes* is not indicated, either for the purpose of allaying pain, or of inducing sleep. When the malady occupies, as it not unfrequently does, an unusual extent of surface, the system is very apt to suffer in the same manner as in severe burns and scalds, and requires, at a very early stage of the complaint, the employment of soothing measures. The remedy, which is commonly one of the salts of morphia, is administered upon the same principles as in other inflammatory affections, either by itself, or in union with other articles, especially diaphoretics, in quantities proportioned to the exigencies of each particular case. As a general rule, the object is best attained by a full dose, repeated once or twice in the twenty-four hours. To an adult, laboring under great pain and restlessness, provided there is no cephalic trouble, not less than half a grain of morphia should be given at a time. Thus administered, the effects of the remedy are much more decided and beneficial than when it is exhibited in smaller doses, as is too often the case with practitioners, not only in this, but in other inflammatory maladies. Delirium, or cerebral disorder, does not necessarily contra-indicate the use of *anodynes*; on the contrary, persons so affected are often immensely benefited in a short time by their judicious exhibition. To no class of patients is this remark more applicable than to habitual inebriates, and individuals worn out by previous disease, loss of blood, protracted drainage of the system, or constitutional irritation. Such persons absolutely require, at an early period, and in every stage of the malady, the use of *anodynes* in large doses, in order to prevent exhaustion, and afford time and opportunity for the more efficient action of other remedies.

Mercurials are sometimes usefully exhibited in this disease. They are particularly valuable in the erratic form of erysipelas, and when there is a tendency in the malady to linger in the system, after its principal force has been exploded, but when it is still disposed, as it were, to dispute with the practitioner every inch of its possessions. In such cases, they occasionally act like a charm, even when they are not carried to the extent of ptyalism, which, however, is often necessary, before the disorder will relinquish its grasp. During the epidemic erysipelas which prevailed in Louisville and its vicinity in 1844, '5 and '6, I treated quite a number of cases upon this plan, with the most happy results, although now and then a patient was lost, even after the establishment of slight salivation. *Mercurials* should be most scrupulously avoided in erysipelas attended with a low, typhoid state of the system in old, worn-out subjects, and in persons exhausted by intemperance and dissipation. The best form of exhibition, when the remedy is indicated, is calomel with a small quantity of opium and ipecacuanha, or Dover's powder, to restrain its action on the bowels and allay nervous irritation. In urgent cases two grains of the metal may be given to an adult every four or six hours, combined with half a grain of the *anodyne*. When a less rapid impression is desired, blue mass, iodide of mercury, or the gray powder may be used. In whatever form or manner the remedy be given, its effects should be most carefully watched, and they should never be carried beyond the limits of the slightest possible ptyalism.

The late Professor John K. Mitchell informed me that he had, for many years, derived more benefit, in this disease, from the use of *iodide of potassium* than from any other remedy. His plan was, after gentle alvine evacuation, to begin at once with the article, giving it, largely diluted with water, every two or three hours, in doses of five to ten grains, until the attack was arrested, which, it would seem, usually happened in a few days. In the few trials which I have made of this remedy, I have witnessed no material benefit, and in several cases I was obliged to suspend it at an early period, on account of its disagreeing with the stomach.

Stimulants and tonics are required when there is, as occasionally happens

even in the early stage of the disease, a tendency to excessive prostration. A hard, dry, and brownish tongue, sordes on the teeth, a small, feeble, and frequent pulse, twitching of the muscles, coolness of the surface, and copious sweats, with or without delirium, clearly indicate the necessity of the employment of this class of remedies, which are sometimes alone capable of arresting the disease and of establishing convalescence. The most reliable articles for this purpose are quinine and iron, in the form of the tincture of the chloride, a scruple of the former being dissolved in an ounce of the latter, and the mixture given in doses of fifteen to thirty drops every three or four hours. When this combination disagrees with the stomach, the articles may be employed separately. The treatment should be aided by the liberal use of brandy, milk punch, wine, ale or porter, and a generous diet.

Throughout the whole treatment, the greatest attention should be paid to the ventilation and temperature of the patient's apartment; the body and bedclothes should be daily changed, and the cutaneous surface should be frequently sponged with tepid salt water, or some slightly alkaline solution. As disinfectants, free use is made of the chlorides, bromine, or permanganate of potassa. As soon as his strength admits of it, the patient should take gentle exercise in the open air, and, if possible, sleep in another apartment.

All *topical* remedies in the treatment of this disease are to be regarded rather as auxiliary than as curative agents. Looking upon the cutaneous eruption merely as a local manifestation of a constitutional disorder, the philosophical practitioner will place his reliance mainly upon internal means, and consider all external ones as of secondary moment. Nevertheless, it would be wrong, even in many of the milder cases, wholly to neglect these, since experience has abundantly attested their utility. A vast variety of applications, many of them of the most opposite character, have been recommended with this object, as warm and cold, dry and moist, astringent and relaxing, stimulating, vesicant, and anodyne. It would seem, indeed, as if almost every article of the *materia medica* had been called into requisition, as if to show what little confidence, as a general rule, is to be placed in their efficacy.

At the head of the list of local remedies may be placed *leeching*, concerning the efficacy of which, however, practitioners are still divided in opinion. My conviction is that it may often be employed with great advantage, though, in general, it is entirely unnecessary. The fact that the operation is occasionally followed by erysipelas does not, in my judgment, prove that it may not at times be beneficial. It is only in rare cases, and under peculiar circumstances, as when the patient is of a very irritable habit, or when the leeches are sickly, that such a result is at all likely to occur. Against such a contingency the judicious practitioner will, of course, always guard. The use of the remedy is particularly indicated in erysipelas of the throat and larynx, the scalp, eyelids, vulva, toes, and fingers. The number of leeches must vary according to circumstances, as the intensity of the morbid action and the vigor of the patient; and the flow of blood should always be encouraged by warm fomentations until the desired quantity is obtained.

One of the great topical remedies at the present day for the cure of erysipelas is *iodine*, either in the form of tincture or solution. I generally give the preference to the former, diluted with an equal quantity of alcohol, and laid on by means of a large camel-hair pencil, the end of a stiff feather, or a soft cloth mop, until the surface is of a yellowish, brownish, or mahogany color. The application should embrace a small portion of the sound skin, and should be repeated at least twice, if not thrice, in the twenty-four hours. In the milder grades of erysipelas a single application will occasionally suffice for a cure; while in the more aggravated a considerable number may be required before the disease is finally dispersed. The remedy is sometimes productive of severe pain, especially in nervous, irritable, and thin-skinned persons, which may persist for several hours, and which hardly anything, save time, will allay. To obviate this occurrence, the first application should always be very light; if no inconvenience arise, the medicine may afterwards be used more freely, and may even, in some instances,

be advantageously carried to the extent of vesication. If, notwithstanding this precaution, the pain is very severe, the part should be freely sponged with a weak solution of iodide of potassium, and covered with a starch poultice.

I have employed the tincture of iodine in the form and manner here indicated for many years, both in the sporadic and the epidemic varieties of the disorder, and can confidently assert that I have derived more benefit from it than from any other article. Resorted to in the early stage of the disease, it generally promptly relieves pain and tension, rapidly promotes the removal of effused fluids, and greatly assists in checking morbid action. When applied very freely it occasionally vesicates, and is thus instrumental in unloading the cutaneous capillaries. Doubtless, it also acts advantageously upon the blood and its vessels, indisposing them to further effusion.

Nitrate of silver, employed either in substance, or in strong solution, is another highly valuable agent in the treatment of this disease. It is applied either directly to the affected surface, or a belt is drawn around it upon the healthy skin, to prevent its further spread. I commonly prefer the former method, using the solid nitrate instead of the solution, so strongly recommended by Mr. Higginbottom. In order to apply this substance properly, it is necessary, as a preliminary step, that the surface should be divested of all greasy and perspirable matter, otherwise it will refuse to unite with the epidermis, and so prove, in great measure, inert. The part should then be gently moistened with soft water, when the caustic is passed firmly and efficiently over it until the whole has been thoroughly touched. Thus employed, it speedily blackens the epidermis and coagulates its albuminous matter, thereby forming an excellent defence to the delicate tissues beneath. When used more freely it generally vesicates, elevating the scarf-skin into tolerably large blisters. Mr. Higginbottom applies a strong solution of the nitrate of silver, consisting of three drachms of the salt to the ounce of water, with the addition of a small quantity of nitric acid. I have no experience with the remedy in this form. The probability is that nitrate of silver produces its beneficial effects very much in the same manner as the tincture of iodine, changing the tone of the capillary vessels and promoting the absorption of effused fluids, besides serving as a direct defence to the cutaneous surface by its union with the albuminous matter of the superficial layer of the skin.

Dr. Gilbert, of this city, has long been in the habit of using pure *creasote* as a remedy in erysipelas. He applies it lightly once a day to the affected surface with a camel-hair pencil, and has found it more effectual in arresting the disease than any other article he has ever tried. It destroys the cuticle, converting it into a whitish substance, which thus defends the inflamed surface from the contact of the air.

Solutions of acetate of *lead* and opium, Goulard's extract, hydrochlorate of ammonia, alcohol, chloride of sodium, carbonate of potassa, sulphate of copper, and quinine, often prove beneficial. They are employed of varying strength, and are generally most grateful when used tepid, upon flannel cloths, frequently renewed. In warm weather, and in strong, plethoric subjects, they may be applied cold, but when this is done their effects should be sedulously watched, lest they repel the disease, or throw it upon some internal organ.

Dr. Pitcher, of Detroit, strongly recommends, as an external application, bichloride of *mercury*, in the proportion of twenty grains of the salt to the ounce of alcohol. During the prevalence of the epidemic already so frequently alluded to, I had occasion to try this treatment in quite a number of instances, and came to the conclusion that it possessed no advantage whatever over iodine and nitrate of silver. In nearly all the cases, upwards of twenty, the application was promptly followed by vesication and excessive pain, and, in a few, by pretty profuse ptyalism; effects which greatly aggravated the local and constitutional suffering, and rendered a speedy discontinuance of the remedy necessary. I have since tried the medicine in weaker solution, but without any encouraging results.

Velpeau has great confidence in the use of sulphate of *iron* as a local remedy in erysipelas. The praises, however, which he has lavished upon it have not been realized by practitioners generally, and the probability, therefore, is that they are

undeserved. In the trials which I have made with it, I have been sadly disappointed. It may be employed in solution, in the proportion of half an ounce to two-thirds of a quart of water; or as an ointment, prepared by mixing one drachm of the impalpable powder with an ounce of lard. The former is applied by means of compresses, frequently moistened; while the latter is rubbed on freely several times in the twenty-four hours.

Dr. Holston, of Washington, has strongly recommended the local use of *chloroform*, washed over the affected surface for a few minutes with a large camel-hair brush, the parts being immediately afterwards covered with wadding, and the application repeated, if necessary, at intervals of three to four hours. Prompt relief, it is asserted, usually follows, the disease, even if extensive, often yielding in a very short time.

Bromine has been highly extolled as a local remedy in this disease, having been extensively tried by our army surgeons. It is applied directly to the inflamed surface in solution, from twenty to forty drops being mixed with the ounce of water, according to the severity of the morbid action. A small quantity of bromide of potassium may sometimes be advantageously combined with it.

In the milder varieties of erysipelas I have occasionally witnessed excellent results from a *liniment* of equal parts of laudanum, ammonia, and olive oil, applied with a soft, thin compress. When the skin is very delicate, the proportion of ammonia may be diminished. The common soap liniment, with the addition of a small quantity of tincture of iodine, is also a valuable remedy in simple erysipelas.

Various *greasy substances*, cerates, and unguents have been recommended by practitioners, and employed by the vulgar, in the treatment of this affection; but there are few surgeons who place much reliance in any of them. Perhaps the best is the mercurial ointment, first advised in this complaint by Dean and Little, of Pennsylvania. A thick layer of this is spread upon cloth, and secured to the part by means of a bandage; or, what is preferable, rubbed gently but efficiently upon the surface. The article has been highly lauded by Rayer and others, but my own experience has not supplied me with any facts in its favor; indeed, it is doubtful whether it possesses any advantage whatever over common lard, suet, or simple cerate. In infantile erysipelas, I have sometimes derived excellent effects from the application of oxide of zinc ointment, diluted with two parts of lard. Professor Gibson speaks favorably of the use of British oil; and Dr. Coates, of this city, has successfully employed tar ointment.

Dusting the affected surface with starch, flour, arrowroot, prepared chalk, carbonate of zinc, pearl powder, and similar substances, is a popular remedy, which is sometimes useful in the more simple varieties of erysipelas, but entirely unavailing when the disease is deep-seated, or of a phlegmonous character. In the former, they sometimes prove beneficial by relieving the disagreeable itching, smarting, or burning sensation of the skin. In superficial erysipelas, I have occasionally obtained advantage from painting the inflamed surface with collodion; the application appears to impart a healthful stimulus to the cutaneous capillaries, to incite the absorbents, and to contract the skin and subjacent cellular tissue.

The treatment of erysipelas by *blisters*, formerly so much in vogue in this country, has of late fallen into undeserved neglect. In my own practice I have frequently resorted to it, and in hardly any case has it disappointed my expectations. The remedy is peculiarly valuable in the phlegmonous form of sporadic erysipelas, and in erysipelas supervening upon wounds, ulcers, chancres, buboes, and abrasions. My custom is to apply the blister directly to the inflamed surface, together with a small margin of the sound skin, and to retain it until it has produced thorough vesication. The serum is then discharged with a needle, and the part dressed with a light starch, elm, or linseed poultice. In children, and old or sickly persons, the blister must be removed at an earlier period, otherwise serious mischief may ensue.

Of the importance of *punctures* and *incisions*, as means of relief in this complaint, no one acquainted with its character can entertain the slightest doubt in

any case, accompanied by suppuration, great tension, or impending gangrene. Under such circumstances, indeed, all other means must be regarded as of secondary consequence; the knife alone is to be trusted, and the sooner it is resorted to the better. A few incisions, or a number of large punctures, will obviate an immense amount of mischief, by affording vent to effused fluids, as serum, lymph, pus, and even blood, relieving capillary strangulation, and removing pain and tension. The practice is indicated the moment there is the slightest perceptible fluctuation, and, in violent cases, even as soon as pain and throbbing show themselves. By thus anticipating the suppurative process, the patient escapes much suffering, as well as loss of texture; for, if the matter is retained in the parts, its inevitable tendency is to burrow among the surrounding structures, and to contaminate the system. From neglect of this treatment, many patients perish that might otherwise be saved, and many limbs are lost, or rendered useless for life.

In practising incisions for the relief of erysipelas, it is not necessary that they should be made three, four, or five inches in length, as formerly recommended by Mr. Lawrence and other British surgeons. Such a course is eminently cruel and reprehensible, and it is difficult to conceive how it should ever have received the sanction of enlightened practitioners. Independently of the pain which attends it, it is liable to be followed by copious hemorrhage, which, occurring at a time when the patient is perhaps ill able to bear it, is well calculated, in many cases, to hurry him on to a fatal issue. I must, therefore, solemnly protest against such a barbarous proceeding. Incisions, I repeat it, are often eminently serviceable, if, indeed, not indispensable both to the part and system; but they must be made in a proper manner, and of proper dimensions. A cut from half an inch to an inch and a half in length, and deep enough to liberate the pent-up fluids, ought to be sufficient in any case, unless there has been great mismanagement on the part of the patient, or his professional attendant. In such an event, the incisions may be multiple, being placed at suitable intervals from each other. It is hardly necessary to add that, in performing the operation, the knife should not be carried in the direction of any important structures, as large vessels, nerves, or joints. If hemorrhage be unavoidable, it is to be arrested by the usual means, as compression, styptics, or ligation. The best application after the bleeding has ceased is an emollient poultice, or the warm water-dressing, either simple or medicated. The loss of a small quantity of blood is often of essential benefit in relieving the disease.

Punctures are more particularly useful in the oedematous forms of the disease, to evacuate the serous fluid upon which the distension depends, and which is often a source of so much mischief. When suppuration or gangrene is threatening, punctures, as already stated, give way to incisions. The number of punctures, the depth to which they should be carried, and their proximity to each other, must depend upon circumstances. The best instrument for making them is a very narrow, sharp-pointed bistoury, introduced perpendicularly to the surface, with the necessary care to avoid important structures.

In erysipelas of the extremities, valuable aid may be derived, in almost every case, from the application of the *bandage*. It is particularly efficacious in the early stages of the disease, as it tends, if judiciously employed, to support the affected structures, and to prevent vesication and suppuration. The application should be made as equably as possible, and with a certain degree of firmness, its effects being carefully watched, and aided by simple or medicated lotions.

Finally, it is proper to add that much may be accomplished, in the epidemic form of this disease, by way of *prophylaxis*. Among the more important elements in this kind of treatment are isolation of the sick, thorough ventilation, personal cleanliness, and an abundance of good, wholesome food. These precautions are particularly necessary in hospitals, prisons, asylums, camps, barracks, and ships. Whenever persons are crowded together, in narrow and confined situations, the air is speedily contaminated, and the disease is sure to spread with fearful rapidity and violence, especially if the body is affected with wounds, contusions, ulcers, or compound fractures. The best internal prophylactic is the

tincture of the chloride of iron, given in doses of twenty to thirty drops every four or six hours, either alone or in union with quinine, the latter remedy being particularly valuable when the disease is of a malarious character.

SECT. II.—FURUNCLE, OR BOIL.

A furuncle, vulgarly called a boil, is a peculiar inflammation of the skin and cellular substance. Liable to occur upon any portion of the body, excepting, perhaps, the palm of the hand and sole of the foot, it is most common upon the face, nape of the neck, buttocks, and fingers, often forming in considerable numbers, either simultaneously or successively, although generally there is only one. Both sexes, and all periods of life, are subject to it; the young, however, suffer more frequently than the old and middle-aged. Some persons are habitually affected with boils, being seldom entirely free from them at any time for years. Now and then they disappear for a while, and then suddenly break out again. Boils are a very common sequel of eruptive affections, as smallpox, measles, scarlatina, and typhoid fever, and, under these circumstances, they occasionally display a marked epidemic tendency. In the latter event, they are very liable to occur in association with carbuncle and whitlow. Children during dentition, and during chronic attacks of cholera, sometimes suffer excessively from this disease. I have often, in these complaints, seen the whole surface literally covered with boils, the patient experiencing great pain and prostration.

The causes of furuncle are generally inappreciable. Occasionally we can trace their formation to external violence, as a contusion, or the concussion sustained by the skin and cellular substance in riding on horseback. In the majority of cases, if not in all, it is obviously connected with a disordered state of the digestive organs, or with some derangement of the secretions. Thus, persons who labor habitually under disease of the liver, and females who are troubled with irregularity or suppression of the menses, are very prone to suffer from its attacks. Large, painful, and obstinate boils not unfrequently follow the application of blisters, especially in young broken-down children and elderly subjects. Cold water, used endermically for any considerable time, as a therapeutic agent, is liable to give rise to similar effects.

A boil consists essentially in a circumscribed inflammation of the skin and subcutaneous cellular tissue, eventuating in suppuration and sloughing. It usually begins as a small, hard, red pimple, which, as it proceeds, gradually assumes a conical figure, the apex being formed by the skin, and the base by the cellular substance, its volume varying from that of a current to that of a pigeon's egg. The pain which accompanies it is, at first, of a burning, smarting character, but afterwards, especially when matter is about to be deposited, it becomes throbbing and exceedingly severe. A sense of tension is also commonly present. The skin is of a dusky, reddish aspect, and exquisitely sensitive to the slightest touch. As the tumor increases, a little vesicle forms at its apex, containing a drop of serum, and indicating the point where the boil will discharge itself. If the furuncle is large, or multiple, there will usually be more or less constitutional disturbance, as manifested by the want of appetite, a bad taste in the mouth, headache, chilliness, and a feeling of great uneasiness. Finally, if the disease occur in the lower extremity or upon the buttock, there will often be sympathetic enlargement of the glands of the groin, and in the upper extremity of the glands of the axilla. The period required for a boil to reach its height varies from three to eight days.

If a section be made of a boil, with a view to the examination of its structure, it will be observed to consist of a mass of dead cellular substance, ordinarily called a core, immersed in thick yellowish pus, the parts around being very hard, matted together with lymph, and preternaturally vascular. The skin is also indurated, and abnormally tense, red, and injected. Occasionally the contents of the swelling are almost wholly made up of blood, or of a mixture of blood, pus, and slough. This form of boil, to which the term hematoid may be applied.

is most common in elderly persons of a broken constitution, and is usually attended with a great deal of local and general distress.

It is seldom, under any circumstances, that a furuncle can be made to abort, or to terminate in resolution, its invariable tendency being to suppurate and slough. In its very incipency, I have occasionally succeeded in arresting its course by a brisk purge, and the application of iodine, but if it has already made some progress, such an attempt will prove altogether futile. The best plan generally is at once to poultice the part, and to make an early and free incision to let out its contents. The relief experienced from the operation is always prompt and decided. If the sore is slow in healing, either from the retention of dead cellular tissue, or want of healthy action from other causes, its surface should be well touched with nitrate of silver; the same article, iodine, or a small blister being applied to the surrounding surface. In most cases the patient will be benefited by purgative medicine and light diet.

When there is a decided furuncular diathesis, as when a great number of boils exist simultaneously, or form in pretty rapid succession, benefit may be expected from an emetic, and from mercurial purgatives, with the internal use of iodide of potassium and Donovan's solution. Sometimes Fowler's solution of arsenic answers a good purpose, or, what I prefer, arsenic in substance, from the twentieth to the thirtieth of a grain three times a day. In very obstinate cases slight ptyalism may be required before the disease finally yields. When boils are developed as a consequence of exhausting diseases, tonics, mineral acids, a nutritious diet, and country air are indicated. Alkalies should be used when there is evidence of acidity of the stomach and bowels. Daily bathing with salt water, or water impregnated with potassa, will occasionally be serviceable, especially when there is unusual torpor of the skin.

SECT. III.—ANTHRAX, OR CARBUNCLE.

The most accurate definition that can be given of a carbuncle is that it is a boil on a large scale, it being, like that affection, a peculiar inflammation of the cutaneous and cellular tissues, not circumscribed, however, as in that disorder, but disposed to spread. Its most common seat is the posterior part of the trunk, particularly the nape of the neck, near its junction with the occiput. The gluteal and sacral regions are also liable to the disease, but it is very seldom that it occurs in the extremities. A bad form of carbuncle occasionally exists upon the chin and lower lip.

Elderly persons are most prone to carbuncle, and it is generally believed that such as are fat and indolent, or addicted to the pleasures of the table, are more frequently attacked than the lean and active. In my own practice, however, this has not been the case. On the contrary, the greatest number of instances has occurred in thin subjects, after the age of fifty, whose constitution had been broken down by long-continued intemperance, impoverished diet, deficient clothing, and mental anxiety. In London carbuncle is said to be remarkably common among the lower orders, in consequence of the enormous quantities of ale and porter which they habitually consume. The disease is more frequent in winter than in summer, and in men than in women; occasionally it displays an epidemic tendency. Carbuncle is one of the symptoms of plague. The extent of the inflammation varies from that of a dollar up to that of a large saucer, its average being about that of the palm of a small adult hand.

Of the exciting *causes* of carbuncle nothing satisfactory is known. Most commonly the outbreak of the disease is ascribed to the effects of cold, to disorder of the stomach, over-eating, constipation of the bowels, loss of sleep, excessive venery, and other debilitating influences; but how far, or in what degree, these circumstances tend to favor its development it is impossible to say. I have myself long regarded the malady as essentially of a constitutional nature, resembling, in this respect, erysipelas and some other affections; and a careful study of the history of the disease certainly warrants such an inference. A long course of debauch, or indulgence in the pleasures of the table, attended with a vitiated

state of the secretions, is, as is well known, eminently conducive to the development of carbuncle in its worst forms. When a person has been for years in this condition, eating and drinking luxuriously, and taking hardly any exercise, the slightest exposure to cold, suddenly checking the cutaneous perspiration, would, it may easily be imagined, tend to produce the disease in a part habitually congested and enfeebled in its action. There is then not merely a bad state of the solids; the blood also comes in for a share in the proceeding, surcharged, as it must be, with irritating materials which the solids have long been unable to throw off as recrementitious substance. Whether, however, this conjecture is correct or not, the fact is indisputable that carbuncle is rarely, if ever, of traumatic origin, or found in persons of a vigorous and healthy circulation.

One of the first *symptoms* of carbuncle is generally an itching, burning, or smarting, with a sense of numbness, in a particular part of the skin, which, on examination, is found to be of a dusky, reddish color, slightly tumid, and somewhat tender on pressure. As the disease progresses, the local distress sensibly increases; the pain soon becomes throbbing and exceedingly violent, the part feeling as if it were in contact with melted lead; the surface assumes a livid hue; the swelling spreads both in circumference and in depth; and the slightest touch of the finger is intolerable. Along with these phenomena, the patient usually experiences a sense of weight and tension, which greatly adds to his suffering. The part is hard, and circumscribed, feeling like the rind of bacon, and occupying a space from the size of a dollar to that of the palm of the hand. Presently vesicles begin to form at the focus of the inflammation, containing a dirty turbid, yellowish, or sanguinolent fluid, and generally not exceeding the diameter of a pea, though occasionally they are quite large. Upon bursting, these vesicles expose a corresponding number of openings in the true skin, giving the surface a cribriform appearance, and leading down into the cellular substance, which is already in a state of mortification. The ulcers, for so they may be called, have an irregular, ragged appearance, and are the seat of a foul, irritating discharge, which is often very abundant and exhausting.

Upon dividing the affected structures, the skin is found to be remarkably dense and firm, cutting very much like the rind of bacon. The cellular substance be-

Ulcerated carbuncle.

neath is converted into a slough, having the appearance of a mass of wet tow, bathed with ill-looking matter, and intermixed with flakes of lymph, or matter

like putty, thick pus, or curds. When the disease is of unusual extent, there may be considerable involvement of the aponeuroses and muscles, but in general these structures are excluded from the morbid action, the skin and subjacent cellular tissue alone suffering. At the periphery of the disease the parts are always uncommonly dense, the boundary between it and the healthy structures being established by a deposit of plastic matter, less organizable, however, than in furuncle, the morbid anatomy of which that of a carbuncle so closely resembles. The subjoined sketches, figs. 188 and 189, represent this disease in its earlier and more advanced stages.

The *constitution* always, at an early period of the disease, strongly sympathizes with the part affected. Hence, fever is generally present soon after its commencement, and sometimes, indeed, almost before there is any marked evidence of the local affection, the first symptom being often a severe rigor, followed by high vascular excitement. However this may be, the case soon assumes an *asthenic* type, indicative of the depraved condition of the solids and fluids so intimately concerned in the production of the disease. The tongue speedily becomes dry, hard, and brown, sordes collect upon the gums and teeth, the appetite fails, gastric derangement exists, the bowels are constipated, the urine is scanty and high-colored, the skin is hot and arid, the mind is disposed to wander, and the pulse is frequent, soft, and without force. Vomiting is often present to a considerable extent, and the alvine evacuations are generally excessively fetid.

The *diagnosis* of anthrax is sufficiently easy. Its large size, the severity of the attendant pain, and the great constitutional disturbance will always readily distinguish it from furuncle at its commencement, and afterwards the discrimination will be still further aided by the vesicated and cribriform condition of the skin, so characteristic of carbuncle. The only affection which it at all resembles is a bedsore, but the history of the case, and the situation of the swelling, will always serve as unerring means of distinction. Malignant pustule begins as a little circumscribed pimple, not as a diffused swelling, as in anthrax, and soon forms a large vesicle, raised above the surrounding level, and resting upon a hard, solid base, which rarely acquires much extent, at least not until the affection has made considerable progress.

The *prognosis* is variable. In general a carbuncle may be regarded as dangerous when it is multiple, or when it occurs in old, fat subjects, addicted to indolence and over-feeding. The site of the disease also exerts a marked influence upon the issue of the case. Thus, a carbuncle situated on the back part of the head and neck will, other things being equal, be more likely to produce death than when it occupies the back, nates, or extremity, inasmuch as it is very liable to involve the brain and arachnoid membrane, causing effusion of serum and lymph. Young and comparatively healthy persons will often recover, though generally not without great suffering, whatever may be the site of the malady.

Treatment.—The treatment of carbuncle must be conducted with special reference to the improvement of the secretions and the support of the system. Few patients will be found to bear bleeding, or anything like active purgation. It is only when there is extraordinary plethora, combined with great vigor of constitution, that these means should be carried into effect. In all other cases, their inevitable tendency is to do harm, by bringing on premature exhaustion. Efficient purging, however, may be regarded as an indispensable remedy in almost every instance, the object being not only to get rid of irritating fecal matter, but to produce a change in the secretions. For this purpose the medicine should be given early in the disease, and a mercurial cathartic should always be preferred to any other. When marked gastric derangement exists, as indicated by nausea, headache, and pain in the limbs, no time should be lost in administering an efficient emetic, or an emeto-cathartic, as ten grains of calomel and from ten to twenty of ipecacuanha, followed by large draughts of chamomile tea, or infusion of valerian. Clearance having been effected, and function improved or restored, stimulants and tonics will come into play, exhibited warily,

especially if cerebral trouble is threatened, yet efficiently if evidence of exhaustion is present, the most suitable articles being ammonia, quinine, chloride of iron, and brandy, with nourishing broths. Anodynes will generally be required, in large doses, to allay pain and procure sleep. After the first few days a mild laxative, as blue mass or castor oil, is occasionally given. Determination to the brain must be promptly met by a large blister applied as near as possible to the occiput.

The best *topical application*, in the early stage of carbuncle, is the warm water-dressing, medicated with acetate of lead and opium. Pencilling the surface well with tincture of iodine, and then covering it with a mixture of equal parts of olive oil, laudanum, and spirits of turpentine, sometimes produces a very soothing effect. In many cases, there is nothing so promptly beneficial as a blister, large enough to include a considerable portion of the healthy skin, and retained until it has caused thorough vesication; it drains the vessels of serum, allays pain, and makes a salutary impression upon the general system. Leeches are commonly inadmissible, as they cause severe pain, and undue depletion. But the great remedy for carbuncle, as for furuncle, is free incision, the knife being carried into the healthy substance beneath, not at one point, but at a number. The operation, which should be practised as soon as possible at the focus of the disease, and afterwards towards the periphery, should there be any necessity for it, at once relieves the horrible pain and tension of the part, affords nature an opportunity of casting off the sloughs, and puts an effectual barrier to the further extension of the morbid action. I cannot see any reason why practitioners should still continue to apply caustics in these cases when the knife is so much more prompt and effectual in its action. If the dead tissues are slow in coming away, their extrusion may be expedited with the scissors, the surface of the ulcer being well touched immediately afterwards with the dilute acid nitrate of mercury, or the solid nitrate of silver, to promote the formation of healthy granulations. As soon as this has been brought about, the part is dressed with some mild unguent, as the opiate cerate, elemi ointment, or ointment of the balsam of Peru.

After recovery, the tendency to a recurrence of carbuncle, which is sometimes very strong, should be counteracted by a change of air, attention to diet, a proper regulation of the secretions, and the avoidance of exposure to cold and fatigue, aided by an alterative course of iodide of potassium, the dose of which should not exceed two grains and a half thrice in the twenty-four hours. If there has been much disorder of the secretions, a very minute quantity of bichloride of mercury may be advantageously conjoined with the potassium. When there is marked derangement of the digestive functions, attended with acidity and flatulence, recourse may be had to the chlorate of potassa, given three times a day, in doses of from five to ten grains, until there is manifest improvement in the tone of the stomach and of the general health. A change of air is often indispensable to complete convalescence.

SECT. IV.—GANGRENE AND BEDSORES.

The skin is liable to gangrene, both idiopathic and traumatic, simple and specific, acute and chronic; but as these several varieties have already received a sufficient share of attention, nothing need be said respecting them here. There is one species, however, which may be briefly described in this place, inasmuch as no special mention has been made of it elsewhere. I allude to what is called *white gangrene* of the skin; an affection whose true character is still involved in obscurity, nothing that has yet transpired having thrown any light either upon its pathology or treatment.

White gangrene usually comes on without any appreciable cause, or premonitory symptoms, in patches of irregular shape, from one to three inches in diameter. The sloughs are of a dead, milky color, and of a hard, dryish consistence, yielding little, if any, moisture on pressure. Any portion of the body may be the seat of this affection; but observation has shown that the arms, back, and

chest are the regions most frequently implicated. The disease has hitherto been observed chiefly in old persons of a broken, anemic constitution. The treatment is to be conducted upon general principles, special reference being had to the improvement of the health by tonics, brandy, and nutritious diet.

Bedsore.—There is another variety of gangrene of the integuments which, from the frequency of its occurrence, and the severity of the attendant suffering, merits special attention here. Its immediate cause is steady and protracted pressure, impeding, and generally arresting, the circulation; hence it is exceedingly liable to arise on the sacro-lumbar region, the iliac projections, on the nates, and over the great trochanter, in consequence of long-continued confinement to one particular posture, as happens in typhoid fever, in severe fractures and wounds, and after surgical operations. It is also very common after violent injury of the spine. I have at this moment under my charge a tall young man, affected for the last six months with paraplegia, who has a large and excessively painful ulcer upon the left buttock, simply from the pressure sustained in sitting on a chair. Occasionally a sore of this kind forms with extraordinary rapidity, leading to the belief that it is due rather to the irritation of the spinal cord or the nerves thence arising than to any direct compression.

The disease is always necessarily preceded by inflammation, but in consequence of the absence of the usual symptoms, the want of proper care in examining these parts and keeping them clean, or the impossibility which the patient experiences in communicating a knowledge of his suffering, as when he is exhausted by typhoid fever, or other causes, it does not always attract attention until great mischief has been done, eventuating in extensive sloughing, and the establishment of painful, irritable ulcers, which it is often extremely difficult to heal. In some instances the first intimation which the patient has of the approaching mortification is a sense of prickling in the affected parts, as if he were lying upon some rough substance, as sawdust, or coarse salt. At other times, he feels severe pain, of a stinging, burning, or biting character, within a few days after he has been exposed to the pressure, and which is often so constant and distressing as to deprive him both of appetite and sleep. Upon examining the parts to which the suffering is referred, the surgeon finds that they are red, or marked by an erythematous patch, slightly swollen, with a dense base, congested, and excessively tender on pressure. Ulceration, if it has not already taken place, will be sure to begin in a short time, unless suitable measures are adopted for the patient's relief, and will be speedily followed by mortification, or mortification may take place without being preceded by ulceration.

The extent to which the gangrene may proceed is variable; we occasionally see it occupying an immense surface, perhaps as large as the crown of a hat, and reaching down to the very bones; at other times it is more limited both in diameter and depth, laying bare merely the muscles, or being even in great degree confined to the skin. In rare cases, the ravages involve the osseous tissue, and even the coverings of the spinal cord.

Bedsore, unless of very trivial extent, are among the most formidable complications that are liable to arise during the progress of fevers and other diseases, as well as after accidents and operations. As they seldom occur until the vital powers have been materially depressed, the excessive pain and drainage occasioned by them are often so severe as to destroy the patient, or, at all events, greatly retard his convalescence.

The *treatment* of bedsore, or gangrene from pressure, is prophylactic and curative. In the first place, whenever there is any probability from the nature of the case that the confinement is likely to be tedious and attended with constant decubitus, or a helpless state of the patient, means should be promptly adopted for hardening those parts of the surface which long experience has taught us as being most liable to suffer under such circumstances. For this purpose they should be brushed once or twice a day with tincture of iodine, at first diluted, and then pure, or washed repeatedly with a saturated solution of alum and tannin. The greatest possible attention should be paid to cleanliness, and to the arrangement of the sheets and clothes, that they may not be rolled

up under the body, and thus become a source of suffering and disease, as too often happens in the hands of careless and thoughtless practitioners. As to the use of plasters, I have very little patience with them, for, unless they adhere well, they are extremely apt to become rumpled, much to the detriment both of the part and system. Change of posture should receive early attention, though this is not always practicable, from the inability of the patient to maintain himself in any other situation than that on the back. When he can afford it, he should use an air bed.

The moment any decided suffering is experienced, or the parts become red and inflamed, a ring-shaped air cushion should be provided for the purpose of equalizing the pressure, or, in the absence of this, an ordinary cushion, with a suitable central hole, the edges being broad and well padded with wool or horse hair. Such a contrivance, however, is a very imperfect substitute for an air or water cushion.

When gangrene is threatened, the best application is the tincture of iodine, aided, if there is much pain and tension, by one or two moderately free incisions, and followed by a yeast or port-wine poultice, sprinkled with laudanum, morphia, or powdered opium. Cleanliness is promoted by the liberal use of the chlorides and by the early removal of the sloughs. When granulations begin to spring up, the best dressing will be opiate cerate, a mixture of equal parts of castor oil and balsam of copaiba, or mild mercurial, elemi, balsam of Peru, or blue ointment.

In the more rapid varieties of bed sore, dependent upon spinal irritation from external injury, with paralysis, Dr. Brown-Séquard strongly recommends the application of cold and heat, in the form of pounded ice and hop poultices, frequently alternated, with a view of effecting a salutary change in the circulation of the part. He also speaks favorably of the galvanic current. These remedies are, of course, proper only in the incipient stages of the complaint, before the occurrence of ulceration.

The constitutional treatment of bed sores must be conducted according to the general rules followed in typhoid states of the system from whatever cause proceeding. Nutritious food, wine, brandy, milk punch, quinine, iron, and anodynes are the means chiefly to be relied upon for upholding the flagging powers of nature. This treatment can hardly be commenced too soon whenever there is any tendency to the formation of bed sores, for the very fact that such a disposition exists is a sufficient reason for redoubling our efforts to support the patient's system.

SECT. V.—BURNS AND SCALDS.

There are few accidents which are of more common occurrence than burns and scalds, or which entail a greater amount of suffering and deformity. The progress of civilization, and the improvements in the arts and sciences, have greatly multiplied their frequency and severity, and call for corresponding attention on the part of the surgeon. From what I have seen of these lesions, I am satisfied that few practitioners understand their character, or treat them with the success of which they are capable. One reason, perhaps, of this is that every one has a remedy for them, and that hardly any two agree as to the kind of treatment best adapted to their relief.

Burns and scalds differ from each other simply in this, that the one is the result of dry heat, and the other of moist. They both present themselves in various degrees, from the slightest erythematous blush of the skin to the total destruction of all the structures of a limb. Their extent is also exceedingly variable, both as it regards their depth and their superficial area. Thus, while in one case they may involve only a little patch of skin hardly the size of a half dime, in another they may occupy an immense extent of surface; or, instead of being diffused over a large space, the injury may be concentrated upon a small spot, but penetrate to a considerable depth. These differences are of great practical importance, on account of the influence which they exert upon the issue of the case. The division of Dupuytren of burns and scalds, so generally adopted at the present day, seems to me to be most complex and unscientific, and therefore well

calculated to embarrass the progress of the inquirer. No one can doubt that the more simple the arrangement of a subject is, the more easily, in general, it is understood. In accordance with this idea, I shall describe burns and scalds as consisting of two classes, the simple and complicated; comprehending under the former term those lesions which, however extensive, give rise merely to inflammation, and under the latter those which cause the death of the parts, either on the instant, or within a short time after their infliction.

Burns are most common in winter, among the poorer classes, who are very liable to have their clothes set on fire from the manner in which they crowd around the hearth and grate to keep themselves warm. Women, on account of the peculiarity of their occupation, are more subject to them than men, and children than grown persons. Blacksmiths, plumbers, glass-blowers, and foundry men are particularly exposed in this way. The introduction of gas and camphene has been a fruitful source of these accidents. Scalds, on the other hand, are most common in kitchens, breweries, factories, especially soap and candle, and, in short, in all places where steam is employed, whether for domestic or public purposes. On our western waters, where steamboat explosions are of such frequent occurrence, many persons are annually destroyed by the effects of hot water. Those parts of the body which are habitually exposed, as the hands and face, are most liable to suffer both from burns and scalds, particularly the latter, steam often penetrating the clothes in every direction. Dry and moist flame, hot water, and steam often enter the mouth and throat, producing violent, if not fatal, effects. A heated iron has been known to be thrust up the rectum for the purpose of homicide, as in the famous case of Edward II.

It is well known that different agents possess different degrees of capacity for caloric, and that, consequently, they are capable of producing different effects when brought in contact with the living tissues. Thus, experience has shown that boiling metal will cause a more severe impression than boiling oil, and boiling oil than boiling water. The intensity of the injury, however, is not always in proportion to the relative capacity of the substance for heat; for it is well ascertained that copper will, other things being equal, occasion a more violent effect than iron, although the latter possesses a greater capacity for caloric. This fact can be explained only on the assumption that some articles are not only better conductors of heat than others, but that they adhere more firmly to the surface, thus favoring its protracted extrication. Alcohol and ether, from their great volatility, usually produce only superficial burns.

In the milder forms of these accidents there is merely an erythematous appearance of the skin, such as may readily be produced by exposing the back of the hand for a few moments to a stove, or by applying hot water to it. The discoloration is usually very transient, but at times it is more permanent, lasting for a number of hours, and being perhaps soon followed by slight vesication. The pain, of a smarting, pungent character, is comparatively trifling, and soon goes off. The constitution remains unaffected.

The application of heat, whether dry or moist, unless sufficient instantly to destroy the vitality of the part, or so slight as to make only the most superficial and transient impression, is always speedily followed by an evolution of vesicles, containing a thin, watery fluid, identical with the serum of the blood, from which it is derived. When the vesicles are more slow in forming, as when they are the product of the resulting inflammation rather than of the immediate effect of the caloric, their contents are, in general, partly fluid and partly solid, the latter consisting either of lymph or of fibro-albuminous matter. Their volume varies from that of a pin-head up to that of a fist, their number being usually in an inverse ratio to their dimensions. Cases are occasionally met with where the epidermis nearly of a whole limb, or of the greater portion of the trunk, is elevated into one enormous blister, establishing a most frightful drainage upon the system.

The surface around the vesicles is of a scarlet color, more or less tumefied, and exquisitely tender on pressure, or on exposure to the atmosphere. The pain is of a burning, scalding character, and so severe as to cause the most violent agony. The part rapidly swells, feels

a throbbing character. Well-marked constitutional symptoms are always present, especially if the lesion is at all extensive, and the patient may be delirious, excessively restless, and intensely thirsty.

These injuries are said to be *complicated* when they are attended with the destruction of the vitality of the part, or some other serious lesion, as a wound, fracture, or dislocation. The loss of life may be limited to the skin and subjacent cellular tissue, or it may extend much deeper, involving muscle, aponeurosis, vessel, nerve, and bone all in one common eschar. Such accidents are never produced in any other way than by burns, as when a person falls into the fire, or gets his limb in a stove, grate, or furnace. Dreadful scalds, however, sometimes occur from the protracted application of boiling fluids, as happens now and then in breweries and soap factories. Under such circumstances, the loss of vitality, although not as extensive as we sometimes find it from the operation of dry caloric, is yet sufficient to be productive of the most terrible ravages. The epidermis comes off in large sheets, no vesicles exist, or only around the border of the injured surface, and the skin is of a dirty grayish, cineritious, or yellowish color, sodden, insensible, and marked, here and there, by a purplish line, indicating the course of a subcutaneous vein.

Besides the pain which invariably attends all burns and scalds, however slight, there is ordinarily more or less *constitutional* disturbance, coming on at a variable period after the accident; sometimes immediately, at other times not for several hours, days, or weeks. When the injury is at all extensive, the patient will have all the symptoms of one laboring under a severe shock. He will feel exceedingly cold, or, perhaps, have violent rigors; the pulse will be small, frequent, and feeble; the respiration will be oppressed; and there will be extreme restlessness, along with great thirst and sickness at the stomach. He is, in fact, in great torture, pale, prostrated, agonized. Reaction taking place, he will have violent fever, a flushed countenance, and a quick, irritable pulse, with a tendency to delirium; pain, of a pungent, burning character, forming all the while the prominent suffering. If the excitement run high, there will be danger of over-action in the part, and of inflammation of some of the internal viscera, the arachnoid membrane, and the mucous lining of the bowel. Numerous cases have been published within the last twenty years going to show that ulceration of the duodenum is one of the most frequent secondary lesions of scalds and burns; and, in the more chronic forms of these accidents, the same disease is sometimes

widely diffused over the colon, thus accounting for the profuse and obstinate diarrhoea then so often present.

Among the more common local *consequences* of burns and scalds are, the formation of vicious scars, the adhesion of contiguous surfaces to each other, the retraction of the affected parts, ankylosis of the joints, and various transformations of the cicatricial structures, especially the keloid. The scars, which are often of frightful extent, and horribly disfiguring, possess an extraordinary contractile power, which does not cease for a long time, which it is almost impossible to counteract, and which frequently draws out of place every tissue that is brought under its influence, bone not excepted. Owing to this circumstance, the chin is occasionally

Fig. 190.

Vicious cicatrices of the face and neck, caused by a burn.

drawn down against the sternum, as seen in fig. 190, and the lower maxilla singularly changed in shape. The fingers may be retracted like claws, or literally buried in the palm, the hand thrown back at a right angle with the wrist, or the forearm drawn up against the arm, which is itself, perhaps, firmly pinioned to the side. Similar effects occur in the inferior extremity. Thus, the foot is sometimes tied to the forepart of the leg, or the leg to the posterior surface of the thigh. In neglected burns of the hand, the fingers are often united to each other, so as to give them a webbed appearance.

Burns and scalds are among the most *dangerous* of accidents. If at all extensive, they often terminate fatally from mere shock of the system, without, perhaps, even the slightest attempt at reaction; or, reaction occurring, life may afterwards be assailed by inflammation of some internal organ; or death may take place at a more remote period, in consequence of the secondary effects of the lesion. A superficial injury of this kind is generally dangerous in proportion to its extent. Thus, a scald involving an entire limb or the greater portion of the trunk, although merely affecting the external layer of the true skin, is always a most serious accident, liable to be followed by the worst results. On the other hand, the danger is hardly less when the lesion is very deep, even if it be not more than a few inches in diameter. When depth and great extent of surface are combined, the chances are that death will occur without reaction, or, at all events, soon after the establishment of reaction from constitutional irritation. A prognosis, therefore, should not be given without due regard to these circumstances.

Such injuries are, other things being equal, more dangerous in infants and children than in adults, on account of the greater susceptibility of their nervous system. Old persons, too, are very intolerant of them, and are liable to suffer severely, both primarily and secondarily. Pregnant females occasionally abort from their effects; and in the intemperate they often lead to the development of delirium tremens and other distressing symptoms. A burn on the neck and scalp is liable to cause arachnitis; of the chest, inflammation of the lung and pleura; of the abdomen, peritonitis and enteritis. Finally, a patient, after having manfully struggled against ebb and tide, as it were, for weeks and months, may finally perish from the effects of profuse discharge and hectic irritation.

Treatment.—The indications in the treatment of these lesions are, first, to produce reaction and calm the system; secondly, to limit the resulting inflammation; thirdly, to promote the sloughing process, when death has taken place, and to favor the development of granulations; fourthly, to moderate contraction, and prevent ankylosis; and, lastly, to sustain the strength during the wasting effects consequent upon the protracted suffering which so often occurs when the patient has escaped from the primary effects of these injuries.

To raise the system from the *depression* or collapse into which it so frequently sinks, even in comparatively slight burns and scalds, immediate recourse should be had to a full anodyne, along with hot toddy, ammonia, sinapisms to the extremities, and the warm bath, the immersion being cautiously continued from thirty minutes to an hour, according to the exigencies of the case. The quantity of morphia, or whatever form of opium may be used, should be at least double what it is in ordinary accidents, the system being always, under these circumstances, uncommonly tolerant of the medicine. A large dose will not only be conducive to speedy reaction, but will greatly assist in allaying pain and calming the system. If the shock has been unusually severe, it may be necessary, in addition to these means, to use stimulating injections and to rub the spine with some irritating lotion. In the child and old man, care is taken not to urge on the reaction too rapidly, or to give opium without a certain degree of caution, lest the subsequent excitement should over-tax the enfeebled brain and heart, thereby leading to visceral effusion. As the circulation comes up, the stronger stimulants are gradually withdrawn, the more simple alone being now trusted to for relief.

The second indication is to moderate the resulting *inflammation*. With this

view various remedies may be employed; but what these remedies ought to be is a point respecting which there is still much contrariety of opinion. In the milder forms of burns and scalds the surgeon can hardly go amiss if he uses almost any of the more common popular articles. He will find that, at one time, the part and system are most comforted by cold applications, at another, by warm; that the one is borne best to-day, the other to-morrow; that one patient is benefited by an ointment, another by a lotion; that in one case he may employ moist applications with most advantage, in another, dry; in short, that the utmost diversity obtains in regard to the tolerance of this remedy or that.

Cold applications are chiefly adapted to very young, robust subjects, during the heat of summer, but even then they should not be resorted to without great care, for fear of internal congestion and effusion. The proper plan is to use them only so long as they are grateful and soothing to the system, and to discontinue them the moment they are found to be disagreeable. They may consist simply of cold water, spirits and water, or weak solutions of acetate of lead; and the same articles may be applied warm, care being taken, when the one class follows the other, that the transition is gradual and gentle, not sudden and violent. If the lesion is very slight, the surface may be covered with poultices of scraped potato, apple, turnip, starch, arrowroot, or slippery elm; carded cotton; saturnine unguents; or cloths wet with soap liniment, or a liniment made of lime-water and linseed oil. The latter constitutes the famous application so much used at the Carron Iron Works in Scotland; it is, however, exceedingly filthy and disgusting, and should, therefore, be discarded from genteel practice. Carded cotton, an American remedy, has always stood high in the estimation of the public, and there are few articles that are more constantly or more advantageously employed in the treatment of burns and scalds. A remedy from which I have often derived great benefit in the milder varieties of these affections is the tincture of iodine diluted with two parts of alcohol. It is only applicable, however, when the skin is unbroken. The burning, scalding, or smarting sensation, attendant upon this class of injuries, is often promptly relieved by pencilling the affected surface with a weak solution of nitrate of silver, and covering it immediately after with a thick layer of cotton.

In my own practice, I have experienced the most signal success in the treatment of burns and scalds from *carbonate of lead*, in the form of white paint; and in 1845 I called the attention of the profession to the subject in a short article in Dr. Bell's Bulletin of Medical Science. Numerous observations made since that time by myself and others, have only served to confirm the views then expressed. From its great efficacy, and the readiness with which it may usually be employed, this mode of treatment deserves to come into more general use. It is not applicable merely to the milder forms of burns and scalds, but it may often be advantageously used, no matter what may be the extent or depth of the injury.

As the lead of the shops is very stiff, and, consequently, unfit for use, the proper plan is to incorporate with it a sufficient quantity of linseed oil to make it of the consistence of thick cream. Thus prepared, the affected surface is thickly and thoroughly coated with it by means of a large camel-hair pencil, a soft mop, or a small paint-brush. If vesicles exist, their contents are evacuated with a fine needle, and the parts are well dried; otherwise, the lead will not adhere. The dressing is completed by covering the painted surface with a layer of carded cotton, old muslin or linen, supported by a moderately firm roller. In mild cases, one application of this kind, allowed to remain on for four or five days, will usually suffice to effect a cure. In the more severe forms of the lesion, on the contrary, a considerable number may be required. Whenever the dressings become stiff or saturated with secretions, they should be removed, others being immediately substituted.

I have never witnessed any bad effects from white lead paint, applied as here directed, although I have used it very freely in numerous cases. In one instance, that of a negro girl, sixteen years of age, who had a most severe and extensive burn of the neck, chest, and abdomen, I continued the remedy for upwards

of five weeks, consuming more than a quart of the lead, without observing the slightest injury. In short, my experience induces me to believe that the treatment is perfectly safe in all cases, whatever may be the extent or depth of the lesion, or the age of the patient. When a counter-poison, however, is deemed necessary, it will readily be found in the occasional exhibition of a dose of sulphate of magnesia, which, while it keeps the bowels in a soluble state, combines with the lead, forming an inert sulphate.

White lead paint probably produces its good effects in two ways: first, by forming a varnish to the affected surface; and, secondly, by directly obtunding its nervous sensibility. In many cases, it literally acts like a charm; the patient, in a few moments, becoming perfectly calm; and passing, as it were, from torment into Elysium.

Professor T. G. Richardson, of New Orleans, has employed with excellent effect *subnitrate of bismuth* in the treatment of burns and scalds. His mode of using it is to rub the bismuth in a mortar with a sufficiency of glycerin to convert it into a thick paint, which is then freely spread upon the affected surface with a suitable brush, the parts being afterwards covered with carded cotton, retained by a roller. In the milder forms of the accident a single application often effects a cure.

In Boston, a plan of treating burns and scalds is used with much advantage, consisting of the application of a thick coating of mucilage of gum Arabic, which is immediately after well dusted with dry powder, the whole forming a complete defence to the raw surface beneath. Mr. Meadows, of London, has recently recommended, for a similar purpose, a mixture of collodion and castor oil, in the proportion of two parts of the former to one of the latter. The preparation, which may be kept ready for use for any length of time in an air-tight bottle, is applied by means of a camel-hair brush, and is speedily converted into a firm, adherent covering, the thickness of which may afterwards be increased if deemed proper. In the more simple forms of scalds and burns, the application of glycerin is occasionally very beneficial; and Dr. John H. Packard, of this city, has derived the happiest effects from the use of fresh lard, both in the mild and more severe varieties of these accidents.

When a stimulant effect is required, as when the parts are in a condition verging upon gangrene, the most eligible dressing, perhaps, is Kentish's ointment, composed of one ounce of basilicon ointment and one drachm of spirits of turpentine, and spread upon strips of old muslin, bound on lightly with a roller; or, instead of this, the surface may be carefully pencilled with a weak solution of nitrate of silver, nitric acid, or acid nitrate of mercury, and then covered with a yeast, port wine, or tannin poultice. Thick soft soap also answers a good purpose, often promptly allaying the smarting consequent upon burns and scalds.

Along with these means, proper attention is paid to the state of the constitution, the bowels are maintained in a soluble state, diaphoretics are given to restore the functions of the skin, and the diet is carefully adapted to the particular emergencies of the case. The internal organs, especially the brain and lungs, are sedulously watched, and any approach of danger promptly counteracted by suitable measures for preventing inflammation.

If, despite the utmost care and attention, the injury terminates in *mortification*, or if the vitality of the parts was destroyed in the first instance, an effort should be made to check its further progress, and to promote the separation of the sloughs. The most eligible remedies for this object are such as are in use for ordinary gangrene. Feter is corrected with the chlorides. If the sloughs are very firm, the knife may be used, but not without the greatest caution, lest pain and hemorrhage be induced.

As soon as the sloughs have dropped off, the indication is to promote the development of granulations; a circumstance which often requires much judgment and practical skill. The best remedies are the warm water-dressing, with the use of a very weak solution—not more than two drops to the ounce of water—of nitric acid. Sometimes the calamine cerate is very soothing, and seems to do good when almost everything else fails. If the granulations manifest a

tendency to become exuberant, as they are very apt to do, they must be repressed with the scissors, nitrate of silver, and systematic compression, tonics being given to support the system. Cases occur in which these bodies are rendered exquisitely sensitive, the slightest touch being followed by the most lively pain. We usually find that this condition is attended with an irritable state of the constitution, and that, consequently, it requires something more than mere topical medication to get rid of it. A judicious course of anodynes and tonics, with the occasional application of nitrate of silver, and the constant use of an elm-bark poultice, constitutes the proper treatment. Occasionally, no local remedy is so soothing as white lead paint. Whatever means may be employed, it will be found that they will require to be frequently varied; as one loses its effects another taking its place.

To obviate *deformity* constitutes the fourth indication in the treatment of these injuries. The points to be attended to are threefold: first, to prevent adhesions between contiguous surfaces; secondly, to counteract the tendency to vicious contraction; and, thirdly, to guard against ankylosis.

The tendency which the contiguous surfaces have to unite to each other during the progress of these accidents has already been alluded to. This tendency is not confined to the fingers and toes, but is also exhibited in other parts of the body, as between the arm and trunk, the two labia, the thigh and scrotum, the ear and scalp. Wherever it appears, it must be carefully counteracted by the use of the bandage and the interposition of lint, aided, if need be, by splints. It does no credit to a surgeon to send forth his patient, after the completion of cicatrization, with webbed hands and feet, or with his arms pinioned to the side of the chest, although such occurrences are not always entirely avoidable.

The disposition to contraction in burns and scalds attended with loss of substance is always great, and is often productive of the most frightful deformity. To counteract this disposition, recourse should be had, early in the treatment, to carved splints and tin cases, judiciously applied, and steadily used, not only until the parts are well, but for a long time afterwards; experience having shown that the tendency to contraction continues for months, if not years, after the completion of the cicatrization.

If, from neglect, mismanagement, or unavoidable circumstances, the contraction has seriously impaired the usefulness of the part, or greatly marred the person's good looks, relief should be attempted by the division of the offending cicatrice, or, perhaps, by its excision, the raw edges being afterwards united by suture, or adapted to a flap of integument from the neighborhood.

This operation, constituting what is termed *dermoplasty*, should not, however, be undertaken without due preparation of the system; for it is easy to perceive that, when the cicatrice is very large, two most extensive wounds would have to be made, thus inflicting a violent shock upon the constitution, extremely liable to be followed by erysipelas and a low form of fever, under which the patient might easily sink. At least a fortnight should be spent in this kind of preliminary treatment.

The operation should be performed while the patient is under the influence of chloroform, and great care should be taken to dissect out every particle of the inodular tissue. To accomplish this, the surgeon is sometimes obliged to pass deeply among important vessels and nerves, which must, of course, not be interfered with. In conducting such an operation about the neck, the precaution must be used of preventing the entrance of air into the veins. The bleeding which attends the excision of the cicatrice is generally trifling, and is easily arrested by torsion: when the ligature is unavoidable, it should be brought out at the nearest point of the wound, or through a small opening in the transplanted integument.

The skin for filling up the gap left by the removal of the inodular tissue, should always be taken from the immediate vicinity of the part. Thus, in the neck, it is usually obtained from the shoulder or top of the chest, and, when the wound is very large, two flaps are generally made, one on each side, the object being to guard against sloughing from inadequate nutrition. Due allowance must always

be made for shrinkage. Hence the flap should invariably be at least from one-fourth to one-third larger than the wound, have a good broad pedicle, and be well stitched in its new position, although care must be taken not to place the sutures too near each other for fear of embarrassing the circulation. The central portions of the flap must be loosely confined with adhesive strips, and the edges covered with charpie, soaked in oil. The wound made by the transplantation of the integument is immediately closed in the usual manner. The parts are kept perfectly at rest, being immovably fixed by suitable apparatus, and the case is afterwards managed according to the general principles of plastic surgery.

The results of this operation have been much lauded; I have not, however, I must confess, much confidence in its ultimate efficacy, experience having taught me that, sooner or later, the deformity is sure to return, though not always in its original extent. I have seen enough of these procedures, both in my own practice and in that of others, to convince me that they ought not to be classed among the triumphs of surgery. It is only when the cicatrice is very soft and superficial that they hold out any prospect of a very favorable result. When the contraction affects the muscles, tendons, fibrous membranes, and bones, forcing them out of their natural shape and position, the art of surgery can be of no avail.

Joints often become involved during the progress of burns and scalds, either from direct inflammation, or in consequence of the contraction of neighboring muscles, tendons, and aponeuroses. The parts are carefully watched, being moved from time to time, and constantly retained in splints, until all tendency to ankylosis has ceased.

Finally, the secondary *constitutional irritation* and drainage, so common, and so hazardous in the more severe forms of these accidents, must be met by stimulants, tonics, and anodynes, along with a nutritious diet, and exercise in the open air. If wasting diarrhœa be present, it must be checked with opium and astringents, of which acetate of lead and sulphate of zinc deserve particular mention, the former being given in doses of two grains, and the latter in half that quantity, with half a grain of opium, three times in the twenty-four hours. Night-sweats are controlled with quinine and elixir of vitriol.

Secondary amputation may be rendered necessary, when, an attempt having been made to save the part, death is likely to happen from the excessive discharge and hectic irritation; or when the part is found not only to be useless but to be greatly in the way of the patient's comfort and convenience.

SECT. VI.—FROST-BITE AND CHILBLAIN.

Man, as is well known, possesses in an eminent degree the faculty of resisting the influence of physical agents. His constitution is able to bear almost any amount of heat and cold, provided the transition from the one to the other is not too great or sudden, and that he himself is at the time in the full enjoyment of his bodily powers. The experiments of Fordyce, Blagden, and others, show what an amount of artificial heat may be endured without entailing any serious effects, and the experience of travellers, as Banks, Solander, and Kane, is equally decisive in regard to his capacity of withstanding the effects of low degrees of temperature. It is only, or chiefly, when the alternation from heat to cold is very rapid, or when the application of cold is made in a very concentrated form, upon a part of the body whose circulation is naturally very languid, that severe consequences are apt to ensue. Baron Larrey, who enjoyed extraordinary opportunities of studying the effects of cold, during Bonaparte's celebrated retreat from Russia, was forcibly struck with the little suffering which the soldiers experienced when exposed even for several successive days to the influence of a very low, dry, uniform temperature. Thus, after the battle of Eylau, although the mercury had fallen fifteen degrees below zero of Réaumur's thermometer, none of the French troops complained of frost-bite, notwithstanding many of them had remained in the snow, in an almost inactive state, for upwards of twenty-four hours. Presently, however, a fall of sleet coming on, during which the tem-

perature rose suddenly from eighteen to twenty degrees, immense numbers of those who had been exposed began to suffer from the effects of cold, consisting principally in sharp, pricking pains in the remote parts of the body, especially in the feet, and in a disagreeable sense of numbness and weight. Severe swelling soon followed; the skin assumed a dusky, reddish appearance; the joints became stiff and insensible; feeling and warmth rapidly diminished; and black spots formed at the roots of the toes and on the back of the foot, announcing the occurrence of gangrene, the extremity looking dry and shrivelled, as in chronic mortification. It was observed that those who had warmed themselves at fires suffered more severely than those who had been more discreet in this respect.

Frost-bite was very prevalent among the English troops during their first winter in the Crimea, and the French suffered in still larger numbers, as well as more severely. The habit which the men had of sleeping in their wet boots, at one time almost universal, contributed greatly to its production, wet and cold combined diminishing the circulation and vitality of the feet and toes. On the 21st of January, 1855, when, according to Dr. Macleod, the thermometer stood at 5°, not less than 2500 cases of frost-bite were admitted into the French ambulances, and of these 800 died, death in many having no doubt been expedited by the effects of erysipelas, pyemia, and hospital gangrene.

The first effect of dry, cold air is a sense of numbness and weight with a peculiar prickling or tingling, and an afflux of blood to the surface, giving it a lively reddish appearance. If the impression be maintained for any length of time, the parts become stiff and perfectly insensible; and the blood, retreating from the surface, leaves it of a pale, whitish aspect, contrasting strikingly with the previous discoloration. When the cold is intense, and suddenly applied, so as speedily to overwhelm the parts, the skin occasionally exhibits a mottled appearance, depending upon the presence of coagulated blood in the subcutaneous veins.

The effects of moist cold are very similar to those of dry cold. Upon immersing the hand, for instance, in iced water, there is generally an immediate rush of blood to the surface, and a decided augmentation of its color, soon succeeded by an unpleasant tingling sensation and a marked degree of numbness. By and by, however, the surface becomes white, the skin contracts, exquisite pain arises, and the whole limb notably shrinks. There is thus, in fact, no essential difference in regard to the effects of these two varieties of cold; and the observer cannot fail to perceive how closely the first impressions of both resemble those produced by the application of artificial heat, especially in its dry form.

All parts of the body are liable to suffer from the effects of cold; excepting, however, those rare cases, where the impression has been maintained for an unusual length of time, the toes, feet, heels, fingers, hands, nose, and ears, together with the lips and cheeks, will be found to be more frequently affected than any other structures. Accidents of this description are most common among the poorer classes, those wretched beings whose system is broken down by starvation, intemperance, and every kind of exposure and hardship, calculated to depress the vital powers, and predispose to the development of disease. Sailors and the boatmen on our lakes and rivers are particularly prone to frost-bite, and there are few seasons that do not furnish a large supply of such cases.

The primary effects of cold upon the general system are those of an agreeable stimulant; the circulation is increased in force and frequency, a slight glow pervades the surface, and the individual is universally exhilarated. By and by, this agreeable feeling is changed into one of pain and torpor; the brain is oppressed as if under the influence of a powerful narcotic; the whole body is cold and benumbed; and the person, overwhelmed by drowsiness, is obliged to make the most powerful efforts to keep awake. If, in an unlucky moment, he should yield to his inclinations, away from friends and assistants, he sleeps to wake no more; the blood rapidly settles in the internal organs; the nervous fluid ceases to be generated; the respiration becomes heavy and stertorous, and death takes place very much as in ordinary apoplexy. Should the individual, after long and severe exposure, be suddenly brought into a hot room, or placed near a fire, he

will run the risk of speedily perishing from asphyxia, brought on by the repulsion of the blood to the brain and lungs; or, should he survive a short time, the frost-bitten parts will be seized with gangrene, the spread of which, as observed by Larrey, is often so rapid and striking as to be perceptible by the eye.

Such are some of the more important local and constitutional effects of cold, when applied in its more severe and protracted forms. As just seen, it may prove destructive both to the part and system, or, reaction taking place, the patient may recover, although he will be likely afterwards to suffer more or less in various parts of the body, especially the feet, ears, nose, and fingers, from the secondary effects of his accidents, which are often as distressing to him as they are perplexing to the practitioner.

The *treatment* of frost-bite requires no little judgment and adroitness to conduct it to a successful issue. The great indication is to recall the affected parts gradually to their natural condition by restoring circulation and sensibility, in the most gentle and cautious manner, not suddenly, or by severe measures. The first thing to be done is to immerse them in iced-water, or to rub them with snow, the friction being made as carefully and lightly as possible, lest over-action be produced, as they are necessarily greatly weakened. If no ice or snow is at hand, the coldest well water that can be procured must be used; and, if immersion is inconvenient, wet cloths are applied, with the precaution of maintaining the supply of cold and moisture by constant irrigation. Moderate reaction is aimed at and fostered. All warm applications, whether dry or moist, are scrupulously refrained from; the patient must not approach the fire, immerse his limbs in hot water, or even be in a warm room. Attention to these precepts is of paramount importance, and should on no account be disregarded, since its neglect would be almost certainly followed by mortification or other disastrous consequences.

As soon as the natural temperature has been in some degree restored, slightly stimulating lotions will be found serviceable, such as weak solutions of camphor, soap liniment, or tincture of arnica with the addition of a few drops of ammonia to each ounce of fluid. The parts are placed at rest, in an easy and rather elevated position, and lightly covered with a blanket, or, what is better, exposed to the warm air of the apartment, there being now no longer any necessity for keeping the patient in a cool room, as there was in the earlier stages of the treatment. Some mild cordial may now also be given in small quantity, along with a little warm gruel or panada. If the local reaction threaten to be severe, it must be checked by astringent and cooling lotions, attention to position, a properly regulated diet, and the exhibition of a purgative. For incipient mortification, consequent upon cold, the best remedy is dilute tincture of iodine.

Dr. Hayes, the companion of Dr. Kane in his last Arctic voyage, gives an account of a mode of treatment of frost-bite pursued by the Esquimaux, which deserves brief mention, although it does not differ essentially from that just laid down. A native, says the writer, who had his leg frozen above the knee, to such an extent that it was stiff, colorless, and apparently lifeless, was placed in a snow-house at a temperature of 20° below zero. The parts were now bathed with ice-cold water for about two hours, and then enveloped in furs for about twice that period. At the end of this time frictions were commenced, first with the feathery side of a bird skin, and then with snow, alternately wrapping the limb in furs, and continuing the rubbing for nearly twenty-four hours. The limb was now carefully covered, and the temperature of the room elevated by lamps above zero. On the third day the man was removed to his own house, and in seventy hours he was able to walk about, with only a slight frost-bite on one of his toes.

When a person has been overpowered by cold, or is nearly frozen to death, the attempts at restoration must be conducted upon the same general principles as when he is suffering merely from the local effects of cold; that is, he should be put in a cool room, and be gently but efficiently rubbed with flannel, wet with brandy, spirits of camphor, or ammoniated liniments, gradually followed by dry frictions and warm covering. If he can swallow, brandy should be given by the

mouth, or this or some similar article should be thrown into the rectum; stimulants should be cautiously applied to the nose, especially snuff, and sinapisms to the precordial region, the stomach, and spine. As the circulation and respiration improve, the temperature of the apartment may be gently elevated, and warm broths, or wine-whey, or, what is better, warm toddy, administered. The efforts at resuscitation should not be discontinued too soon, since they have occasionally been crowned with success long after all reasonable expectation of recovery had ceased. The practice formerly recommended of immersing the whole body in cold water, under these circumstances, cannot be too much deprecated, as it cannot fail to prove exceedingly injurious.

Pernio or *chilblain*.—The secondary effects of cold are usually described under the name of *pernio* or *chilblain*, and there are several varieties of form in which they may present themselves, as the erythematous, ulcerated, and gangrenous. These effects may supervene upon slight exposure, and hence they are occasionally met with among the better classes of citizens, the parts most liable to suffer being the toes, heel, instep, ears, nose, and fingers. They are usually preceded by slight vesication, and by burning, tingling sensations, as if the surface had been held near the fire. These effects may soon subside, or they may prove a source of annoyance for many months; in general, however, they are of a transient nature, but the parts, instead of getting completely well, remain weak and congested, and are liable to new attacks of suffering from the slightest causes. Any sudden change in the weather is extremely prone to bring on a paroxysm; the affected structures become red, or of a dusky purplish hue, swollen, painful, and œdematous; the epidermis is often raised into little blisters, distended with yellowish, turbid, or sanguinolent fluid; and there are few cases in which itching, sometimes almost insupportable, is not a prominent symptom, the patient feeling as if he could tear the parts to pieces.

Ulcers not unfrequently form, as an effect of frost-bite. Generally preceded by slight vesication, they are superficial, irritable, and indisposed to heal, the discharge being of a thin, ichorous character; the parts around are red, inflamed, and congested, and the erosive action often spreads over a considerable surface. In some cases it extends very much in depth, and may thus ultimately invade a neighboring joint, bone, tendon, or muscle.

Gangrene is more frequently a primary than a secondary effect of frost-bite; the affected part is of a dark brownish, or blackish color, cold, insensible, and exquisitely fetid; in some cases the slough is dry and shrivelled, like a rotten pear, in others, it is moist and expanded. In persons of weak constitution, and in the more remote parts of the body, where the circulation is naturally very feeble and languid, it often spreads to a considerable extent; but in general its tendency is to limit itself to a small space. When considerable, it may invade all the component tissues of a limb, the soft parts as well as the bones and joints.

Pernio may, as already stated, last for many years, alternately disappearing and recurring under the slightest local and constitutional changes. Atmospheric vicissitudes generally exercise a marked influence upon these attacks, the patient being often a complete barometer: a combination of cold and moisture is particularly prejudicial. During the dry weather of summer the disease not unfrequently goes off spontaneously, but is sure to return on the approach of winter. In this manner life may be rendered perfectly miserable, especially when the chilblain is seated in the feet, the patient being hardly ever able to walk about with any degree of comfort or satisfaction.

The *treatment* of *pernio* is generally too little regarded by the practitioner, who, knowing that it never endangers life, is too apt to overlook its just claims to his sympathy. Of the various remedies that have been, from time to time, recommended for its relief, those that are of a slightly stimulating character are most entitled to confidence. The milder forms of the disease are often speedily relieved by immersion of the part in cold water, followed by the use of a strong solution of acetate of lead and opium, or, what is preferable, the dilute tincture of iodine, which, on the whole, I have found to be more beneficial than any other article.

Sometimes prompt amelioration is afforded by the application of carded cotton, soap liniment, spirits of camphor, or some other stimulating embrocation.

When blisters form they should immediately be opened, and the affected surface freely touched with solid nitrate of silver, or painted with tincture of iodine. Not unfrequently excellent effects follow the use of the dilute citrine ointment, or of the ointment of the oxide of zinc. In obstinate cases I have derived great advantage from a blister, retained until thorough vesication is produced.

The gangrenous form of *pernio* must be treated upon general principles. Feter is allayed by the chlorides, and sloughs are removed as they become detached. Amputation is refrained from until there is a well-marked line of demarcation, and even then the surgeon should hesitate if the system is not in a healthy condition. Baudens asserts that most operations of this kind, performed in the Crimea, on account of frost-bite, were unsuccessful, owing to the shattered and wasted state of the sick, the great majority of whom had been affected with diarrhoea.

In all cases proper attention must be paid to the general health; the diet must be regulated, the bowels evacuated, the secretions improved and restored. From neglect of these precautions great temporary suffering is often induced.

SECT. VII.—MORBID GROWTHS.

The skin is subject to a great variety of morbid growths, some of a benign, others of a malignant character. Among the more simple formations belonging to the former class are warts, corns, horny excrescences, and the so-called sebaceous tumor, which, as its name implies, has its seat in the sebaceous follicles, so common in different regions of the cutaneous surface. Fibrous, fibro-cellular, or fibro-plastic growths are also sometimes met with, although they are infrequent; they are never malignant, but are extremely apt to return after extirpation. The most common and interesting development of this description is what is termed the keloid tumor, incidentally referred to in the chapter on the general history of morbid growths. Finally, the skin is occasionally remarkably hypertrophied, either congenitally, or as a result of interstitial deposits.

The number of malignant growths of the cutaneous tissues is quite considerable, and, as they are of frequent occurrence, and often followed by disastrous consequences, it becomes necessary to study them with more than ordinary care and attention. The principal affections, recognized by pathologists, as appertaining to this class of diseases, are scirrhus, melanosis, eiloid, lupus, epithelioma, and the peculiar bark-like formation first described by Dr. Warren under the name of lepid.

1. WARTS OR VERRUCOUS GROWTHS.

Warts are those peculiar excrescences, or prominences, so often seen upon the hands and face of young persons, although the old are by no means exempt from them. They consist essentially of a hypertrophous condition of the papillary structure of the skin, and sometimes occur in such numbers as to constitute a genuine verrucous diathesis. When this is the case, they are not only developed with remarkable rapidity, but are apt to attain an extraordinary size. Of the exciting causes of warts, nothing is known; they often occur in several members of the same family, and instances are observed in which they betray a hereditary tendency.

A wart is a hard, insensible excrescence, generally of a conical shape, more or less movable, and attached by a broad base, although sometimes the reverse is the case, the union being effected by a very narrow pedicle; its surface is rough, fissured or tuberculated, and usually a few shades darker than the adjacent skin; its size seldom exceeds that of a common pea. When cut, it is painful, and bleeds somewhat. Its structure is essentially cellulo-fibrous. The fluid which follows a section of a body of this kind, has been supposed, but erroneously, to be contagious, or inoculable. A wart on the face, arm, or shoulder sometimes becomes the seat of carcinoma, especially when it is constantly rubbed or irritated.

The *treatment* of warts is very simple. In young persons, in fact, they often disappear spontaneously. The best local remedy is chromic acid, with equal parts of water, applied with a glass brush. It instantly turns the skin black, and forms an eschar, which drops off in six or eight days, leaving a healthy, granulating sore, which soon heals. Tincture of iodine, acetic acid, bichloride of mercury, and sulphate of copper, also, answer an excellent purpose. When a verrucous diathesis exists, recourse must be had to the exhibition of arsenic, or Donovan's solution. Excision is necessary when a wart displays a tendency to malignancy.

2. SEBACEOUS TUMORS.

The sebaceous tumor, essentially consisting of an enlargement of a sebaceous gland with a retention of its secretion, has been described under various names, founded either upon the character of its walls, the fancied nature of its contents, or the kind of structure in which it originates; as encysted, atheromatous, meliceric, steatomatous, and follicular. *Wen* was the familiar appellation by which it was known by the older surgeons. The term sebaceous seems to me to be preferable to any other, as it is fully expressive of the nature of the affection.

The manner in which the sebaceous tumor is formed is easily explained. The first link in the morbid chain is the obstruction of a sebaceous gland, or cutaneous follicle, either in consequence of adhesive inflammation, or the inspissated condition of its own secretion, thereby offering a mechanical impediment to its escape. Being thus forcibly retained, the matter gradually increases in quantity, and as it does so it necessarily presses everywhere upon the walls of the gland, which, in time, expands into a strong sac, fig. 191, varying in size from that of a pea up to that of a small orange. Essentially, then, the tumor is an encysted tumor, consisting of an enlarged or hypertrophied condition of the sebaceous gland, and of an altered state of its own secretion, both the direct and inevitable result of the closure of the natural outlet.

The *contents* of the sebaceous tumor are extremely variable, both in color and consistence; in general, they are thick and whitish, looking and feeling very much like a mass of lard or tallow; occasionally they present the appearance and consistence of honey; and cases are met with in which they bear a very close resemblance to putty, or a thick mixture of flour and water. Some-

times the contents of a tumor of this kind are thin, almost watery, and exceedingly offensive. At other times, again, short hairs, very soft, and having well-

formed roots, are found in them, as represented in fig. 192.

Pilous matter is most commonly found in sebaceous tumors about the forehead and eyelids. I have repeatedly seen it in these situations, particularly in very young subjects. It is not likely that the hairs that are found here are developed in the morbid growth; on the contrary, the probability is that they are intercepted during the process of occlusion of the cutaneous follicle, and that, after they have fallen into the cavity of the cyst, they are capable of attaining a certain development, but ultimately cease to grow, and so become effete matter.

The sebaceous tumor is sometimes filled, either partially or completely, with

Fig. 191.

Sebaceous tumors of the scalp, one of them being laid open to show its cyst and contents.

Fig. 192.

Cyst of a sebaceous tumor, with hairs in its interior.

calculus matter, consisting of phosphate and carbonate of lime, cemented together by a minute quantity of animal substance. A case has been recorded where the integuments of the buttocks were completely studded with small collections of this description; they occurred in a young lad, and evidently had their seat in the skin-follicles. Similar formations have been observed on the forehead, scalp, nose, shoulders, trunk, and scrotum.

The young sebaceous tumor has generally a very thin, soft, delicate *cyst*; whereas in an old one the cyst is nearly always very thick, tough, and fibrous; occasionally, indeed, fibro-cartilaginous, fibro-plastic, or even calcified. Externally the cyst is rough, and more or less intimately adherent to the surrounding parts; internally, on the contrary, it is smooth and glistening, not unlike the inner surface of the dura mater. Small sacs are sometimes observed in its interior, and I have several times seen indistinct partitions thrown across it, the result, apparently, of plastic, organized deposits.

The sebaceous tumor is free from pain, has few vessels, and is generally very tardy in its development, except when the *cyst* remains for a long time uncommonly thin, when it may be quite rapid. I have never known it to manifest any malignant tendency, although occasionally it inflames and ulcerates, and becomes the seat of a very fetid discharge. It originally occupies the substance of the skin, but, as it increases in size, the cyst gradually pushes its way through, so that the connection between them is ultimately completely lost. Meanwhile, the skin itself is remarkably attenuated, and often, in great measure, deprived of hair, especially on the scalp, where, particularly in cases of long standing, the surface is frequently quite hard. Here, too, the steady, persistent pressure of such a tumor occasionally indents the skull.

The degree of *mobility* of the morbid growth is extremely variable, depending upon its age and volume, but, above all, upon the amount and laxity of the cellular tissue in the structures in which it is developed. Its shape is for the most part globular; but when it is subjected to considerable pressure, it is not uncommon for it to have a compressed, flattened appearance.

The most common *sites* of the sebaceous tumor are the face, forehead, and scalp. It is also met with on the neck, eyelid, shoulder, back, buttock, and scrotum. On two occasions I have seen it on the prepuce, the patients being small boys who had been circumcised at the usual period at which that operation is performed according to the rites of the Jewish Church. It is very rarely seen on the extremities.

The *number* of sebaceous tumors, although usually small, is extremely variable. Sometimes there is only one, while at other times there may be as many as five or six on the same person. In one instance, in a man aged forty, I counted upwards of two hundred, mostly upon the head, face, and neck. Nearly all began when he was quite young, soon after bathing in cold water. They were of the meliceric kind, the contents of many being visible at the enlarged and partially obstructed follicle, where they had concreted, and presented a yellowish, dirty, wax-like appearance. They were of a globular or ovoidal shape, and varied in volume from that of a pea up to that of a hen's egg.

Childhood and adolescence are the periods of *life* most obnoxious to the formation of these morbid growths. In 1862, I removed at the Clinic of the Jefferson Medical College, from the left temple of a child, aged two years and a half, a small sebaceous tumor, which, judging from its history, had evidently an intra-uterine origin. It lay in close contact with the frontal bone. More recently I operated upon a similar case, in a child three months old, the tumor occupying the right side of the forehead, just above the eyebrow. Its contents were remarkably fluid, as they usually are when the disease is congenital.

Occasionally these tumors occur in several members of the same family; and now and then they display an evident *hereditary* tendency, as in a case which fell under my observation in 1844, in which the disease existed upon the scalp of a young woman of twenty-seven, and also upon that of her father, a paternal aunt, and her paternal grandmother. The tumors were, respectively, from four to seven in number, and varied in volume from that of a marble to that of a

walnut. Since then four other instances of a similar character have come under my notice.

The *diagnosis* of the sebaceous tumor is sufficiently easy. Its chronic march, indolent character, soft, doughy consistence, mobility, and peculiar situation, together with the absence of enlargement of the subcutaneous veins, and the normal appearance of the skin, always serve to distinguish it from other morbid growths.

The only *remedy* for this variety of tumor is thorough excision; not a particle of the cyst or wall should be left behind, otherwise repullulation will be inevitable. When the tumor is situated upon the scalp, a single longitudinal incision may be made across it, the flaps being dissected off from each side, and the morbid mass lifted out bodily, without exposing its contents. In most other regions, however, the best plan is to lay the tumor open from within outwards, turn out its contents, and then tear away the cyst. When the integuments are diseased, it may be proper to include the altered structures in an elliptical incision. However performed, the operation should never be undertaken without due preparation of the system, as I have repeatedly known it to be followed by erysipelas. In 1863, I removed a small sebaceous tumor from the back part of the head of a young gentleman; for the first few days the case went on well, then erysipelas appeared, and in a short time this was followed by an immense carbuncle, which came very near proving fatal. The bleeding after such an operation is usually trifling.

3. MOLLUSCOUS TUMORS.

There is a variety of cutaneous tumor, to which, from its fancied resemblance to the knots on the bark of the maple, the term molluscosus has been applied. When fully developed, it is about the size of a ripe currant, which it further resembles by having a central depression upon its surface, caused by the peculiar arrangement of its contents. Its form is variable; some are round or oval, some elongated, and as if compressed, some pedunculated, and some wallet-shaped. In color, they are usually red, reddish-brown, or dusky yellowish; in consistence, soft and spongy.

Molluscosus tumors occur upon various parts of the body, as the face, neck, back, shoulders, nates, and extremities, and often exist in such immense numbers as to constitute a genuine molluscosus diathesis. What is singular is that they are sometimes met with in several members of the same family; a circumstance which, together with their rapid and consentaneous development, has led to the idea of their being occasionally contagious, or communicable from one person to another by contact. Whether this, however, is really so or not remains to be proved.

The disease, although it has been noticed at a very early period, as in children under five years of age, is most common in adult and elderly subjects. Its progress is frequently very rapid, a large portion of the surface becoming studded with tumors in a few weeks. How the disease is excited we are uninformed, nor is anything known of its predisposing causes. The immediate influence under which it is developed is inflammation of the sebaceous glands, giving rise to a rapid secretion of sebaceous matter, which, becoming too thick to escape at the natural outlets, accumulates in the interior of these reservoirs, pressing asunder their walls, and giving them a lobulated appearance, as is rendered evident on a section of them.

The *contents* of these little tumors consist mainly of epidermic scales, in union with ovoid, oblong, or cuboid cells, heaped together like a pile of eggs, and occupied either by granular matter, oil globules, or a peculiar homogeneous substance, of whose nature we are ignorant.

Left to themselves, molluscosus tumors nearly always pass into ulceration, generally beginning at their summits, and gradually progressing until their contents are completely discharged, when the parts usually readily heal; or they are invaded by gangrene, which occasionally extends deeply into the subjacent

tissues, and thus leads, in the event of recovery, to disfiguring scars. Finally, cases occur in which the tumors become atrophied, or transformed into little pendulous wart-like excrescences.

The *treatment* of these molluscos formations is best conducted with topical stimulants, of which the most efficacious are tincture of iodine, acid nitrate of mercury, sulphate of copper, chloride of zinc, and chromic acid, all more or less diluted to adapt them to the exigencies of each particular case, or the tolerance of the parts, the object being rather to produce a sorbefacient than an escharotic effect. In general, it will be found that brushing the surface of the tumor freely once a day with tincture of iodine will not only promptly arrest its development, but rapidly promote its removal. Laying open the morbid growth, and touching the raw surface slightly with the solid nitrate of silver, is sometimes highly efficacious. The most expeditious method of all, is to cut it away with the knife, or to effect its strangulation with the ligature. Such a procedure, however, can only be adopted with any degree of propriety, when the number of tumors is very small.

Constitutional treatment is not to be neglected. Occasionally the molluscos tumor in great degree, if not entirely, disappears, simply under the influence of a change of air, a judiciously regulated diet, and attention to the bowels and secretions. When the general health is much disordered, the first object should be to amend it by the interposition of suitable remedies, medicinal and hygienic. Cleanliness is of great importance, and must not be overlooked. When there is a scorbutic state of the blood, iron and quinine, with subacid drinks and vegetables, will be indicated.

4. MOLES.

Moles are congenital spots, occurring upon various portions of the external surface of the body, usually of a dark, grayish, blackish, tawny, or brownish color, and closely covered with short, thick, almost bristly hairs. They occasionally project somewhat above the surrounding level, but in general this is not the case; they are usually a little harder than the natural skin, and they present themselves in various forms, of which the round and oval are the most common. Some persons are remarkably prone to the formation of moles, and it is then not uncommon to see a number of them scattered over different parts of the body. When single, or existing in small numbers, they generally occur on the face, shoulder, neck, or arm. Their size varies from that of a three-cent-piece to that of a dinner-plate.

The color of these spots is due to a redundant deposit of the natural pigment of the mucous network of the skin, with an altered condition of the proper substance of the dermis, and probably also of the cuticle and of the hair follicles.

Long-continued local irritation, such as is caused by friction, pressure, or want of cleanliness, may occasionally awaken ulceration of these bodies, but in general they remain perfectly stationary and innocuous. A few years ago, I excised from the back part of the arm of a gentleman of upwards of eighty a mole which had been a source of annoyance to him, more or less, for thirty years. It had latterly become ulcerated, had often bled, and was the seat of a very fetid discharge. It was included in an elliptical incision, the parts healing kindly, and there being no return of the disease.

It is not often that moles become subjects of surgical interference; it is only, in fact, when they cause serious disfigurement, or when they fall into ulceration, that professional aid is sought. It has been proposed to get rid of them by mild caustic applications, as Vienna paste, chromic acid, or chloride of zinc; but as such a procedure might be followed by keloid, the best plan always is to use the knife, the morbid structures being included in an elliptical incision, the edges of which are afterwards healed, if possible, by the first intention.

5. HYPERTROPHY OF THE SKIN.

Hypertrophy of the skin is now and then observed, chiefly, if not exclusively, as a congenital affection. It is characterized by a soft, pendulous condition of the skin, which hangs off in loose folds from the surface to which it is naturally attached, as if it had been stuck on without any special object. In all other respects, the integument is apparently perfectly normal, there being not the slightest alteration of color, consistence, or structure, at least so far as we are enabled to judge from inspection. The most common sites of hypertrophy of the skin are the nates, scrotum, prepuce, and vulva. The most remarkable example that I have met with occurred, as a congenital vice, on the back of the neck of a female child, upwards of a year old; the integument formed a large pendulous mass, of a doughy, inelastic feel, extending from ear to ear, and causing a very unseemly deformity. The child was, in other respects, well formed.

When the hypertrophied integument forms an unsightly mass, or when it proves inconvenient by its bulk, the surgeon will be appealed to for advice, in regard to the propriety of removing the offending structures. Should an operation be decided upon, the parts should, if possible, be included in an elliptical incision, care being taken not to cut away so much of the skin as to interfere with reunion. If the tumor is very large, and the patient of tender age, recourse to the knife should be postponed until the constitutional stamina are sufficiently developed to enable the child to bear the shock attendant upon so severe an operation. Special pains should be taken to guard against hemorrhage, which might otherwise be profuse.

6. ELEPHANTIASIS, OR HYPERTROPHY OF THE SKIN AND CELLULAR TISSUE.

Arabian elephantiasis, Egyptian sarcocoele, or the glandular disease of Barba-dos, as it is variously denominated, although uncommon in this country, deserves passing notice not less on account of the hideous deformity which it induces than its obstinate and intractable character.

Fig. 193.

Elephantiasis of the foot and leg.

The favorite seat of this singular disease is the leg, which often acquires an enormous volume and a most grotesque appearance, causing a striking resemblance to the leg of the elephant, whence its name. It is not, however, confined to this part of the body; on the contrary, it is liable to occur in various organs, particularly the scrotum, prepuce, and pudendum, which, in consequence, sometimes acquire an enormous bulk. A tumor of this kind, presented to me by Dr. Bozeman, and removed by him from the genital organs of a negro, weighed forty pounds; and Clot-Bey extirpated one, occupying a similar situation, which weighed one hundred and ten pounds. The adjoining cut, fig. 193, taken from a clinical case, affords a good illustration of elephantiasis of the foot and leg.

The disease is met with in both sexes, but much oftener in males than in females; it occurs in various races of men, and frequently begins at an early age, although it is most common in young adults. In this country and in Europe the affection is very rare, but in certain parts of Asia, Africa, Syria, Arabia, Egypt, and the West Indies, it is extremely prevalent, and sometimes even endemic.

Of the causes of elephantiasis nothing satisfactory is known. The disease is evidently of an inflammatory character, but how this is brought about we are

entirely ignorant. It has been supposed that it is owing to an obstruction of the principal veins of the affected parts, impeding the return of blood, and thus creating congestion and irritation, followed by plastic exudation in the interstices of the cutaneous and cellular tissues. From the fact that attacks of erysipelas are not uncommon in the earlier stages of the disease, or, rather, that this affection not unfrequently precedes the outbreak of elephantiasis, it has been imagined that it is essentially dependent upon the disturbance which it occasions in the nutritive and secretory functions of the parts. Others, again, have been led to conclude that the malady essentially consists in an inflammation of the lymphatic vessels, attended with plastic deposits within and around these vessels, whereby their caliber is choked up, and, as a necessary consequence, their contents are prevented from discharging themselves into the thoracic duct. This view is, on the whole, extremely plausible, for it really comprises all the cardinal elements of a consistent theory, which the others do not. That there is, in this disease, serious mechanical obstruction of some kind or other, is unquestionable, and I know of none that would be more likely to produce such a result than compression of the lymphatic vessels. If then, it is allowable, in the existing state of the science, to frame a doctrine in respect to the origin of an affection so obscure as elephantiasis is acknowledged to be, we may conclude that it is an inflammation of the absorbents, attended with obstruction of their caliber, and deposits of plastic matter, which, becoming gradually organized, is ultimately converted into an analogous fibrous tissue, thereby completely changing the character of the primitive structures, especially the cutaneous and cellular.

Dissection shows that the epidermis in this disease is very much thickened, rugose, and so firmly adherent as to come off with difficulty. The true skin is of a whitish color, striated in its texture, and very hard and dense, cutting almost like the rind of bacon. In many cases it is from a quarter of an inch to half an inch in thickness. The papillæ are enormously hypertrophied, and of an elongated shape, forming large bodies which stand off prominently from the substance of the true skin. The cellular tissue is completely changed in its character; its areolæ are obliterated, and their place is supplied by a dense, inelastic fibroid substance, exhibiting none of the properties of the original. In elephantiasis of the leg, the muscles, compressed by the new matter, and deprived of activity, are found to be wasted, pale, and in a state of fatty degeneration. The bloodvessels are generally very much enlarged, and hence, when an attempt is made to extirpate the morbid mass, as when it occupies the genital organs, tremendous hemorrhage is to be expected. In some cases, however, the larger veins are obliterated, especially in elephantiasis of the lower extremity. The principal nerves have a white, flattened appearance, and are apparently augmented in size.

The *symptoms* are variable. Often, if, indeed, not generally, the disease comes on suddenly and unexpectedly, without any apparent local or constitutional cause. At times, however, its development is directly traceable to local injury, as a blow, sprain, or contusion; and in quite a number of cases it has seemingly followed upon the protracted immersion of the parts in cold water, the occupation of the individual compelling him to pursue such a habit. The symptoms are at first of an inflammatory character; the affected surface, red and painful, pits on pressure, and imparts a nodulated, cord-like sensation to the finger; the subcutaneous cellular tissue is hard and infiltrated; and the movements of the diseased structures soon become stiff, awkward, and embarrassed. Sometimes red lines or streaks extend along the course of the lymphatic vessels, as high up as the nearest ganglions, which are themselves more or less tender and swollen. Considerable febrile commotion is generally present, but this soon subsides, and the disease gradually lapses into a chronic state, which often ceases only with the patient's life.

The *diagnosis* of elephantiasis is unmistakable: there is no other affection which bears any resemblance to it. Once seen, it can never be forgotten. The part is not only enlarged, but enormously increased in weight and consistence; it feels heavy and cumbersome, and is as hard, dense, unyielding, and rough as the leg of the animal from the resemblance to which it has derived its name.

The surface of the skin, usually much darker than natural, is fissured, grooved, nodulated or tuberculated, and completely deprived of its normal sensibility. Sores occasionally form upon it, and, gradually spreading in diameter and depth, add greatly to the local distress. Sometimes small, hard, shining scabs exist, not unlike those of ichthyosis. The chronic march of the disease, the remarkable deformity of the affected parts, and the peculiar condition of the skin will always prevent it from being confounded with anasarca, the only lesion which bears any resemblance to it.

The disease, once fully established, may remain completely stationary for years, or even during the remainder of life, or it may go on gradually increasing until the affected parts have acquired a volume and a weight many times beyond the natural state. Even under these circumstances, however, the suffering is chiefly of a mechanical character, the general health often continuing good to the last. It is only, in fact, when intractable ulcers form, and there is an abundant discharge of pus, that the constitution is likely to give way under the local drain and irritation. The prognosis is of course most unfavorable in those countries where the disease is endemic; in Europe and the United States, where it occurs only as a sporadic affection, very few die of it.

The *treatment* of elephantiasis is, at best, very unsatisfactory, however early it may be commenced, or however perseveringly and judiciously it may be conducted. Regarding it as essentially consisting in an inflammation of the lymphatic vessels, or of these vessels and the veins, the most rational plan of treatment that suggests itself is the antiphlogistic, of which leeching, blistering, and the application of tincture of iodine are among the more important and reliable means. The object, in the first instance, should be to reduce local action, and thereby prevent subversion of structure. Hence the sooner these remedies are applied the more likely shall we be to obtain resolution. As a sorbefacient, there is no article in the whole materia medica that holds out such strong hopes of relief as tincture of iodine, used either pure or variously diluted to suit the exigencies of each particular case. It not only promotes the removal of effused fluids, but produces a powerful revulsive and antiphlogistic action, and should be employed, steadily and persistently, for many months together. The effects of the treatment will be greatly augmented, if, superadded to it, the parts be occasionally scarified, to relieve engorgement, kept at rest in an elevated position, and well bandaged, strapped, or mechanically compressed. Inunction with mild mercurial ointment also sometimes proves beneficial; and, in the earlier stages of the complaint, lotions of acetate of lead, hydrochlorate of ammonia, and of rectified spirits, are worthy of trial, especially when there is much pain, with a tendency to rapid effusion and organization.

Constitutional treatment is not to be disregarded in this disease. It will, in general, greatly assist the action of local remedies if the patient be put under proper restraint in respect to his diet, if he take occasionally a brisk cathartic, and if he be kept pretty constantly under the influence of the saline and antimonial mixture, with a few grains of calomel every night at bedtime, until slight ptyalism is produced. Even general bleeding might be advantageously employed at the beginning of the treatment, if there is a robust and plethoric state of the system.

When the malady has attained an extraordinary degree of development, or has gone on for many years progressively increasing, or has remained stationary for a long time, no treatment of which we have at present any knowledge, not even ligation of the principal arteries of the affected tissues, will be likely effectually to eradicate the disease, or, more properly speaking, enable the parts to resume their primitive condition. All topical and general means are, under such circumstances, absolutely unavailing; and the utmost that can reasonably be expected from cutting off the supply of blood to the part is a diminution of its size, not a complete restoration of it to health. Professor Carnochan deserves great credit for the laudible effort which he has made, in several cases of elephantiasis of the leg, to arrest the morbid growth, and ultimately cause its absorption by ligating the femoral artery; but, although his patients, three in

number, were, from all accounts, much benefited, it is questionable whether, in any, a complete cure has been effected. In the summer of 1857, I was present at the Philadelphia Hospital, when Dr. Campbell, then surgeon-in-chief, performed an operation of this kind upon a negro, aged about fifty, who had long been afflicted with this complaint in one of his legs; but the result was not at all encouraging. I saw the man occasionally afterwards for many months, and during my last visit to him, more than a year after the operation, the limb had not undergone any material change, either in volume or consistence. Indeed, such a procedure could hardly be expected to eventuate favorably, when we take into consideration the excessive disorganization of the parts and the astonishing enlargement of the branches of the femoral artery. The operation might, if performed early in the disease, and if conjoined with the use of sorbefacients and the bandage, be worthy of further trial; but I should certainly not feel inclined to recommend its indiscriminate employment.

When the diseased mass is very large, greatly incommoding by its weight and bulk, and entirely unamenable to treatment, the only resource is removal with the knife. If it occupy a limb, amputation will be both safe and easy, but if it involve the scrotum, penis, or pudendum, excision may prove not only extremely difficult, but exceedingly perilous, life being endangered, in the first instance, by shock and hemorrhage, and afterwards by erysipelas, pyemia, and exhausting suppuration.

7. KELOID TUMORS.

The keloid tumor, so called from its fancied resemblance to a crab, is an affection of the skin, first accurately described by Alibert, in his treatise on cutaneous diseases, in 1810. It is characterized by the existence of hard, semi-elastic, prominent excrescences, of a cylindrical or rounded form, more or less discolored, and the seat of an unpleasant itching sensation. Processes, roots, or branches usually extend from it into the neighboring parts, the whole looking very much like the cicatrice of a burn.

The disease is generally described as being extremely infrequent; but judging from my own experience I am far from thinking that this is the fact. I have notes of at least thirty cases, and many more have come under my observation of which I have neglected to keep a record. It occurs in all classes of society, in both sexes, in nearly all parts of the body, and at almost all periods of life. The youngest case of it that has been under my charge was that of a little girl three years and a half old; on the other hand, I have repeatedly seen it after the age of sixty. A number of my patients were negroes; but whether they are more subject to the disease than whites I am not prepared to affirm, although this is highly probable.

The exciting *causes* of keloid are not always the same. In some cases, though these constitute a marked minority, it arises spontaneously, and is then very liable to show itself in various parts of the body, as if the individual was laboring under a real keloid diathesis. Of this form of the affection I have seen two remarkable examples. In general, keloid succeeds to some local injury, sometimes of a severe, but more commonly of a trivial, character, as, for instance, a scratch, puncture, or abrasion. In four of my cases it supervened, respectively, upon the operation of cupping, the application of a blister, the contact of nitric acid, and the cicatrices left by smallpox. In another instance it broke out upon a vaccine scar. In a young lady of seventeen, it was produced by the application of caustic potassa, employed for destroying an enlarged lymphatic ganglion of the neck. In several cases I have known it to follow the use of the knife in the extirpation of tumors. Thus, in an elderly lady from whom I removed the right mammary gland, two well-marked keloid growths came on, soon after the operation, at the site of two small incisions made to ease one of the flaps with a view to more accurate approximation; and the occurrence of the disease after the ablation of keloid tumors both at the line of union of the edges of the wound and at the parts transfixed by the pins used in introducing the twisted suture, is familiar to every operator. But the most common causes of keloid, so far as my observa-

tion extends, are burns and scalds, the great majority of the cases that have come under my notice having been produced in this way.

The period which intervenes between the occurrence of the exciting cause and the actual development of the disease is altogether uncertain; in many cases it is quite short, not exceeding a few weeks, or, at farthest, a few months; on the other hand, however, the time is occasionally much longer. In several of my cases, the tumors had acquired a large bulk in the space of a single year. When fairly commenced, the disease generally proceeds with marked rapidity, especially when it is the result of some traumatic cause; the same is also true, at least occasionally, when it arises spontaneously. Thus, in an instance recently under my observation, an immense number of these excrescences appeared spontaneously upon different parts of the body within a few months after the first manifestation of the morbid action.

The peculiar *external characters* of keloid will readily be understood from the annexed drawing, fig. 194, taken from a colored man upwards of fifty years of

Fig. 194.

Keloid tumors.

age, whose body was literally covered with morbid growths of this kind. They were particularly numerous on the neck and trunk, both in front and behind and also on the shoulders and arms, while the forearms, hands, and lower extremities were entirely free from them. In size they ranged from that of a small Lima bean up to that of a sausage, from six to eight inches in length. They were of all shapes; some round or cylindrical, some elongated and flattened, some angular, some crucial, some crab-like or full of processes, roots, or prongs; in short, nature seemed to have exhausted her ingenuity in devising figures for their representation. The surface of nearly all was rough, wrinkled, or puckered. Most of them projected from a line and a half to an inch and a quarter above the surrounding level; some were isolated, others ran into each other, thereby adding still farther to their grotesque appearance. Their consistence varied; most of them were remarkably hard and firm, feeling very much like a mass of fibro-cartilage with a slight degree of the elasticity inherent in that tissue. In regard to their color,

Some resembled the natural skin, but the great majority of them were several shades lighter. The intervening integument was sound up to the very borders of the keloid tumors, which were all distinctly circumscribed, and slightly movable, allowing themselves to be raised up with the thumb and index finger; only a few seemed to be completely tied down.

This remarkable case had commenced early in life, but had for years past been almost stationary. The man was well conditioned when I saw him, and his general health had all along been excellent; the only annoyance which he experienced was an itching or stinging sensation in some of the tumors, which, although at times very severe, especially when he labored under constipation or accidental overheating of the body, left him sufficient comfort for sleep and other enjoyment.

Through the kindness of Dr. Hazard, of this city, I had an opportunity, in 1859, of seeing another very interesting case of spontaneous, universal keloid disease, in a young gentleman, aged 18 years, a native of Cuba. Up to twelve months previously, when it first began to show itself, he had always enjoyed excellent health, and, so far as he knew, he was perfectly free from hereditary taint of every description. The tumors were, for the most part, of a rounded or oval shape, not very hard to the touch, movable, vascular, and of a dusky reddish hue. In a few places they existed as distinct ridges, from a line to an inch in width, projecting prominently beyond the level of the surrounding surface. The hands and feet were covered with them, particularly the joints of the fingers and toes; they were also found on the legs, knees, buttocks, right arm, and elbow. They were free from pain, and quite tolerant of manipulation. The general health was somewhat impaired, the youth looking dyspeptic, and laboring under partial paralysis of the left superior extremity.

In white persons the keloid tumor is generally a few shades redder than the adjoining skin; occasionally, indeed, it has a very fiery appearance, and is pervaded by numerous, delicate, superficial vessels, in a state of habitual congestion.

The site of the keloid tumor presents nothing of a definite character. When traumatic, it may occur in any part of the body, and the same thing, as already stated, may happen in the idiopathic form. It is generally supposed to be particularly prone to appear on the chest, but, judging from my own observation, this is doubtful.

Pathologists have made a distinction between keloid tumors by separating them into two *varieties*, the true and the spurious. The former, it is alleged, arise spontaneously, whereas the latter are always caused by some local injury, such as that already referred to. From my knowledge, however, of this disease, I am satisfied that such a division is altogether arbitrary, and, consequently, without any foundation in nature; the structure in both of the so-called varieties being perfectly identical.

Keloid, although a troublesome, is not a *dangerous*, disease, inasmuch as it rarely, if ever, degenerates into malignancy. Of all the cases that have come under my notice, not one has exhibited such a tendency. When excised, however, it nearly always soon returns, rising with increased activity, like a phoenix from its ashes; so that the second state is generally much worse than the first. In some cases, the tumors remain completely stationary for a long time; in others, on the contrary, they gradually advance until they have acquired a considerable bulk, when they usually become passive, and so continue for many years. Occasionally, in consequence apparently of prolonged pressure or local irritation, they take on ulcerative action, but such an occurrence is very uncommon.

In regard to their *structure*, keloid formations belong to the class of fibroplastic growths, described in the chapter on tumors. The fibres cross each other in every possible direction, intercepting cells or spaces occupied by plastic matter, of a softer nature. A section presents, to the naked eye, a whitish, homogeneous aspect, or, if the mass is old, very much the appearance of an unripe pear or turnip. It creaks slightly under the knife, and is of a dense, firm consistence, with very little elasticity. Hardly any vessels are perceptible in its interior, but the surface of the growth is usually, as already stated, quite vascular,

the vessels passing over it in distinct lines, more or less tortuous and varicose in their arrangement. The minute structure of keloid is well seen in fig. 195, drawn from one of my specimens by Dr. DaCosta.

Fig. 195.

Microscopical characters of keloid.

The *treatment* of keloid is altogether unsatisfactory. So far as I know, there is no remedy which exercises the slightest influence in arresting its progress or promoting its removal. Sorbefacients and alterants of every description, in every form of combination, and in every variety of dose, have been employed, and yet I am not aware of a solitary instance in which their exhibition, however protracted, has been followed by a cure, or even by a tendency towards such a result. The different preparations of iodine, arsenic, chloride of barium, hydrochlorate of ammonia, and other kindred articles, so serviceable in some other morbid growths, have all signally failed in effecting any beneficial changes in this. The excessive itching, burning, or stinging, which is a source of such annoyance when the tumors are large or numerous, is best relieved, according to my experience, by a proper regulation of the diet, an occasional active purgative, the exhibition of the antimonial and saline mixture with Fowler's solution of arsenic, and the frequent use of the tepid bath, either simple, or medicated with soda, potassa, common salt, or bran. Anointing the tumors occasionally with oil or mild pomatum will also prove serviceable. Everything like pressure or local irritation must be carefully guarded against. If ulceration arise, none but the most soothing remedies should be employed.

As to *excision*, my experience is decidedly opposed to it. In the many cases in which I have tried it, signal failure has been the result, the disease always returning at the site of the cicatrice within a short time after. It is only when the tumors act obstructingly, as when they impede the opening of a natural outlet, or become a source of great disfigurement, that interference should be considered as warrantable. In some cases relief might possibly be afforded by a plastic operation, but on this point I am not able to say anything from personal experience.

8. FIBROUS TUMORS.

Fibrous, cellulo-fibrous, or fibro-plastic tumors, are occasionally met with in the skin, especially in young adults; they usually come on without any assignable cause, are always very tardy in their development, and are free from malignancy,

although capable of repullulation after extirpation. Their most common sites are the neck, chest, and shoulder, but they may occur at all points of the body, even upon the fingers and toes. Varying in size in different cases, they seldom exceed, when attention is first called to them, the volume of a hazelnut or an almond; they are of a firm consistence, dense, and inelastic, creaking under the knife, and exhibiting, when divided, a homogeneous appearance not unlike that of an unripe pear or turnip, with but little evidence of vascularity. Their surface is generally smooth, or slightly fissured, pervaded by small straggling vessels, and somewhat lighter than that of the skin in the substance of which they are developed. Movable at first, they manifest a disposition, as they increase in bulk, to extend into the subcutaneous areolar tissue, to contract adhesions, and to become affected with sharp, darting pains, seldom, however, so severe as to cause much annoyance. In time, a process of disintegration may be set up in them, eventuating finally in ulceration, especially if the part is habitually fretted or compressed. The general health never suffers.

The microscopical characters of this class of tumors was well illustrated in a specimen which I removed a few years ago from the neck of a young woman, a patient at the clinic of the Jefferson Medical College. It was about the size of a small almond, of a whitish appearance and firm consistence, and had been progressing for upwards of eight years, without causing any particular inconvenience. The minute structure exhibited the usual stroma of fibrous growths in other situations, inlaid by nucleated cells.

In the *treatment* of these tumors nothing is to be expected from sorbefacient remedies; as long as they remain inactive, or when they are so situated as to occasion no inconvenience, they may be let alone, but when the reverse is the case, they should always be extirpated.

9. EILOID.

The eiloid tumor is extremely uncommon, only a few cases having hitherto been met with. It was first described by Dr. John C. Warren, who gave it the present name in consideration of its peculiar coil-like disposition. In its earlier stages it presents the appearance of a small elevation, similar to that occasioned by a burn, which goes on gradually increasing, without pain, heat, redness, or ulceration, until it acquires a large bulk, and sensibly affects the general health. The rolls, in the case of the Boston surgeon, lay in close contact with each other, each being about four inches in length, the whole together looking very much like a triple coil of inflated intestine. The growth seemed to have begun on the right side of the neck by a narrow base. The patient was a negress, about fifteen years of age, whose health had not been good for some time past. The tumor, although removed along with a portion of sound skin, soon returned. When the girl was seen eighteen months afterwards, it occupied the same site, but was not as large as the original one. Being again extirpated, it rapidly reappeared, and soon proved fatal, the patient dying dropsical. Dissection of the body revealed important disease of the liver, water in the splanchnic cavities, and great enlargement of the lymphatic ganglions of the abdomen.

Of the anatomy of eiloid nothing is known. It probably takes its rise in the substance of the dermis, but how, or in what particular part, has not been determined. It is to be regretted that Dr. Warren has omitted to state whether the secondary growth had the same coil-like appearance as the primary one. The only remedy, of course, for this disease, is early and efficient extirpation, with proper attention afterwards to the general health.

10. LEPOID.

The lepoid formation is most generally observed upon the face, nose, and forehead of elderly persons, usually males, of a delicate florid complexion, with a habitual tendency to congestion of the capillary vessels, light eyes, and light, brown, or reddish hair. Although occasionally single, I have more commonly

found it to be multiple. In some instances, indeed, quite a number of lepoid spots are observed, scattered about in different directions, with intermediate healthy skin. It generally makes its appearance in the form of a small, circumscribed speck, not larger, perhaps, than a mustard seed, and of a dirty, grayish color, which becomes covered with a very rough, brownish crust or scale, resembling the bark of a tree, whence its name. This, falling off, is soon succeeded by another, of the same complexion, form, and consistence. Thus the disease is often kept up for many successive years. At last, however, ulceration sets in, and the dermis exhibits a red, glossy surface, spicular, pitted, or granular, and throwing out a thin, ill-elaborated pus. The skin, upon inspection, is found to be almost of a gristly hardness, its internal surface being studded with numerous little, whitish, rounded bodies, connected together by a dense, grayish substance. The progress of the disease is attended with hardly any pain; but the patient is generally very much annoyed by itching, leading to an irresistible desire to scratch, which always aggravates it.

The nature of lepoid is undetermined. Without being able to speak positively, I am strongly inclined to believe that it is merely a variety of lupus or epithelioma; a supposition deriving plausibility from the circumstance that, although generally disposed to remain long stationary, or to make but little progress, it often ultimately takes on malignant action; pursuing then very much the same course as the milder forms of lupus.

The best remedy for this disease is non-interference. The rough, bark-like scale may occasionally be softened with a little very dilute citrine ointment, or covered with a mixture of two parts of collodion and one of castor oil, to serve as a defence from the air. All irritating applications must be refrained from. If the disease is inclined to spread, the tissues may be destroyed with the Vienna paste, or removed with the knife; but in general it will be safest to eschew all operative interference, as likely to aggravate the case by an early recurrence of the formation, and its more rapid tendency to malignancy.

11. LUPUS.

Under the term lupus are comprehended two varieties of disease, the chief peculiarity of which is a tendency to destructive ulceration of the skin and areolar tissue, or of these and the more deep-seated structures. In point of fact the two affections are identical: the only difference is that the one is milder than the other, more tardy in its progress, and less disposed to spread, its ravages being generally limited to the cutaneous textures, or to the parts in which it is originally located. The former of these affections is called the non-exedent, stationary, or serpiginous ulcer; the latter the exedent, eating, or corroding ulcer. It is also known as the canceroid or voracious ulcer. The older surgeons described it under the appellation of *noli me tangere*, in reference to the exquisite sensibility by which it is so often characterized. The term lupus, signifying wolf, is suggestive of the destructive tendency of the affection.

Of the causes of lupus, nothing definite is known. In general, it comes on spontaneously, or without any assignable reason, and soon exhibits its peculiar features. Occasionally its origin is apparently referable to some local injury, as a scratch, abrasion, or contusion, or to the irritation of some warty growth. It is commonly supposed that a scrofulous state of the constitution predisposes to its occurrence, and this is probably true, although in a much less degree than has been imagined. My own experience certainly does not warrant the conclusion that the origin of the disease has, in general, any such relation; in most of the cases that have come under my observation, the patients seemed to be peculiarly free from strumous taint, both as it respected the actual state of their own system, and everything like hereditary transmission. Persons of a delicate, ruddy complexion, with light hair, blue eyes, and an unusually active capillary circulation, are most prone to the disease, not only as it regards its frequency, but also the rapidity of its progress and the extent of its ravages. How far a syphilitic taint of the constitution may act as a predisposing cause of lupus is a

point that has not been ascertained; unfortunately, it is seldom in the power of the practitioner to obtain a sufficiently accurate account of his cases to enable him to trace, in a satisfactory manner, their various relations.

Although lupus may occur in any part of the body, it manifests a peculiar predilection for the nose, cheeks, and eyelids, especially the lower. It rarely occurs until after the age of forty. When it attacks the face, it sometimes breaks out simultaneously, or nearly so, at several points. The ulcers, in both varieties of the affection, are usually of an intractable nature, or if, as occasionally happens, they heal at one place, they are sure to spread at another. The discharge is ichorous, and the surface is covered by a brownish, characteristic scab. If reparation take place, the new skin is always very hard, white, irregular, and prone to take on disease from the slightest causes.

1. The *non-exedent lupus*, often described as the serpiginous ulcer of the face, generally begins either as a small, hard, white, shining tubercle, or as a fissure, crack, or excoriation, with indurated edges, and a thin, brownish incrustation. In either case, it soon exhibits its characteristic tendency to spread, not in depth, but circumferentially, for it rarely, at least in its earlier stages, penetrates beyond the substance of the true skin, or even far into that. In fact, it is essentially a superficial ulcer, passing generally from one point to another, but seldom involving the deeper structures, except, perhaps, when it appears on the ala of the nose, where it occasionally evinces a highly erosive disposition. When it affects the eyelids, it may, in time, extend to the fibres of the orbicular muscle, and even to the tarsal cartilage, but in general it remains limited for years to the skin, or skin and areolar tissue. The parts around the ulcer are hard, puckered, tender, and usually somewhat reddish, although very often they retain their normal color. The ulcer is the seat of occasional, darting, stinging, or shooting pain, and of more or less itching, generally much more disagreeable than the pain itself. When the scab, which is usually very thin, and of a brownish, or blackish color, drops off, it is speedily succeeded by another of a similar kind. When the surface is thus exposed, it is occasionally found to be covered by very red, vascular, sensitive granulations, smeared over with thick, yellowish, viscid pus, and disposed to bleed on the slightest touch. The edges of the ulcer are usually steep, jagged, and slightly everted. As the sore spreads in one direction, it often heals in another, leaving a whitish, leucoid, or milky scar, strikingly contrasting with the surrounding parts.

The non-exedent form of lupus is said to be most common in young scrofulous females, but, if this be the fact, my experience has failed to afford me any evidence of it. In most of the cases that have fallen under my observation, and they have been very numerous, it appeared after middle life, in both sexes, with a complexion that was either very florid at the time, or had been so shortly before the attack. My opinion is that writers often confound this affection with the effects of a syphilitic taint of the system, exhibiting itself in the form of one or more superficial, foul, obstinate ulcers, which, when their nature is properly understood, may always be made to disappear promptly under the use of iodide of potassium and bichloride of mercury.

In the *treatment* of this variety of lupus, none but the mildest and most soothing applications should be employed. The one from which I have derived most benefit is the dilute tincture of iodine, which, while it changes the action of the secernent vessels, promotes the removal of effused fluids, and serves as a protective against atmospheric and other injurious impressions. As long as the scab remains on the surface of the ulcer, it should not be disturbed; otherwise it may be covered with a piece of lint, spread with a small quantity of the ointment of nitrate of mercury, largely diluted with simple cerate. Occasionally a little powdered opium forms a valuable addition. Brushing over the part once every three or four days with a mixture of collodion and glycerin often answers a good purpose. When the ulcer is foul, and has a disposition to spread, it should occasionally be touched, very lightly, but effectually, with nitrate of silver or dilute nitric acid. All severe applications must be avoided, as they generally do immense harm.

Along with these topical remedies, special attention must be paid to the state of the general health, which is often not a little disordered. The diet should be light, simple, unirritant, and chiefly, if not exclusively, of a vegetable character, the drinks consisting of water, milk, or weak tea; the bowels and secretions should be regulated with blue mass and ipecacuanha, or blue mass and colocynth; and, if signs of debility exist, tonics should be resorted to, in combination with alterants, of which the best are quinine and iodide of iron, with a minute quantity of bichloride of mercury and arsenious acid. Of late, very favorable mention has been made of the use of the chloride of arsenic in the treatment of this affection, in doses varying from eight to fifteen drops thrice a day, and a number of cases illustrative of its beneficial effects have appeared in the medical journals. Of its efficacy, however, I can say nothing from personal experience. When the vital forces are much impaired, cod-liver oil and milk punch must be pressed into the service.

2. The other variety of lupus, the *exedent*, corroding, or devouring lupus of authors, belongs unmistakably to the class of affections known under the name of epithelioma, or cancrroid disease. It is a genuine cancerous development, generally beginning in the form of a hard tubercle, crack, or warty excrescence, and rapidly extending in different directions, both in circumference and depth, until it has occasioned the most frightful ravages, and the most dreadful and disgusting deformity. Thus, it often consumes the whole of the nose, one cheek, the entire lip, the chin, or perhaps the forehead and orbit of the eye, the ball of which may ultimately be severed from its connections and drop down into the frightful chasm below. To witness some of these cases is a truly pitiful and shocking sight. The progress of the disease is often remarkably rapid, great mischief being sometimes done in a few months; at other times its march is more slow, or the malady, after having evinced a most destructive tendency, may suddenly stop, with all the appearances of a complete cessation of hostilities. A case has been reported to me where the morbid action, after having destroyed the greater portion of one cheek with the corresponding antrum, has remained in a state of abeyance for the last ten years, although it had been steadily pursuing its course for upwards of fifteen.

The ulcer in this variety of lupus has an excavated appearance, as if it had been punched out of the parts on which it rests; its edges, however, are generally somewhat everted, or everted at one place and slightly overhanging at another, ragged, and often as if worm-eaten; the bottom is foul and covered with unhealthy granulations, or granulations and aplastic lymph; the discharge is ichorous and irritating; and the surface around is indurated, tender, and more or less discolored and œdematous. The pain is generally severe, being of a sharp, biting, darting, or shooting character, and liable to temporary exacerbations from exposure, irregularities of diet, and atmospheric vicissitudes. The general health, at first perhaps entirely sound, becomes seriously affected during the progress of the disease; the appetite and sleep are impaired; the strength declines; marasmus gradually ensues; and the patient, worn out by suffering, finally dies completely exhausted.

The great object in the *treatment* of the corroding form of lupus is to arrest the morbid action, either with the knife, or some suitable escharotic, as the acid nitrate of mercury, or the Vienna paste. In regard to the first of these measures, I have no great confidence in its efficacy as a means of preventing a recurrence of the disease, since it does not appear to be capable of exerting upon the capillaries in the neighborhood of the affected parts that alterant influence which is necessary to cause a permanent suspension of the specific action upon which the malady originally depended. In most of the cases in which I have employed the knife, the result has been anything but flattering, notwithstanding the most thorough excision and the most careful attention in regard to the after-treatment. Indeed, I have often been struck with the apparent avidity, so to speak, with which the disease returns. My opinion, therefore, is that excision, as a general rule, should give way to escharotics, either such as have been just alluded to, or, what I believe is preferable, in nearly all cases, the actual cautery. The hot iron not only

effectually destroys the diseased tissues, but it seems to create a wide spread salutary influence among the surrounding parts, eminently unfavorable to repullulation. Notwithstanding, however, all the care and precaution that may be employed both to get rid of the disease and to oppose its return, it must be confessed that our efforts are generally, in the end, unavailing, the malady usually coming back, and ultimately terminating fatally.

As long as the disease is stationary, it will be best, as a general rule, not to interfere with it in any manner; the scab, if there is any, should be let alone, or, if the surface is exposed, it should be treated with the most soothing and gentle means.

The general health must, in this as in the more simple variety, receive, throughout, proper attention; alterants and tonics will often afford essential service; and the strictest vigilance should be exercised in regard to the diet, bowels, and secretions. Arsenic, bichloride of mercury, and iodide of iron are particularly deserving of trial as constitutional remedies.

12. MELANOSIS.

Melanosis of the skin, fig. 196, is very uncommon, and probably never occurs as a primary disease, being apparently always propagated from the subcutaneous cellular substance, or from some lymphatic ganglion. It nearly always coexists with melanosis in other parts of the body, and is, therefore, merely an evidence of a general taint of the system. In a case that was under my observation, some years ago, in a man, aged fifty-eight, it involved nearly all the principal organs, and, of course, finally proved fatal. In another instance which occurred in this city, while I was a pupil of the late Dr. George McClellan, an immense number of melanotic tumors existed in the skin and cellular tissue of the abdomen, varying from the volume of a small pea up to that of a mass the size of a large almond; they were of a firm, fibro-cartilaginous consistence, slightly movable, exquisitely painful, and of a bluish-black color. The remedy, in this case, was excision, a few of the larger tumors being removed at a time; the operation was repeated every ten or twelve days, for several months, when, as but little progress had been made towards a cure, the patient became tired, and declined further interference. He finally died completely exhausted by his disease.

When melanosis is confined to the integuments, and occurs as a circumscribed tumor, the proper remedy is early and free excision; but under opposite circumstances, or, when it coexists in other parts, or is extensively diffused through the cutaneous and areolar tissues, all interference of the kind should be avoided, as likely to accelerate the fatal crisis.

13. SCIRRHUS.

Scirrhus of the cutaneous tissue is also exceedingly uncommon; it is, however, occasionally met with in various parts of the body, particularly the face, forearms, and hands. It generally begins in the form of a whitish, milky, or leucoid spot, commonly a little elevated above the surrounding level, but now and then apparently somewhat depressed, of a dense, firm consistence, more or less rough, and completely inlaid in the substance of the skin. Large vessels frequently extend across the affected parts, the redness contrasting strikingly with the whiteness of the intervening surface. Movable at first, the tumor gradually contracts adhesions, and, in time, involves the subcutaneous cellular substance. If a section

Fig. 196.

Nodule of black cancer in the true skin.

be made, it will be found to be traversed by white lines, and to yield, on pressure, a small quantity of lactescent fluid.

Although the progress of this affection is usually slow, its tendency ultimately is to disintegration and decay, the resulting ulcer having an irregular, jagged appearance, with everted edges, and a foul bottom, the discharge being of a sanious or ichorous nature. More or less pain, of a sharp, lancinating character, generally attends. As the morbid action proceeds, new leucoid spots are often superadded to those already existing; the health gradually gives way, and the patient finally dies exhausted, though commonly not until carcinomatous disease has developed itself in some of the internal organs, particularly the lungs, pleura, and liver. Occasionally the affected parts assume a true encephaloid character, and in this way a tumor of considerable size may ultimately be formed, very tender, vascular, and subject to frequent hemorrhages. Finally, the scirrhus matter sometimes exists as an infiltration, although such an occurrence is very infrequent.

Secondary scirrhus of the integuments is by no means uncommon; it is most frequently seen in carcinoma of the mammary gland and lymphatic ganglions, and generally presents itself in the form of small, hard, shot-like tubercles, firmly and immovably fixed in the substance of the skin. The number of these little bodies is sometimes very great; they are usually quite painful, seldom attain much bulk, and do not often ulcerate, the patient nearly always dying of the primary disease before this event has had time to take place.

The intimate character of these secondary formations is not well understood; in most cases, especially when of long standing, and of large size, they contain encephaloid matter and true cancer juice. Melanotic substance is sometimes interspersed through them.

Scirrhus of the integuments presents the same unrelenting character as this disease in other parts of the body; extirpation, the only resource in the early stage of the malady, holds out no prospect of permanent relief, and hence all that can generally be done is to palliate the patient's suffering.

SECT. VIII.—INSECTS IN THE SKIN AND CELLULAR TISSUE.

The skin and cellular tissue are liable to be infested by certain insects, which although not poisonous, are capable of inducing serious suffering, especially in persons of a nervous, irritable temperament. I refer more particularly to the chigoe and the Guinea worm.

The *chigoe*, which is very common both in this country, South America, and the West Indies, is a little insect, scarcely half the size of the smallest pin head, which penetrates the skin of the hands and feet, as well as of other exposed parts of the body, for the purpose of sustenance and hatching. It is a species of flea, with a rostrum as long as the body, of a pale-brownish, semi-transparent appearance, with legs of a light lead color, which often deposits its eggs in immense numbers. The first effect is an itching sensation, which is soon followed by heat, redness, and swelling, and, ultimately, by an ugly, irritable, spreading ulcer. If the part, when it has attained this stage, be carefully examined, it will be found to contain a cyst, about the size of a pea, and of a bluish color, in which the ova live and multiply with astonishing rapidity. When a number of chigoes penetrate the skin together, the suffering produced by them may be so great as to cause violent constitutional disturbance and even death.

The *treatment* consists in picking out the insect and its eggs with a fine needle, care being taken not to rupture the cyst, otherwise the young brood may produce further mischief. Clearance having been effected, the part is well washed with salt water, tobacco juice, or spirits of turpentine, and thoroughly painted with dilute tincture of iodine. The female slaves in the West Indies are said to extract these insects with great dexterity.

The Guinea worm, or little dragon, technically called *filaria medinensis*, also buries itself in the body. It is chiefly met with in hot countries, particularly in Egypt, Arabia, Persia, Abyssinia, and Guinea, the inhabitants of which are often

sorely afflicted by it. Of a white color, and of a filiform shape, it has an orbicular mouth, and a slightly pointed tail, its usual length being from five to ten inches, and its thickness that of a small violin string. Its ordinary abode is the subcutaneous cellular tissue of the feet and legs, though it is also found in other parts of the body, as the face, neck, scrotum, hands, and arms. It is commonly coiled up circularly, and is inclosed by a distinct cyst, which thus separates it from the surrounding parts. The animal enters the skin when quite young, and gradually increases in size, exciting intolerable itching, inflammation, swelling and suppuration, often attended with fever, and sometimes followed by gangrene. The precise situation of the worm is generally indicated by a sort of boil, or a hard, ridge-like elevation. When ulceration sets in, the head of the creature usually protrudes at the opening, thus confirming the diagnosis of the case.

In the *treatment* of this affection, the proper plan is to cut down at once upon the part, and extract the intruder. It is worse than useless to waste time in the application of leeches, liniments, and embrocations, which, so long as the cause of irritation lies buried under the skin, can produce none but the most transient effect. If the tumor is already open, and the head of the animal is protruding, extrusion may be promoted by gentle traction.

CHAPTER II.

DISEASES AND INJURIES OF THE MUSCLES, TENDONS, BURSES, AND APONEUROSSES.

SECT. I.—MUSCLES.

THE muscles are liable to wounds and lacerations, inflammation, atrophy, hypertrophy, and different kinds of transformations, especially the fatty, which occasionally exists in a very high degree, and over a considerable extent of the body. They are also subject to some of the carcinomatous formations, and to the development of hydatids and serous cysts.

1. *Wounds*.—When a muscle is divided by a sharp instrument, or accidentally ruptured, its fibres immediately retract so as to drag the edges of the wound more or less widely asunder. The extent to which this separation may be carried varies, in general, according to the length and thickness of the muscle, from a few lines to as many inches. In transverse fractures of the patella, the action of the straight muscle of the thigh often draws the superior fragment from three and a half to four inches away from the inferior; and it is reasonable to conclude that fully as extensive a gap would be produced between the ends of this muscle if it were cut in two, or torn asunder. In rupture of the straight muscle of the abdomen, the edges of the subcutaneous wound have repeatedly been found to be separated from an inch and a half to two inches. In the operation for the cure of strabismus, the retraction of the posterior extremity of the divided muscle is seldom less than from four to six lines, and often even considerably more.

The above facts are highly interesting in a practical point of view, inasmuch as they point out the propriety of adopting prompt and energetic measures for effecting and maintaining apposition of the ends of the divided muscle; for observation has shown that the more accurate this is the more speedy and perfect will be the cure. If the edges are brought fully and intimately together, the union will necessarily require but a small quantity of plastic matter for its early and complete consolidation. If, on the other hand, the gap amounts to several inches, either no union will occur, or it will be effected through the intervention

of a large quantity of cellulo-fibrous tissue, possessing none of the properties of muscular fibre. Hence the affected structures must always remain proportionately weak and disabled. But this is not the only inconvenience that follows such an accident; in wounds of the abdominal muscles, for example, the gap is sure to give rise to hernia, and it is easy to see that a deficiency of this kind elsewhere would hardly be productive of less serious effects.

2. *Laceration*.—Rupture of the muscles is often produced by very trifling causes, the most common of which are leaping, or jumping across ditches or over fences, lifting heavy weights, or falls from a considerable height, in which the person makes a powerful effort to ward off injury. Cases are upon record of women having lacerated the abdominal muscles during parturition. Injuries of this kind are most likely to happen, other things being equal, when a muscle has undergone the fatty degeneration, which, by rendering its fibres soft and lacerable, acts as a powerful predisposing cause of rupture. Long continued inactivity of a muscle followed by sudden and violent contraction may be mentioned as another predisposing cause of the accident.

The muscles which are most liable to rupture are the straight muscles of the abdomen, the psoas, deltoid, the two-headed flexor of the arm, the straight femoral, and gastrocnemius.

The place where the rupture usually occurs is near the junction of the fleshy fibres with their tendons; but occasionally a muscle may give way at its middle, or, in fact, at almost any portion of its extent. In twenty-one cases of this affection analyzed by Sédillot, the rupture, in thirteen, took place at the insertion of the fleshy fibres into their tendons, while in the remainder it was seated in the body of the muscle itself. The laceration is sometimes limited to a few fibres; at other times it involves the entire thickness of a muscle, or of a muscle and its aponeurotic envelop. Finally, cases occur in which a number of muscles are ruptured.

The *symptoms* attendant upon this lesion are not always well marked, especially when the affected muscle is deep seated. In general, it may be assumed that the accident has occurred, if, at the moment of some violent bodily exertion, as in leaping a ditch or fence, the individual has heard a distinct noise or snap, like the crack of a whip, feels severe pain in some particular spot, and either falls down, or has but an imperfect use of himself. Upon examining the suffering part, a vacuity will probably be noticed at one point, and an unusual prominence at another, followed by more or less discoloration and tenderness under manipulation. Occasionally the accident is attended with a rather copious hemorrhage, caused by the rupture of an artery of considerable size, as, for instance, the epigastric in laceration of the straight muscle of the abdomen. The pain which follows the injury is often very sharp, and rarely entirely disappears until after the primary effects of the lesion have measurably passed off.

Temporary lameness and inability to move about for some time are, in general, the most serious consequences to be apprehended from this accident, provided it is properly managed immediately after its occurrence. In most cases, a considerable period must necessarily elapse before the reunion of the torn structures will be sufficiently firm to justify their accustomed use. Occasionally violent symptoms have supervened upon the accident; and an instance has been reported of a young man who died from rupture of the psoas muscle, death having been preceded by severe inflammation and infiltration of pus.

The *treatment* of this lesion cannot be the same in all cases, or under all circumstances. Whenever it is practicable, from the superficial situation of the affected muscle, its ends, whether they have been cut or ruptured, should be freely exposed, and then carefully approximated by a sufficient number of stitches to hold them in contact until firm union has been established. For this purpose the threads should be carried nearly through the entire thickness of the muscle, the object being thorough apposition both of the superficial and deep portions of the wound. In case the muscle has been ruptured, the edges of the wound may be so ragged as to require some retrenching before placing them in contact, precisely as in a lacerated wound of the integuments. If the precaution of stitching

ts be neglected, the results above adverted to will be inevitable, and it is, re, impossible to insist too strongly upon the importance of attention to le, which is so much neglected by surgeons.

parts being properly approximated are next placed in an easy, elevated, lax position, splints and bandages being employed for this purpose, if ry; they are then treated upon general antiphlogistic principles. If the ed muscle is deep-seated, our chief reliance must be upon rest and relaxa- ided by soothing and astringent applications, along with suitable internal es, to moderate the resulting inflammation. In laceration of the muscles extremities, important advantage may always be obtained from the use of llers, applied in opposite directions, as the ends of the wound may thus not e more effectually approximated, but the contraction of the fleshy fibres asily controlled, than in any other manner.

Inflammation.—Inflammation of the muscles may present itself in two es of form, the acute and chronic; both, however, are uncommon, and are observed as consequences of external injury, as blows, wounds, or contu- such as we meet with in fractures and dislocations; or as effects of gout eumatism. The sheaths of the muscles very frequently, if not generally, pate in the morbid action. When the inflammation is at all severe, con- ple effusion of serum and lymph may take place, but it is seldom that the e runs into suppuration, much less mortification. The latter termination fly met with in erysipelas and carbuncle, in old worn-out subjects, and in s of different descriptions after violent external injury. It is easily recog- by the dark greenish color of the fleshy fibres, by their softness and lacera- and by their excessively fetid odor. The parts are detached in ragged , bathed in a thin, sanious, dirty, and offensive fluid.

ite inflammation of the muscles is characterized by excessive pain, of a darting character, or by dull, heavy, aching sensations, accompanied with ng of soreness, and aggravated by the slightest motion and pressure. In ases, as when the disease supervenes upon fractures or the amputation of , it is attended by a remarkable twitching or jerking, occasionally amount- real spasm, which only yields to large doses of anodynes, and hot, sooth- plications.

onic myositis is not uncommon; like the acute variety, to which it gener- ceeds, it is more frequently met with, surgically considered, as a secondary s a primary affection. When long continued, it is very prone to give , fatty degeneration, softening, ulceration, and other changes, which it is mpossible to cure.

Fatty Transformation.—Fatty degeneration of the muscles is often, if not lly, a result of chronic inflammation, especially when conjoined for any erable period with steady, persistent inactivity, or want of exercise. er inflammation, however, is always necessary to its formation is still a l question, although it is highly probable that it is. When thus affected shy fibres assume a pale yellowish, whitish, or slightly reddish color, at the ime that they are unctuous to the touch, and so much softened as to yield the most trivial force. On pressure, a clear, oily fluid exudes, which s the finger, is highly inflammable, and is composed of elain, adipocire, dinary fat, in variable proportions. These substances are not deposited, ie have conjectured, between the fleshy fibres, but form actually a portion ir constituent principles; their proper tissue being found, when examined copically, to be filled with granules, partly interposed between their striæ, rtly replacing them.

fatty transformation is most common, as well as most marked, in the s of the loins, hip, thigh, and leg of old persons affected with paralysis. likewise occasionally observed in the heart, and now and then in the mus- round unreduced luxations, large exostoses, and old, deep-seated ulcers. the change is profound and extensive, it sometimes involves the corres- g tendons and aponeuroses, which, in consequence, lose their polished, like lustre. So far as we know, this disease does not admit of cure.

of a large quantity of cellulo-fibrous tissue, possessing none of the properties of muscular fibre. Hence the affected structures must always remain proportionately weak and disabled. But this is not the only inconvenience that follows such an accident; in wounds of the abdominal muscles, for example, the gap is sure to give rise to hernia, and it is easy to see that a deficiency of this kind elsewhere would hardly be productive of less serious effects.

2. *Laceration*.—Rupture of the muscles is often produced by very trifling causes, the most common of which are leaping, or jumping across ditches or over fences, lifting heavy weights, or falls from a considerable height, in which the person makes a powerful effort to ward off injury. Cases are upon record of women having lacerated the abdominal muscles during parturition. Injuries of this kind are most likely to happen, other things being equal, when a muscle has undergone the fatty degeneration, which, by rendering its fibres soft and lacerable, acts as a powerful predisposing cause of rupture. Long continued inactivity of a muscle followed by sudden and violent contraction may be mentioned as another predisposing cause of the accident.

The muscles which are most liable to rupture are the straight muscles of the abdomen, the psoas, deltoid, the two-headed flexor of the arm, the straight femoral, and gastrocnemius.

The place where the rupture usually occurs is near the junction of the fleshy fibres with their tendons; but occasionally a muscle may give way at its middle, or, in fact, at almost any portion of its extent. In twenty-one cases of this affection analyzed by Sédillot, the rupture, in thirteen, took place at the insertion of the fleshy fibres into their tendons, while in the remainder it was seated in the body of the muscle itself. The laceration is sometimes limited to a few fibres; at other times it involves the entire thickness of a muscle, or of a muscle and its aponeurotic envelop. Finally, cases occur in which a number of muscles are ruptured.

The *symptoms* attendant upon this lesion are not always well marked, especially when the affected muscle is deep seated. In general, it may be assumed that the accident has occurred, if, at the moment of some violent bodily exertion, as in leaping a ditch or fence, the individual has heard a distinct noise or snap, like the crack of a whip, feels severe pain in some particular spot, and either falls down, or has but an imperfect use of himself. Upon examining the suffering part, a vacuity will probably be noticed at one point, and an unusual prominence at another, followed by more or less discoloration and tenderness under manipulation. Occasionally the accident is attended with a rather copious hemorrhage, caused by the rupture of an artery of considerable size, as, for instance, the epigastric in laceration of the straight muscle of the abdomen. The pain which follows the injury is often very sharp, and rarely entirely disappears until after the primary effects of the lesion have measurably passed off.

Temporary lameness and inability to move about for some time are, in general, the most serious consequences to be apprehended from this accident, provided it is properly managed immediately after its occurrence. In most cases, a considerable period must necessarily elapse before the reunion of the torn structures will be sufficiently firm to justify their accustomed use. Occasionally violent symptoms have supervened upon the accident; and an instance has been reported of a young man who died from rupture of the psoas muscle, death having been preceded by severe inflammation and infiltration of pus.

The *treatment* of this lesion cannot be the same in all cases, or under all circumstances. Whenever it is practicable, from the superficial situation of the affected muscle, its ends, whether they have been cut or ruptured, should be freely exposed, and then carefully approximated by a sufficient number of stitches to hold them in contact until firm union has been established. For this purpose the threads should be carried nearly through the entire thickness of the muscle, the object being thorough apposition both of the superficial and deep portions of the wound. In case the muscle has been ruptured, the edges of the wound may be so ragged as to require some retrenching before placing them in contact, precisely as in a lacerated wound of the integuments. If the precaution of stitching

the parts be neglected, the results above adverted to will be inevitable, and it is, therefore, impossible to insist too strongly upon the importance of attention to this rule, which is so much neglected by surgeons.

The parts being properly approximated are next placed in an easy, elevated, and relaxed position, splints and bandages being employed for this purpose, if necessary; they are then treated upon general antiphlogistic principles. If the ruptured muscle is deep-seated, our chief reliance must be upon rest and relaxation, aided by soothing and astringent applications, along with suitable internal remedies, to moderate the resulting inflammation. In laceration of the muscles of the extremities, important advantage may always be obtained from the use of two rollers, applied in opposite directions, as the ends of the wound may thus not only be more effectually approximated, but the contraction of the fleshy fibres more easily controlled, than in any other manner.

3. Inflammation.—Inflammation of the muscles may present itself in two varieties of form, the acute and chronic; both, however, are uncommon, and are chiefly observed as consequences of external injury, as blows, wounds, or contusions, such as we meet with in fractures and dislocations; or as effects of gout and rheumatism. The sheaths of the muscles very frequently, if not generally, participate in the morbid action. When the inflammation is at all severe, considerable effusion of serum and lymph may take place, but it is seldom that the disease runs into suppuration, much less mortification. The latter termination is chiefly met with in erysipelas and carbuncle, in old worn-out subjects, and in persons of different descriptions after violent external injury. It is easily recognized by the dark greenish color of the fleshy fibres, by their softness and lacerability, and by their excessively fetid odor. The parts are detached in ragged shreds, bathed in a thin, sanious, dirty, and offensive fluid.

Acute inflammation of the muscles is characterized by excessive pain, of a sharp, darting character, or by dull, heavy, aching sensations, accompanied with a feeling of soreness, and aggravated by the slightest motion and pressure. In some cases, as when the disease supervenes upon fractures or the amputation of a limb, it is attended by a remarkable twitching or jerking, occasionally amounting to real spasm, which only yields to large doses of anodynes, and hot, soothing applications.

Chronic myositis is not uncommon; like the acute variety, to which it generally succeeds, it is more frequently met with, surgically considered, as a secondary than as a primary affection. When long continued, it is very prone to give rise to fatty degeneration, softening, ulceration, and other changes, which it is often impossible to cure.

4. Fatty Transformation.—Fatty degeneration of the muscles is often, if not generally, a result of chronic inflammation, especially when conjoined for any considerable period with steady, persistent inactivity, or want of exercise. Whether inflammation, however, is always necessary to its formation is still a mooted question, although it is highly probable that it is. When thus affected the fleshy fibres assume a pale yellowish, whitish, or slightly reddish color, at the same time that they are unctuous to the touch, and so much softened as to yield under the most trivial force. On pressure, a clear, oily fluid exudes, which greases the finger, is highly inflammable, and is composed of elain, adipocire, and ordinary fat, in variable proportions. These substances are not deposited, as some have conjectured, between the fleshy fibres, but form actually a portion of their constituent principles; their proper tissue being found, when examined microscopically, to be filled with granules, partly interposed between their striæ, and partly replacing them.

The fatty transformation is most common, as well as most marked, in the muscles of the loins, hip, thigh, and leg of old persons affected with paralysis. It is likewise occasionally observed in the heart, and now and then in the muscles around unreduced luxations, large exostoses, and old, deep-seated ulcers. When the change is profound and extensive, it sometimes involves the corresponding tendons and aponeuroses, which, in consequence, lose their polished, satin-like lustre. So far as we know, this disease does not admit of cure.

5. *Ulceration*.—Ulceration of the muscles is an uncommon occurrence. It is chiefly noticed in phagedenic sores of the leg, extending successively through the integuments, cellular tissue, aponeuroses, and, finally, the muscles, which, however, generally resist its encroachments in a very remarkable degree. In some of these cases the fleshy fibres are in a complete state of fatty degeneration, of a whitish color, and so soft as to admit of being scraped away with the greatest facility. When the ulceration is slight, the restorative process usually proceeds kindly, and the breach is soon filled with healthy granulations. No special treatment is required in this disease, apart from the remedies ordinarily employed under such circumstances.

6. *Contraction*.—Another effect of inflammation of the muscles, or of the muscles and their fibrous envelops, is contraction of their fleshy fibres, leading to marked disorder of their functions, along, perhaps, with severe pain, and even great deformity, as is so often seen in wry neck, consequent upon inflammation of the sterno-cleido-mastoid and splenius muscles, and in the muscles of the thigh from the effects of hip-joint disease. In many of these cases the disease is obviously of a gouty or rheumatic character, and it then often occurs at a very early age, the immediate exciting cause being usually exposure to cold or cold and wet.

In the *treatment* of myositis attended with contraction of the affected muscles, the first object should be to ascertain, if possible, the nature of the exciting cause; as to whether it is the result of rheumatism, gout, scrofula, or syphilis, or of external injury, as a sprain, twist, blow, wound, or contusion; for upon the knowledge thus derived must necessarily depend the character of our remedies, and the chance or otherwise of a cure. I have usually received marked benefit in these cases from the use of the wine of colchicum in combination with a full dose of morphia at bedtime; aided by active purgatives and diaphoretics, especially the warm bath, a well-regulated diet, and the frequent application of Granville's lotion in union with laudanum and soap liniment, thoroughly rubbed upon the affected parts. The muscular rigidity attendant upon a syphilitic state of the system is best treated with iodide of potassium, either alone, or conjoined with mercury.

In the more subacute or chronic cases of muscular contraction, great benefit may be expected from the use of the hot and cold douches, employed twice a day, and followed, first, by dry friction, then by the application of stimulating liniments, and, finally, by thorough shampooing. Frequent motion is also generally of great service, to break up adhesions, and to promote the absorption of effused fluids, upon which the rigidity often mainly depends, as is observed in the shortened and rigid state of the limbs after severe fractures and dislocations.

7. *Atrophy*.—Atrophy of the muscles, of varying degrees, is occasionally observed; it may occur in any of the voluntary muscles, but is most common in those of the shoulder and hip, the deltoid suffering perhaps more frequently than any other. It may depend upon different causes, but generally it is produced by inflammation, palsy, or defective circulation; indeed, whatever has a tendency to impair the function of innervation, retard or diminish the supply of blood, or induce permanent inactivity in a muscle, may be considered as so many causes of the affection. Hence it is found that the lesion is usually associated with paralysis, whether proceeding indirectly from disease of the cerebro-spinal axis, or directly from injury of the nerves distributed to the suffering structures. The muscles around luxated joints, especially those of the hip and shoulder, are frequently atrophied, either simply from the want of use, or, what is more probable, the conjoint influence of inflammation and inactivity. In coxalgia, similar effects generally occur, the wasting usually involving all the muscles of the lower extremity. The fact that gout and rheumatism are frequently productive of atrophy of the muscles is familiar to every practitioner.

The extent to which the wasting of the muscles may proceed is variable. When it exists in a high degree, they may be reduced to mere membranous bands, pale, flaccid, and almost devoid of irritability; in some rare instances their fleshy fibres are completely absorbed, a dense cellular substance being all

that is left in their place ; or, instead of this, they are found to be softened and transformed into fatty matter.

In the *treatment* of atrophy of the muscles the first object should be to ascertain, if possible, the nature of the exciting cause, by removing which the lesion sometimes rapidly disappears of its own accord, or, at all events, under very simple management. Atrophy dependent upon imperfect supply of blood is often irremediable, and the same is frequently the case when it is caused by gout and rheumatism, or when it is conjoined with the fatty degeneration. The treatment of atrophy dependent upon loss of innervation, constituting what is called wasting palsy, will receive special attention in the chapter on the diseases and injuries of the nerves, where its consideration properly belongs.

Whatever the cause of atrophy of the muscles may be, much may be done, after that has been removed, towards effecting restoration by the steady and persistent use of the hot and cold douches, stimulating embrocations, dry frictions, and regular, systematic exercise of the affected structures, educating them, so to speak, and thus gradually qualifying them, for the resumption of their appropriate functions.

8. *Tumors*.—Various morbid growths occur in and among the muscles, the principal of which are the hydatid, cystic, fibroid, erectile, melanotic, and encephaloid.

a. It is uncommon to meet with *hydatids* in the muscles, and I have myself seen only one case. The patient, a laboring man, aged twenty-five years, had accidentally discovered a swelling in the substance of the right deltoid muscle six months previously, when it was hardly as large as a hazelnut. At the time of my examination, it was of the volume of an almond with its shell, of a rounded, elongated shape, a little movable, and of a firm, fibrous consistence, with a slight degree of elasticity. Within the last few weeks the tumor had become somewhat painful, especially after exercise, and the pressure made in examining it was productive of considerable uneasiness. The skin over it was perfectly healthy.

The diagnosis of the tumor could not, of course, be determined beforehand ; what it resembled most, especially in point of consistence, was an enlarged lymphatic ganglion, but the rarity of such a disease in this situation invalidated this conclusion, and left me in complete doubt as to the true nature of the case. It was too deep-seated for a sebaceous tumor, and it possessed none of the external characters of a fibrous, fibro-plastic, or fatty one.

Fig. 197.

Hydatid.

During the excision, the knife was carried perpendicularly down over the tumor, in doing which, the point penetrated its interior, an occurrence which was instantly followed by the escape of a small quantity of thin pus, inducing me to think that the tumor, after all, was merely a diseased lymphatic ganglion. On continuing the dissection, however, I soon found that there was a distinct cyst, which, being collapsed, was separated with some difficulty from the fibres of the deltoid muscle, in which it was imbedded. The operation being completed, a small body, fig. 197, was picked up on the floor, which, on inspection, proved to be a globular hydatid, not more than six lines in diameter, and furnished with a distinct sucker. The cyst was very soft and thin, smooth internally, and filamentous externally.

b. Tumors of a *cystic* character are occasionally met with in and among the muscles. In a case of this kind, which I had an opportunity of seeing in 1856, with Dr. Da Costa, the growth, occupying the upper and outer portion of the thigh, was nearly of the volume of an adult head. The patient was a female, aged fifty-eight, who had fallen down a flight of stairs, in which she struck the limb severely, causing deep ecchymosis and great difficulty in walking. At the end of two months a swelling formed, which, gradually increasing, in less than a year acquired the size above mentioned, being at the same time the seat of severe darting pain, with considerable discoloration of the integuments. The tumor fluctuated indistinctly, and a puncture with the exploring needle gave vent merely

to a few drops of fatty fluid. When removed by Dr. Brinton, it was found to be composed of a very thick, dense, fibrous cyst, filled with a sero-oleaginous liquid. The patient gradually recovered from the effects of the operation, but was troubled for a long time afterwards with pain in the limb and difficulty in walking.

Cysts in the voluntary muscle are sometimes occupied by blood. A case has been reported in which a tumor of this kind, situated in the gastrocnemius, in a man, aged thirty-three, contained half a pint of this substance.

c. Tumors of a *fibroid*, fibro-plastic, and fibro-cartilaginous structure, have been found in different voluntary muscles, especially in those of the chest, shoulder, arm, and thigh; they are generally of small size, slow in growth, and of firm consistence, with a tendency, now and then, to recurrence after excision.

d. *Osseous* tumors are uncommon in the voluntary muscles. Mr. W. F. Teevan, in a monograph on morbid growths in this situation, has been able to find only three cases of the kind.

e. Tumors of an *erectile* character have been seen in the sterno-mastoid, semi-membranous, external oblique, long supinator, and semi-tendinous muscles.

f. *Melanosis* sometimes occurs in the muscles, either as an infiltration, or as a distinct tumor, with or without a cyst, of an irregularly spherical shape, firm in consistence, and from the volume of a pea up to that of a foetal head. The morbid product, which generally coexists with similar formations in other parts of the body, is occasionally directly chargeable to external injury, although usually it takes place without any assignable cause.

g. *Encephaloid*, scirrhus, and colloid of the muscles are very uncommon. They obey the same law here as in other parts of the body. In the interesting case of colloid described by Professor J. C. Warren, an immense number of tumors of this kind, varying in size from a pea to that of a small granule, hardly visible to the naked eye, existed in the voluntary muscles, in different regions, especially in those of the thigh and leg.

The probability is that none of these heteroclite formations are developed in the muscular substance, properly so-called, but that they begin in the interfibrillar tissue, from which, as they increase in size, they gradually encroach upon the fleshy fibres, which they thus displace, alter, and finally destroy.

SECT. II.—TENDONS.

The tendons, like the muscles, are liable to wounds and lacerations, but, unlike them, they never suffer from malignant formations, excepting secondarily, and then only very rarely. Inflammation of these structures is also very infrequent.

1. *Wounds*.—Tendons, when divided subcutaneously, readily unite through the intervention of plastic matter, without the occurrence of any considerable degree of inflammation. Indeed, the idea is very common at the present day that such wounds are always repaired without inflammation, it being alleged that this process, instead of being necessary for this purpose, is a positive detriment. I cannot subscribe to such a doctrine. If its advocates mean that the inflammation is very slight, or not characterized by the ordinary phenomena, I perfectly agree with them; but if they wish to be understood as affirming that inflammation is entirely absent throughout, from the beginning to the close of the case, it is what I cannot believe, and what is certainly not true.

When a tendon, such, for example, as that of the heel, is cut across subcutaneously, the first thing that is noticed is the retraction of the divided ends, so as to leave a distinct gap between them, often amounting to from an inch and a half to two inches, according to the size of the cord and its previous tension, or the degree of force employed in stretching the parts with which it is connected. Inflammation, generally of a very slight form, next takes place, and, soon after this is established, plastic matter is poured out, filling up the space between the two extremities of the tendon, which, at the same time, it serves to connect together. As the abnormal action subsides, nucleated cells form in the interior of the effused

matter, and the process of organization thus begun steadily advancing, the new substance is gradually converted into cellulo-fibrous tissue, and this, in turn, at length into tendinous, which, however, although well calculated to fulfil the purpose for which it is intended, is, like all new tissues, a very imperfect type of the original. The reproductive process generally advances very rapidly, so much so that the person soon acquires an excellent use of the affected parts. It is upon a knowledge of this property in tendon, when subcutaneously divided, to speedy reunion, that is founded the operation of tenotomy, one of the greatest improvements in modern surgery.

When a tendon is divided in an open wound, the two ends rarely reunite at all, owing mainly to two circumstances: the first is, that the ends retract too far to enable us to bring them properly together, and the second, that the wound nearly always suppurates; an occurrence eminently inimical to adhesive action. All the earlier operations of tenotomy that were performed according to this principle, failed in consequence of the violence of the resulting inflammation.

The *treatment* of a divided tendon, then, with an open wound, is very different from that where the wound is subcutaneous. In the latter, the application of a bit of adhesive plaster to the puncture to exclude the entrance of the air, and a little attention to rest and position, make up the whole sum of the surgeon's duty. In the former, on the contrary, the cut ends must be carefully approximated by the silver wire suture, the rest of the wound being firmly closed; or the limb with which the tendon is connected must be placed in the most thoroughly relaxed position possible, in order to approximate its extremities, and thus afford them an opportunity of reuniting, an occurrence, however, which, I am sure, will rarely take place under any circumstances, however propitious. The experiments of Dr. Levert, of Mobile, performed many years ago, prove that union between the divided ends of a tendon will be much more likely to proceed kindly and satisfactorily, when the parts are held in contact by a metallic suture than by an ordinary one. My opinion is that practitioners have not profited enough by the results of these researches. The recent introduction of silver wire, by Dr. Sims, into our surgical armamentarium, will, no doubt, tend to re-excite attention to them.

The surgeon is sometimes consulted on account of an ununited tendon, with an intervening gap, perhaps, long after the external wound has healed. Under such circumstances, it has been proposed to puncture the retracted extremities subcutaneously, and it has been alleged that such a procedure is not only safe, but generally quite successful. Safe it undoubtedly is, but, as to its being successful, that is simply impossible, unless, what seldom happens, the two ends remain in close proximity with each other. The proper remedy is to expose the parts by a free incision, and, having pared the retracted extremities, to unite them with silver wire.

2. *Rupture*.—Tendons are sometimes torn away from their sheaths along with the fleshy fibres into which they are inserted, hanging, perhaps, merely by one extremity; when this is the case, it would be useless to replace them, even if this were practicable, as there would be no likelihood whatever of reunion; on the contrary, severe inflammation and sloughing would be inevitable.

When a tendon is ruptured subcutaneously, a loud snap, like the crack of a whip, is generally heard at the moment of the accident, especially if the cord is a large one; the part is instantly deprived of its functions, and a well-marked gap, interval, or hollow is perceptible at the site of the injury. More or less inflammation follows, and a long time usually elapses before the patient regains the use of the affected limb. The tendon which is most liable to suffer in this way is that of the heel, its rupture being generally caused by violent muscular exertion, either for some special effect, as in the case of persons on the stage, or for the purpose of saving the body from a fall, as when the individual makes a false step.

The treatment of a subcutaneously ruptured tendon must be conducted by rest and complete relaxation of the affected structures, so as to enable us to bring the divided ends as closely together as possible. To effect this to the best advantage,

velopment, and were evidently merely so many masses of lymph, which had been originally attached to the inner surface of the sac, but had become separated in consequence of the continual friction of the tendon to which the sac was connected.

The volume of the cyst varies from that of a pea to that of a pigeon's egg; it is of a globular or ovoidal shape, somewhat elastic, perfectly movable, free from pain, and unaccompanied by any discoloration of the skin. A sense of stiffness and of uneasiness, felt chiefly along the course of the tendon on which it is situated, sometimes attends its formation, and induces the patient to apply for advice. I have never known a ganglion to suppurate.

The tumor is most common in the female, and is met with chiefly along the extensor tendons on the back of the hand, wrist, and lower extremity of the forearm. I recollect seeing, some years ago, a case where it was situated over the radial artery, the pulsations of which were so thoroughly imparted to it as to induce the belief, on the part of several physicians who examined it, that it was an aneurism of that vessel. In 1854, I operated upon a young woman who had two tumors of this kind, each of the size of a small bird's egg, upon the dorsal surface of the foot. The affection sometimes appears at an early age. I have met with it in a child only eight years old.

How this cyst is formed is still a mooted point. From what I have seen of it, I am inclined to regard it merely as a sacculated expansion of the sheath of the tendons, and not, as some pathologists do, as a new formation. From the fact that it is most common in hard working people, it, doubtless, owes its origin to inflammation, although it is seldom directly chargeable to external violence.

The most simple and certain method of treatment consists in rupturing the ganglion, and scattering its contents into the surrounding cellular substance, where they are speedily absorbed. I usually perform the operation with my two thumbs, but, if the cyst is old and very firm, it will be necessary to strike it with a book, or to pierce it previously by a subcutaneous puncture. Evacuation having been effected, a compress inclosing a piece of coin is tied upon the part, to promote the adhesion and obliteration of its cavity, the limb being maintained at rest until the resulting inflammation has subsided. When the ganglion is quite young, relief may occasionally be afforded by the application of iodine and systematic compression; ordinarily, however, such means are quite futile. Iodine is sometimes advantageously employed as an injection, in the same manner as in hydrocele. When the ordinary means fail, my practice is to cut up the sac as minutely as possible with a delicate bistoury, inserted subcutaneously, and then to keep up steady compression until obliterative inflammation has taken place. Both excision and direct incision must be avoided, as likely to endanger the functions of the part.

SECT. III.—SYNOVIAL BURSÆ.

The synovial bursæ, *bursæ mucosæ*, or mucous pouches, exist in considerable numbers in various regions of the body, especially about the joints of the extremities, being small, semi-transparent sacs, occupied by a thin, unctuous fluid. They are for the most part interposed between bone and tendon, tendon and tendon, bone and skin, or tendon and skin, their object being to facilitate motion and ward off pressure. Hence, they are always most conspicuous in those situations which are habitually subjected to friction; and for the same reason they are occasionally developed to meet special contingencies arising from accidental causes, as the pressure of a shoe, crutch, or artificial leg. In club-foot synovial pouches are constantly formed upon those parts of the foot which, being partially displaced, are compelled to sustain the weight of the body. Altogether there are about one hundred and fifty of these sacs in the natural state.

The largest and most important synovial pouches, surgically considered, are situated on the acromion process of the scapula, the space between the hyoid

bone and thyroid cartilage, the condyles of the humerus, the olecranon process, the styloid projections of the ulna and radius, the tuberosity of the ischium, the great trochanter, the anterior superior spine of the ilium, the front of the patella, the condyles of the femur, the tuberosity of the tibia, the ankle, the calcaneum, and the heads of the first and fifth metatarsal bones.

The principal diseases of the bursae are inflammation, suppuration, induration and thickening, dropsical accumulations, and the development of fibro-cartilaginous concretions in their interior. It does not seem probable that they are ever the seat of any of the heteroclite formations; at all events, I have never met with any examples of them.

Inflammation of these sacs may occur either in an acute or a chronic form, the latter being, however, by far the more frequent. The usual cause is inordinate and long-continued friction conjoined with pressure. The disease may also be produced by blows, contusions, wounds, and punctures, and, in persons predisposed to gout, rheumatism, scrofula, and syphilis, by exposure to cold, or the sudden repulsion of the cutaneous perspiration. The housemaid's knee, and the collier's elbow, are examples of inflamed and enlarged bursae produced under the influence of concentrated and protracted pressure; another instance, not less striking, is afforded by the bunion which so frequently forms over the inner surface of the metatarso-phalangeal articulation of the big toe.

1. *Acute inflammation* of the bursae is generally productive of very severe suffering; the pain is tensive, throbbing, persistent, and greatly aggravated by motion, pressure, and dependency; the swelling, which is often considerable, is usually due partly to exterior deposits, partly to an accumulation of synovial fluid, the quantity of which is commonly very much increased; the skin is of a dusky reddish color, and deeply congested; and the functions of the affected structures are greatly impaired, if not completely arrested. Not unfrequently the swelling is of an œdematous or erysipelatous character, pitting readily under pressure, and being the seat of a dull, heavy, prickling sensation. In the more severe forms of acute bursitis, there is usually considerable constitutional involvement, the patient being feverish, thirsty, restless, and troubled with headache, loss of appetite and other disagreeable symptoms.

Upon cutting into the affected sac, its inner surface is found to be deeply congested, and roughened with lymph, while its cavity is filled with a bloody, serous, or sero-oleaginous fluid, often in considerable quantity, especially if the disease has been of some standing.

Bursitis occasionally passes into *suppuration*, the symptoms, when this is about to occur, suddenly assuming a more severe form, precisely as when matter is about to be deposited in any other part of the body. The pus, which is usually of a thin, oleaginous character, intermixed with flakes of lymph, may find its way to the surface by ulcerative action, or it may discharge itself into a neighboring joint, although such an event is extremely rare, and is not likely to occur unless the joint has freely participated in the inflammation.

The *treatment* of this disease must be actively antiphlogistic; the part and system are kept perfectly at rest; leeches are applied to the affected surface, followed by anodyne and saturnine fomentations; the bowels, diet, and secretions are duly attended to; and the pain, which is generally severe, is controlled by morphia, or morphia, antimony, and aconite. If matter form, as denoted by an increase of pain and other symptoms, a free and early incision is made, the edges of the opening being kept asunder by a small tent to prevent reaccumulation. The milder forms of bursitis are generally easily combated by rest, cooling laxatives, and the application of tincture of iodine, or, what is frequently preferable, a blister, large enough to extend over the affected surface, and retained sufficiently long to produce thorough vesication.

2. *Chronic inflammation* of the bursae occasionally gives rise to remarkable structural changes, the most common of which is an indurated and hypertrophied condition, the result either of long-continued interstitial deposits, or of the formation of adventitious membranes. However this may be, the walls of the

affected sac are sometimes found to be upwards of a quarter of an inch in thickness, and of a dense fibro-cellular consistence, without the slightest trace of its primitive characters. Under these circumstances, the cavity of the pouch is generally very small, filled with altered synovial fluid, and roughened upon its surface, so as to exhibit an appearance not unlike that of a honeycomb. Now and then shreds of lymph are stretched across its interior, dividing it into different compartments. In cases of very long standing, partial ossification of the cyst has been noticed, but such an occurrence is extremely uncommon.

These chronic enlargements of the bursae are often very obstinate and troublesome, resisting not unfrequently the best directed efforts of the surgeon for their removal. The remedies upon which our chief reliance is to be placed are sorbefacient applications, as iodine and hydrochlorate of ammonia, blisters, mercurial inunctions, and systematic compression. When these means fail, and the tumor is productive of pain and other inconvenience, our only resource is thorough excision, care being taken, especially if a large joint is close by, not to cut too widely away from the morbid mass, lest the synovial membrane of the articulation be inadvertently pierced, or so much injured as to excite violent inflammation.

3. Another result of chronic inflammation of these bodies is an accumulation of their natural secretions, giving rise to what is called *dropsy*, of which one of the best examples is afforded in the so-termed housemaid's knee. The fluid, which varies in quantity from a few drachms to six or eight ounces, according to the size and situation of the affected burse, and the duration of the disease, is generally of a pale straw color, of a slightly unctuous consistence, and of a notably saline taste; now and then it is reddish, or brownish, and remarkably thick and viscid. It is readily coagulable by heat, alcohol, and acids, showing that it is essentially composed of albumen. The presence of the fluid is easily detected by the elastic and fluctuating character of the swelling, and very frequently a distinct friction sound and sensation can be perceived upon handling the tumor: if necessary, an exploring needle is used. The integuments are free from discoloration, there is no enlargement of the subcutaneous veins, and the principal inconvenience experienced by the patient is of a mechanical nature. Now and then there is a good deal of pain, but more generally simply a sense of soreness and stiffness.

The size and shape of the tumor formed by these dropsical collections are subject to great diversity; in general, it does not exceed the volume of an orange, or a goose's egg, but there are cases in which it reaches the bulk of a foetal head, although this is very uncommon. Its shape is generally irregularly rounded or ovoidal, with a compressed, flattened appearance.

Dropsy of the synovial pouches may often be relieved, in its earlier stages, by the diligent application of iodine, astringent and sorbefacient lotions, and, above all, by blisters, conjoined with rest, attention to the bowels, and the use of the bandage. In cases of long standing, however, such treatment is seldom of any permanent advantage, nothing short of a complete and radical change in the action of the secernent vessels answering the purpose. With this view, the water being drawn off with a trocar, the same remedies may be adopted as in the treatment of hydrocele, that is, injections of stimulating fluids, as tincture of iodine, nitrate of silver, or iodide of iron; or, what I deem better, because more certain, the introduction of a small seton, retained for a period varying from three to six days, according to the amount of the resulting inflammation. In either case, the part is carefully kept at rest, and every precaution used to prevent undue morbid action. When the tumor has become solidified and nearly of its original size, it is an evidence that the seton should be withdrawn. From three to six weeks will usually elapse before a complete cure is effected.

The operation by incision is sometimes practised in these dropsical accumulations; but as it is not only severe, but liable to be followed by violent inflammation, sometimes seriously implicating a neighboring joint, it ought, in my judgment, to be abandoned.

4. Intermixed with the fluid above described, or occurring by themselves, there

are occasionally *loose concretions*, of a dense fibrous, fibro-cartilaginous, or cartilaginous consistence, which, from the peculiarity of their appearance, and the troublesome symptoms they occasion, have always been a source of interest with practitioners. They are generally of a light yellowish color, and of a flat oval form, not unlike small melon seeds. Their number is sometimes very remarkable, upwards of fifty having been extracted from a single pouch. The adjoining sketch, fig. 199, affords a good idea of the appearances of these bodies, as they are exposed on dissection, and also of the changes which the bursæ has undergone in consequence of their presence. When existing in considerable numbers, a careful examination will rarely fail to detect their true character. The symptoms which they occasion are such as usually attend chronic bursitis.

Fig. 199.

Fibroid bodies of a synovial bursa.

How are these bodies formed? Two theories have been advanced upon the subject. According to one, they consist essentially of plastic matter, originally poured out in soft amorphous granules or flakes, which, increasing in size and density, are gradually moulded into a determined shape by the pressure of the surrounding parts, as well as by the friction which they exert upon each other as they are pushed about from place to place in their confined situation. The other explanation is that they are originally connected to the inner surface of the sac, from which they receive temporary support and nourishment; but, finally becoming detached, in consequence of the constant friction to which they are subjected, they present themselves as loose bodies, of the shape and consistence here assigned to them. To my mind, this explanation is the more correct of the two; it is certainly favored by the results of dissection, in which we not unfrequently see some of these bodies still firmly adherent to the inner surface of the affected pouch, and by the analogy which exists between them and the concretions met with in some of the movable joints, which, there is reason to believe, are always formed in this manner.

The only way to get rid of these bodies is to effect their extrusion by free incision, a tent being afterwards placed in the bottom of the sac, to promote its obliteration.

Bodies, closely resembling small *hydatids*, have occasionally been found in these pouches. J. Cloquet met with an instance in which there were upwards of one hundred and forty, varying in size from one to three lines in diameter, nearly transparent, and of a lenticular shape. They were situated in a large bursa, between the great trochanter and the tendon of the great gluteal muscle.

SECT. IV.—APONEUROSSES.

The aponeuroses, considered by themselves, offer very little of interest in a surgical point of view, since their diseases are not only infrequent, but very imperfectly understood. From the intimate relations which they sustain, on the one hand, to the muscles, and, on the other, to the areolar tissue, it is obvious that there can be but few diseases or injuries, of a serious character, of these structures, without more or less mutual involvement. At the same time, it is evident that the aponeuroses, from their peculiar arrangement, must necessarily,

in many cases, play a very important part in preventing the extension of morbid action to the muscles which they serve to inclose, just as the periosteum impedes the propagation of disease to bone, and, conversely, from bone to the surrounding textures. This barrier, of course, is often broken in both cases, and then the ravages of the morbid action will be likely to be both rapid and extensive, as we see exemplified in the worst forms of erysipelas, carbuncle, and other affections, in which every variety of structure is rudely and indiscriminately assailed by inflammation, not unfrequently terminating, in a few days, in the destruction of an entire limb.

Acute inflammation of the aponeuroses is an uncommon occurrence, and is chiefly observed as a consequence of external injury, or as an effect of erysipelas, carbuncle, and whitlow. It is generally believed that gout and rheumatism are exclusively seated in the fibrous envelops of the muscles, but the probability is that the tendinous, ligamentous, and bursal structures are nearly always implicated along with them, the two diseases sometimes beginning in the former, and sometimes in the latter, but usually ultimately attacking the whole of them.

A bad form of inflammation of the aponeuroses is occasionally produced by punctured wounds, especially when occurring in the palm of the hand and sole of the foot, in persons of broken constitution, dissipated habits, or nervous temperament. The disease soon assumes an erysipelatous disposition, and leads to excessive suffering, both local and constitutional; occasionally it is followed by tetanus.

Inflammation of the aponeuroses manifests but little disposition to pass into suppuration, ulceration, or gangrene.

Chronic inflammation of these membranes is much more common than the acute, and leads to various alterations of structure, as thickening, atrophy, induration and contraction, often followed by serious, if not irremediable, deformity. Sometimes we find them affected with slight ossification, the new substance presenting itself in the form of bony spicules; and cases are met with where, from long-continued pressure, they are remarkably attenuated, and pierced with numerous apertures, giving them a sieve-like appearance.

I am not aware that the aponeuroses are ever the seat of any of the heteroclitiformations; dissection, however, has shown that they are occasionally affected by them secondarily.

The *treatment* of aponeurosis must be conducted upon ordinary antiphlogistic principles. Anodynes must be exhibited in full and repeated doses to relieve pain and nervous symptoms; if plethora exists, and the local action is severe, blood must be taken from the arm and by leeches from the affected parts; the bowels must be freely moved; and recourse must be had to the saline and antimonial mixture. Free incisions are made if much tension is present, or the formation of matter is threatened; followed by medicated fomentations and emollient poultices.

Aponeurosis dependent upon a gouty, rheumatic, or syphilitic state of the system, must be managed according to the general principles of treatment laid down for the relief of these affections; by colchicum, iodide of potassium, and mercury, in combination with other suitable means.

CHAPTER III.

DISEASES AND INJURIES OF THE NERVES.

SECT. I.—WOUNDS AND CONTUSIONS.

NERVES, when divided, readily unite by plastic matter, which, being effused between and around the severed ends, is gradually solidified, and transformed into an analogous tissue, capable of transmitting the nervous current, although it does not contain any real nerve-substance. In order, however, that the connection shall be satisfactory, the interval between the two extremities must be very short, otherwise the plasma will fail to effect the object, and each end will become expanded into a bulbous mass, having all the characteristics of a neuro-matous tumor, similar to that which occasionally forms in the stump after amputation, and liable, like it, to become the seat of neuralgia. It is worthy of notice that a nerve, slowly divided with a ligature, will generally unite more rapidly and completely than one divided with a sharp knife; in the former case there is commonly very little retraction of the ends, whereas, in the latter, they sometimes separate to a considerable distance, thus requiring a larger quantity of lymph to fill up the gap.

When a nerve is cut completely across, the parts to which it is distributed are necessarily deprived of their functions, an occurrence which, consequently, serves as a diagnostic sign of the accident. Thus, if the nerve is one of motion, the parts will be paralyzed, while, if it is one of sensation, they will be divested of sensibility. If the division be only partial, the loss of function will, of course, be partial also. In general, the structures beyond the seat of injury feel numb and heavy, with a sense of tingling, prickling, stinging, or burning.

Wounds of the nerves must be treated upon general principles. When there is no serious loss of substance, the divided ends should be as closely approximated as possible by attention to position, and by suture of the neurilemma, introduced with a very fine needle. The suture will be particularly serviceable when a large trunk has been severed, or when there is inordinate tendency to separation in the ends of the cord. The operation is very simple, and, if carefully performed, almost free from pain.

A similar procedure may be adopted when a large nerve has been severed, but has failed to unite. An incision being made down to the nerve, the two ends are carefully retrenched, and then tacked together by several points of suture, apposition being favored by attention to the position of the parts.

Nerves, when *punctured*, pricked, or partially divided, usually occasion severe pain, of a neuralgic character, extending up and down the affected parts, and attended with muscular weakness, perverted sensation, convulsive movements, and derangement of the general health. Such effects not unfrequently follow venesection at the bend of the arm, from injury sustained by one of the subcutaneous nerves. The proper remedy is complete division of the affected filament, either subcutaneously, or, when this is impracticable, by free incision. The operation, however, is not always permanently successful, owing to the deep impression which the lesion has made upon the general system. Besides, the divided extremities of the nerve are very apt to take on diseased action, either by being incorporated in the original cicatrice, or by being expanded into a species of neuroma. When this is the case, the proper procedure will be free excision instead of subcutaneous section.

Severe effects often follow *contusion* of the nerves, the parts to which they are distributed becoming numb, cold, withered, more or less painful, and, ultimately, almost entirely useless. Effects of this kind sometimes succeed to accidents of, apparently, the most trifling character. The nerves, so far as we can form an opinion without the light of dissection, soon become inflamed, and are often irretrievably ruined, being effectually and permanently disqualified for the performance of their functions. It is hardly probable that these effects are due, as has been conjectured, to mere concussion of the nerve-substance; if this were so, they would be much more transient, as well as less severe. What corroborates the idea that inflammation is deeply concerned in the production of the secondary suffering is the fact that the parts, although seriously crippled at the start, do not evince much derangement until the disease is established in all its intensity.

Professor Willard Parker has very ably described what he calls *concussion* of the nerves. He considers the accident as similar to concussion of the brain, the nerves receiving a shock eventuating in a sudden suspension of their functions. In a paper upon the subject, in the *New York Journal of Medicine* for September, 1856, he has related six cases illustrative of the nature of the injury. When the paralysis, which is generally temporary, subsides, the affected nerves are in danger of being assailed by inflammation, which, if it cannot be prevented, must be treated in the usual antiphlogistic manner. A long time frequently elapses before recovery takes place, the nerves remaining weak, irritable, and incapable of performing their proper functions. The limb supplied by the affected cords is soon exhausted by exercise, and is the seat of a dull, aching, tired sensation, which is always aggravated by exertion, especially if carried beyond a given limit; in time, it becomes cold, atrophied, and, in great degree, useless. The general health also suffers, though the disease never proves fatal.

The treatment, in the first instance, is rest, absolute and unconditional; and, after the nerves have recovered from the immediate effects of the injury, passive exercise, dry friction, and attention to the general health, which, in the more severe forms of the accident, is always materially, if not seriously, impaired.

Severe pain is often produced by *compression* of the nerves, without, so far as can be determined, any particular disease of the nerves themselves. In aneurism, for example, of the larger arteries the patient often experiences extreme suffering from this cause. The pain, in this case, is either sharp and darting, as in certain forms of neuralgia, or of a burning, tearing, boring, or gnawing character, especially if there is at the same time erosion of the osseous and cartilaginous tissues.

Finally, the nerves are occasionally the seat of *foreign bodies*, introduced during the infliction of wounds, which they thus serve to complicate. Various kinds of substances may be thus carried in, as portions of clothing, pieces of wood, glass, porcelain, or iron, and fragments of bone. Denmark has related a case in which part of a bullet was imbedded in the radial nerve; and Dupuytren met with one in which the end of a lash was buried in the ulnar nerve.

The immediate effects of such accidents are violent pain, spasmodic contraction of the muscles, loss of appetite and sleep, and great disorder of the health. Tetanus and neuralgia are also sufficiently common. The slightest motion and pressure always aggravate the local suffering.

The only remedy is removal of the foreign body, the presence of which is generally indicated by the seat of the pain. Sometimes the substance may be distinctly felt with the finger. When the suffering persists, it may be necessary to excise a portion of the affected nerve.

SEC. II.—TETANUS.

The term tetanus is a generic one, employed to denote a peculiar affection of the nerves, characterized by violent contraction of the voluntary muscles, with irregular intervals of partial, though seldom of complete, relaxation. Different names have been devised to designate the disease, according to the nature of the

predominant local symptoms occasioned by the affected muscles. Thus, when the muscles of the lower jaw are spasmodically contracted, so as to prevent the patient from opening his mouth, the word *trismus* is employed, or, to use a common expression, the person is said to have locked jaw. When the body is bent forcibly forwards by the action of the abdominal muscles, the affection is denominated *emprostotonos*, and *opisthotonos* when it is drawn backwards by the dorsal muscles. The term *pleurothotonos* is used when the body is drawn to one side. A distinction of much greater importance is that of tetanus into traumatic and idiopathic, acute and chronic. The disease occasionally comes on within a few days after birth, and is then designated as infantile tetanus, the *trismus nascentium* of authors.

In this country, especially in its more temperate latitudes, the surgeon has to deal chiefly with traumatic tetanus, the idiopathic variety being extremely infrequent. Cases of it, however, occasionally occur in the more tropical States of the Union, especially in South Carolina, Georgia, Mississippi, Florida, Louisiana, and Texas; while in the West and East Indies it is sufficiently common. The tetanus of new-born infants is met with chiefly in the southern and southwestern States of North America, in consequence, apparently, of injury sustained in the ligation of the umbilical cord. Infantile tetanus seems to be very common in certain portions of Europe. Thus, it is asserted by Dr. Joseph Clark, that, in the year 1782, of 17,550 children born in the Lying-in Hospital of Dublin, 2,944 perished from this cause alone within the first fortnight after birth.

Traumatic tetanus, to which the ensuing remarks are more particularly intended to apply, is not peculiar to any age, to either sex, or to any particular pursuit; on the contrary, it is met with at all periods of life, in females as well as in males, and in all classes of society, from the most refined and affluent to the most filthy and impoverished. It has been ascertained, however, that the young suffer more frequently than the aged, and that it is particularly liable to occur in persons of a nervous, irritable temperament. Ill health, especially disorder of the digestive apparatus, grief, anxiety of mind, and, in short, whatever has a tendency to depress the energies of the system, powerfully predispose to its development. It is generally stated that men are more prone to traumatic tetanus than women, and the statistics that have been published on the subject would, at first sight, seem to warrant such a conclusion; it will be found, however, upon more careful inquiry, that the difference is only apparent, not real, and that it is dependent upon the fact that females are much less obnoxious to the various exciting causes of the disease than the other sex. Blacks and mulattoes are more liable to tetanus than whites. In some portions of the West Indies the disease is almost exclusively confined to the colored population.

Traumatic tetanus occasionally assumes an *epidemic tendency*. In 1858, numerous cases of the disease appeared in rapid succession in several of the London hospitals, the attack having often followed upon the most trifling injuries and operations, as the ligation of a hemorrhoidal tumor or the amputation of a finger. In one of the institutions not less than nine deaths occurred from this disease within two months.

Causes.—The causes of traumatic tetanus are, as the term implies, various kinds of external injury, as punctured, lacerated, contused, and gunshot wounds, burns, scalds, abrasions, compound fractures and dislocations, and surgical operations, as amputations and the excision of tumors. A number of cases have been recorded where tetanus was produced by salivation. Some of the most trivial accidents are, at times, sufficient to produce the disease. Thus, cases have been observed where it followed the application of the scarificator in cupping, the introduction of a seton, and the extraction of a tooth. Baron Larrey mentions an instance in which it was occasioned by the lodgment of a fish-bone in the fauces. Examples of tetanus, consequent upon the ligation of the iliac, femoral, and carotid arteries, have been recorded by Brodie, Dazille, and Dudley. Many years ago, I met with a case from the injection of a hydrocele; now and then the disease follows upon parturition. The fact is, in persons of a nervous, irritable temperament, any injury, however trifling, may readily induce the affection, espe-

cially in hot and damp states of the atmosphere, or during sudden transitions from heat to cold. Exposure to cold draughts, by which the body is suddenly chilled, is, under such circumstances, extremely liable to provoke an attack.

The effect of cold air, when permitted to play directly upon the body, is well illustrated by what occurred after the battle of Ticonderoga, in 1758. The wounded were exposed the whole night after the action, in open boats upon Lake George, and the consequence was that nine of them died of locked jaw. During our war with Great Britain, most of those wounded by fire-arms on board the frigate *Amazon*, before Charleston, were attacked with tetanus on the fourteenth day, from a sudden change of very wet and cold weather following a long drought. Wounded soldiers, lying on damp or wet ground, are particularly prone to attacks of this disease. Thus, after the battle of Bautzen, where the men were left all night on the field exposed to severe cold, more than 100 were seized with tetanus; and similar effects were witnessed after the engagement at Dresden, from the suffering induced by the sudden transition from a hot to a cold, chilly atmosphere.

The injury inducing the disease may be situated upon any part of the body. It was at one time supposed that lesions of the head and face were singularly exempt from tetanus, but more enlarged experience has demonstrated that, although it does not occur with the same relative frequency as when the cause is seated in other regions, yet its invasion after such accidents is by no means uncommon. Injury of the inferior extremity is more prone to be followed by tetanus than a similar affection of the superior extremity; and everybody knows how remarkably liable the disease is to supervene upon wounds involving the tendons and aponeuroses of the hands and feet, especially of the latter. Lesions of the nerves themselves are peculiarly dangerous in this respect, more particularly when they are of a punctured character, or when they are limited to a partial division of their fibres and neurilemma, by a blunt instrument, as a piece of glass or a rusty knife. Fatal cases of tetanus from the ligation of nerves have been reported by Larrey and other surgeons.

The extent of the injury does not, so far as we are able to judge, exert any material influence upon the production of the disease, as it has been known to follow, on the one hand, the most insignificant scratch, and, on the other, the most frightful wound. I believe, in fact, that it may be assumed, as a general principle, that the danger of the occurrence of tetanus is, other things being equal, almost in direct ratio to the diminutive size of a wound. This is certainly true of a majority of the cases that have fallen under my personal observation, an apparently trivial injury, mostly a little puncture, having served as the exciting cause.

Symptoms.—The period which intervenes between the occurrence of the injury and the development of the disease, is liable to considerable variety. In general, it ranges from four days to a fortnight. In some instances, well-marked symptoms manifest themselves within several hours after the receipt of the injury; and, on the other hand, the attack may not take place under-eight or ten weeks. What is remarkable is that the disease occasionally appears after the wound which provokes it is completely closed, owing, doubtless, to some lurking irritation in the nerves of the affected parts, or to the retention of some foreign substance.

Although tetanus may come on suddenly, with hardly any premonition, yet, in general, the attack is preceded by various anomalous nervous sensations which but too clearly foreshadow its approach. The most important and reliable of these precursories are, a feeling of *malaise* or universal uneasiness, aching in the muscles, stiffness about the lower jaw, pain in moving the head, and difficulty in protruding the tongue. If there is a wound, it commonly puts on an unhealthy appearance, discharging a thin, sanious fluid, and manifesting no further disposition to heal. After these symptoms, which are often attributed by the patient to the effects of cold, have continued for a variable, but usually a very short, period, others, more bold and decisive in their character, set in, leaving no longer any doubt respecting their true nature. The jaw now becomes firmly locked;

the faculty of mastication is completely abolished ; attempts at deglutition excite spasm in the throat, with a sense of impending suffocation ; and there is an indescribable distress in the precordial region, extending from the ensiform cartilage backwards towards the spine, as if the chest were tightly encircled by a cord. The muscles of the back and abdomen are rigidly contracted, and, in no long time, those of the extremities become similarly affected. When their action is very violent, the spinal muscles may shorten themselves so much as to draw the trunk into a distinct arch, the body resting only upon the occiput and heels, the affection thus constituting the variety of tetanus called *opisthotonos*, illus-

Fig. 200

*Opisthotonos.*

trated in fig. 200. The opposite state of this, *emprosthotonos*, is extremely uncommon ; for, although the abdominal muscles are usually very firmly contracted, being often as hard as a board, yet it is seldom that they are able to counteract the extensor muscles of the back to such a degree as to bend the head and chest forwards. The disease having reached this stage, may be said to be completely and characteristically established. Frequent spasms now occur, convulsing and agitating the whole frame, and greatly increasing the general suffering. The teeth are firmly clenched ; the eyes are fixed in their sockets, and have a wild, unnatural expression ; the nostrils are expanded ; the corners of the mouth are retracted ; the countenance has an old, haggard, and withered look ; the respiration is laborious and hurried ; and the smallest quantity of fluid is unable to descend the fauces and œsophagus. So great, in fact, generally, is the impediment to deglutition that the very sight of water is a source of suffering. The pain is usually severe, particularly about the jaw, throat, chest, and spine ; while the general sensibility of the surface is so excessive that the slightest breath of air is often sufficient to bring on violent spasms.

Fever is seldom present in traumatic tetanus, even when it has reached its height, although the thirst is generally quite considerable ; the pulse, which rarely exceeds eighty, eighty-five or ninety in the minute, is soft and regular, except, perhaps, during the violence of the muscular spasms, when it may be considerably agitated, small and feeble ; the tongue, at first moist, becomes gradually dry and brownish ; the stomach is extremely torpid ; the bowels are generally obstinately constipated ; the urine is scanty and high-colored ; and the skin is hot and bathed with a copious perspiration, which is occasionally very clammy and offensive, especially towards the latter stages of the disease. The mind is usually unimpaired.

Although such is the most common course of the disease, yet more or less irregularity occasionally arises, giving the symptoms somewhat of an anomalous character. Thus, there may be almost complete absence of pain ; the throat may be free from uneasiness ; the respiration may be gasping, or performed with a

sort of catch; the eyelids may be half closed; the orbicular muscle of the mouth may be firmly contracted over the teeth; and the extremities may remain completely relaxed. The skin is, occasionally, remarkably hot, the temperature, in some cases, having been found to range as high as 110° of Fahrenheit.

Diagnosis.—The diagnosis of tetanus rarely, if ever, presents any difficulties. In general, the history of the case alone is quite sufficient to determine its real character. The only disease with which it can be confounded is hydrophobia, but the symptoms of the two affections are so very different that none but the most heedless practitioner could possibly commit such an error. The period of latency in hydrophobia is, on an average, not less than a month, while tetanus is usually developed in from four to fourteen days from the infliction of the injury which provokes it. Besides, in rabies there is an absence of locked jaw and of opisthotonos, which constitute such striking features in tetanus.

One of the most valuable diagnostic symptoms of tetanus is the terrible distress in the precordium; it is usually described as of a painful, dragging nature, and is no doubt dependent upon spasmodic contraction of the diaphragm. Coming on early in the disease, it generally continues to its close, and is nearly always attended with opisthotonos, the head and shoulders being drawn, as it were, instinctively backward, to relieve pain and to favor the introduction of air into the lungs. In tetanus, the muscular contraction is steady and persistent, though liable to frequent and sudden exacerbations; in hydrophobia it is clonic, occurring paroxysmally, and having distinct intermissions. In tetanus, swallowing is difficult, chiefly by reason of the impossibility of separating the jaws; in rabies, it is dependent upon spasm of the throat and œsophagus; in the former, the mind is calm and unaffected; in the latter, it is often powerfully excited, and, at times, even furious.

Prognosis.—The prognosis in traumatic tetanus is extremely unfavorable. In the great majority of cases death occurs from the third to the fifth day; and, if we occasionally meet with an instance of recovery, the circumstance is to be regarded only as an exception to a general law of the mortality in this affection. In an experience of thirty-five years, I have seen but two cases where the patient escaped with his life, and then only after a protracted and painful struggle. When the disease has once fairly commenced, the tetanic spasms generally continue to recur, with more or less severity, until they prove fatal. There are no reliable signs which can serve to guide us in regard to the prognosis in this affection. The previous state of the general health, the age of the patient, and the character of the pulse, afford no clue as to the probable issue of the case. The young and the robust fare no better, in this respect, than the old and the infirm. Both alike perish from its attacks. The danger is undoubtedly always, other things being equal, in proportion to the violence and duration of the paroxysms, and it has been found that any tendency to chronicity is generally so much in favor of ultimate recovery; although patients sometimes live for several weeks, and then die from the effects of the malady.

The manner in which death occurs is not well understood. In some instances, it is apparently caused by suffocation, from spasm of the muscles of the larynx; occasionally it results from mere exhaustion, life being worn out by the intensity of the suffering; and in a third class of cases, it may probably be induced by convulsions of the heart, interrupting the passage of the blood to the lungs and brain.

Pathology.—It might reasonably be supposed that a disease which is characterized by so much violence during life, would leave some traces of its existence after death; but to show how erroneous such a conclusion is, it is only necessary to refer to the fact that all the dissections that have hitherto been made of persons dead of this affection have utterly failed to throw any satisfactory light upon its pathology and morbid anatomy. Many statements have been reported with reference to these dissections that are entirely without foundation; in fact, in not a few of the cases, natural or accidental appearances have been confounded with morbid, and lesions have been described which existed only in the imagination of the examiners. From the circumstance that tetanus is essentially a nervous affection, the brain and spinal cord, as well as the nerves emanating from them, and

even the great sympathetic, with its plexuses and ganglia, have all been most thoroughly scrutinized in numerous instances, and that, too, by some of the ablest men in the profession, and yet, notwithstanding all this, we are no wiser now in regard to the real lesions of this disease than surgeons were centuries ago. The whole subject is, in truth, still a mystery. I have myself made several dissections of this kind, and have witnessed others, amounting, perhaps, altogether to eight or ten, without, in a single one, observing any morbid appearances that could justly be ascribed to the effects of the disease. It has been noticed in several instances that the nerves leading from the wound which caused the attack were in a state of inflammation, their substance and neurilemma being congested and discolored.

Of the true pathology of tetanus, then, nothing whatever of a satisfactory nature is known; that it is essentially an affection of the nervous system, or of the nerves of particular muscles, must be admitted from the symptoms which characterize it; but in what the peculiar change consists, or to what extent it is carried, are points in the history of the lesion of which we are completely ignorant.

Treatment.—The treatment of this obstinate, and, unfortunately, too generally fatal, disease, is altogether of an empirical character. That this should be so is not surprising when we remember how completely ignorant we are of its pathology, and the fact that there is hardly an article of the materia medica, of any reputed efficacy, that has not been employed, either singly, or in various forms and modes of combination, for its relief. Although patients occasionally get well of this disease, and that under circumstances apparently the most desperate, yet, when the practitioner comes to analyze his treatment, in the true spirit of philosophy, he is generally compelled to confess his ignorance as to the share which his remedies may have exerted upon the fortunate event, and to acknowledge that accident, rather than his own skill, performed the cure. However this may be, it is certain that the disease sometimes either wears itself out, or yields to the most insignificant measures, while at other times it resists the best directed efforts of the ablest and most experienced practitioner. The chances, indeed, of effecting any good, when the malady is fairly established, are very slender in any case, however mild. Hence, whatever is done should be done promptly, and with a view to a prophylactic rather than to a curative result.

It cannot be expected that, in a work of this kind, I should be able to give even an outline of the more important remedies that have been suggested for the cure of this disease; I shall, therefore, content myself with a brief notice of a few of those which general experience has shown to be the most reliable, or most in consonance with the apparent condition of the part and system.

One of the first and most important indications in traumatic tetanus is the removal, if possible, of the exciting cause, which is, of itself, occasionally sufficient to effect a cure. Thus, if any foreign body remain in the wound, or in contact with the living tissues, the surgeon cannot too speedily extract it, especially if there is already some evidence of approaching disease. Sometimes a vicious cicatrice may keep up the tetanic irritation. Many years ago, I attended, in consultation with Dr. Buck, a young girl of fourteen, who had locked jaw from having been accidentally hurt, nearly a month previously, in the right cheek by a small splinter of wood. Although the substance was immediately extracted, yet, the parts continued to be tender, being, at times, even quite painful, and in less than a week tetanus set in. When I saw the case, free use had already been made, without any material benefit, of anodynes and antispasmodics, along with an occasional purgative, and the cheek had been leeches and repeatedly painted with iodine: the girl was pale and feeble, and had lost her appetite. Upon examining the original site of the injury, I found a small circumscribed spot, exquisitely tender under pressure, and of almost fibro-cartilaginous hardness. This being carefully dissected out, no more paroxysms occurred; and in a few days, with the aid of iron and quinine, wine, and a generous diet, complete recovery ensued.

lished, such an occurrence never fails to aggravate the spasms, rendering them both more frequent and violent. The atmosphere of the room should, moreover, be perfectly warm and dry, experience having shown that cold and moisture are extremely prejudicial in all affections of this description.

The most important *internal remedies* are, undoubtedly, anodynes and antispasmodics, of which opium, tartar emetic, aconite, camphor, assafoetida, and Indian hemp occupy the highest rank. They should be administered in large doses, with a view to an immediate and decided impression upon the general system, and should be given either by themselves or in various states and degrees of combination.

The most eligible preparations of *opium* are the acetated tincture and the salts of morphia, particularly the sulphate. Opium in substance is objectionable, on account of its insolubility, the stomach, under such circumstances, being extremely torpid, and unable to act upon it. For the same reason, a much larger quantity of laudanum and morphia is required to produce their specific effect than in ordinary disease. When the patient is young and robust, or when the spasms are violent and obstinate, the anodyne should be combined with tartar emetic, in doses sufficiently large to relax the system. The latter remedy is sometimes employed by itself, and several cases have come to my knowledge where it seemed to have effected a complete cure. I am satisfied, however, that its efficacy will always be materially enhanced by its judicious combination with morphia. In the use of tartar emetic in this disease, it must not be forgotten that the torpor of the stomach renders it necessary to give it in much larger doses than ordinarily. If the practitioner were to content himself with the usual quantity, the effects would greatly disappoint him, and the case might, in consequence, proceed from bad to worse, without receiving any benefit from the remedy.

Aconite is a medicine of great efficacy as a depressant, and may be given as an adjuvant to morphia, or morphia and tartar emetic, in cases of tetanus attended with a robust and plethoric state of the system. It lowers the action of the heart, promotes perspiration, and relieves spasm. *Veratrum viride* acts in a similar manner.

Camphor and *assafoetida*, administered in large doses, occasionally aid in controlling the spasms in this disease, but they should never be trusted to alone. Their influence, as antispasmodics, is far inferior to that of morphia and tartar emetic.

Indian hemp, soon after its first introduction into practice, received a large share of attention in the treatment of this disease, especially from the East India practitioners, some of whom were at one time disposed to regard it as a specific. Subsequent experience, however, has greatly disappointed these expectations, and in this country very little, if any, confidence is placed in the remedy. I certainly have never derived any appreciable benefit from it in the few cases of tetanus in which I have employed it, although the trials in each were very fair. The preparation usually given is the extract, in doses varying from one to two grains, repeated every two hours, or even more frequently, the object being to produce and to maintain narcotism.

Great expectations were entertained, on the introduction of *chloroform*, that at length an effectual remedy had been discovered for the cure of tetanus, and there is no article of modern times which has been so generally employed in the management of this disease. Cases successfully treated by it have been reported by different observers; but how far they were really relieved by this agent is a question which has not been decided. It is certain, however, that it has generally signally failed to cure, although it is usually productive of relief to the spasms, which are a source of so much distress to the patient. It should be administered in the form of inhalation, with an abundance of atmospheric air.

Much comfort is also experienced from the use of the *vapor bath* in the treatment of tetanus; the steam should be conveyed, by means of a tube, from the spout of a tea-kettle, or other suitable apparatus, under the bed-clothes, and may be advantageously medicated with laudanum, or laudanum and chloroform. The remedy possesses no curative agency.

Bloodletting, and *mercury*, carried to the effect of salivation, were at one time much vaunted, on account of their supposed efficacy in the treatment of tetanus. They have, however, of late years, been entirely abandoned. The patient is certainly reduced sufficiently soon without venesection; and, as to mercury, its use has occasionally, as stated elsewhere, been followed by the very disease which it was intended to cure, the saliva streaming at the time from the mouth in enormous quantities.

When much exhaustion exists, brandy, wine, and a generous diet are indicated, along with quinine and other corroborants. The profuse and exhausting sweats which so often attend the disease are best controlled by aromatic sulphuric acid, and frequent sponging of the surface with a strong solution of alum.

Whatever treatment may be adopted, proper attention should be paid to the bowels, which are generally excessively torpid, and, consequently, difficult to be moved. When the patient is in a condition to swallow, he may take ten grains of calomel, with double that quantity of jalap, every six hours, until there are free alvine evacuations. If the medicines are tardy in their action, their operation may be promoted by the addition of a drop of croton oil, or by means of a stimulating injection, as spirits of turpentine and castor oil. Occasionally, croton oil may advantageously be rubbed upon the abdomen. Severe purging should be carefully avoided, as, from its irritating and prostrating effects, it cannot fail to aggravate the complaint.

The treatment of tetanus by *counter-irritation* has, I believe, become in great degree obsolete. It was formerly thought, when the disease was supposed to be essentially connected with inflammation of the cerebro-spinal axis, that extensive and rapid vesication of the spine would afford valuable aid in combating the morbid action, and putting a stop to the spasms; and examples illustrative of the beneficial effects of this mode of treatment have been published by different observers. The remedy usually selected is either the common blister, caustic potassa, or the actual cautery. The late Dr. Hartshorne, of this city, was in the habit of employing a solution of potassa, in the proportion of one drachm and a half to two fluid ounces of distilled water. It produces a powerful rubefacient effect, and may be applied by means of a cloth mop to a narrow line of skin, from the occiput to the sacrum. If the hot iron be used, it should be applied transeurrently. I have, however, great doubts in regard to the propriety of any measures of this kind, believing that they frequently aggravate the symptoms instead of relieving them.

When the disease is chronic, and the wound still open, but indisposed to heal, the best plan is to divide the parts freely with the knife, so as to relieve them of engorgement, and invite a more salutary action. It is under such circumstances that the *actual cautery* occasionally answers a good purpose. In a case which occurred some years ago, in the practice of Dr. W. D. Stewart, of Indiana, and the particulars of which he has kindly communicated to me, an immediate stop was put to the paroxysms by this procedure, after various other means had been fruitlessly tried for nearly a fortnight. No spasms took place after the application, and the patient, a lad nine years of age, made a prompt and perfect recovery. The wound which had provoked the attack was a large, lacerated one, occupying the right side of the scalp, and extending down to the bones.

Anodyne and stimulating *liniments* applied along the spine have sometimes appeared to act beneficially, both in moderating the spasms and in eradicating the disease. Chloroform has of late been used a good deal in this manner, and several cases of its successful employment have been reported in the medical journals; among others, a very interesting one, by Dr. Hinkle, of Marietta, Pennsylvania, of a woman who suffered from tetanus consequent upon the bite of an eel. The treatment was conjoined with purgatives and antispasmodics, as *cannabis Indica*, valerian, and compound sulphuric ether.

Finally, should the patient be so fortunate as to survive the disease, the greatest care must be observed during his convalescence, lest relapse occur, and destroy him, when he is apparently on the verge of returning health. The

clothing should be warm, the diet light but nutritious, the bowels and secretions duly regulated, and exposure to atmospheric vicissitudes sedulously avoided.

SECT. III.—NEURALGIA.

Neuralgia is an affection of the nerves attended with severe, agonizing pain, often paroxysmal in its character, liable to occur in all parts of the body, and generally dependent upon some local irritation, or upon the joint agency of a local and constitutional cause. As it would be out of place in a work of this kind to treat of neuralgia in general, I shall limit my remarks here chiefly to the disease as it manifests itself in certain nerves, particularly those about the face, where the lesion not unfrequently becomes the subject of surgical interference.

Causes.—The causes of neuralgia are various and of the most opposite character. They are predisposing and exciting. Persons of a nervous, irritable or hysterical temperament are more prone to the disease than any other class of individuals. The gouty and rheumatic also frequently suffer from it. Depressing influences, whether mental or corporeal, are among its most common predisposing causes. Dyspepsy and anemia, by lowering the powers of the system, remarkably favor its development.

The disease occurs in both sexes, at all ages and at all seasons; it is most common, however, from the twentieth to the fiftieth year, and in winter and spring, in cold northern regions, and in districts abounding in malarial exhalations. Cold and damp states of the atmosphere are especially favorable to its production. Like gout and rheumatism, the disease occasionally manifests a hereditary predisposition, and in quite a number of instances I have met with it in several members of the same family. No parts of the body are exempt from its attacks. It is particularly frequent in the head, face, and jaws. The hysterical temperament disposes to neuralgia of the spine, joints, and bones.

The exciting causes of neuralgia are of a local and general nature. Among the former, exposure of a nerve to the air, or its compression by some tumor, as an exostosis, or soft growth, is the most common. The most atrocious attacks of this disease are generally witnessed in the branches of the trifacial nerve, in consequence of caries of the teeth, laying open their cavity, and thus allowing the air and other irritating substances to come in contact with the denuded nerve within. Similar effects are often produced by the pressure of a dental exostosis, or by the mere thickening of the periosteum covering the fang of a tooth. Occurrences of a like nature often excite neuralgia in the bones. Sometimes the disease is awakened by the contusion of a nerve, occasioned by a blow, fall, or kick; by the irritation of an old, indurated cicatrice; or by the excitement induced by the presence of a foreign body, as a splinter of wood. In the face, neuralgia may be caused by the lodgment of a piece of dead bone in the nose or antrum. A calculus will occasionally produce the disease in the bladder, worms in the bowels, and the larvæ of insects in the frontal sinus. Neuralgia of the pelvic viscera is often induced by the pressure of a displaced uterus upon the surrounding structures.

A very common exciting cause of neuralgia is exposure to cold while the body is overheated and covered with perspiration. When the predisposition to the disease is very strong, the slightest draught of cold air will often almost instantaneously bring on an attack. Exposure to heat is less injurious, though it is also capable of exciting the disease, especially when the heat is concentrated for any length of time upon one particular locality.

Attacks of neuralgia are sometimes induced by gastro-intestinal irritation, as the presence of a redundancy of acid, indigestible food, worms, impacted feces, or an overloaded state of the bowels. The disease is not uncommon in dysmenorrhœa and in ulceration of the neck of the uterus, in spinal irritation, and in organic lesion of the brain.

Occasionally the cause is seated in the nerve itself, as when it is inflamed, partially ulcerated, or denuded of its natural coverings. After amputation, the stump often becomes affected with neuralgia in consequence of the extremities of

some of the nerves being expanded into neuromatous tumors; and similar effects sometimes supervene upon the division of the nerves in cases of wounds, especially lacerated ones.

Finally, the occurrence of neuralgia, as a consequence of malaria, is familiar to every one. In the southern and southwestern States of the Union, where neuralgia of every form and grade is extremely prevalent, the disease, in the great majority of cases, recognizes no other cause. The attacks, under such circumstances, are generally of a distinctly intermittent type, very similar to those of intermittent fever, recurring once every day or every second day, and, after having continued with great severity for several hours, gradually going off, to reappear about the same period on the next day; each paroxysm being, perhaps, ushered in by chilly sensations, and terminating in more or less profuse perspiration.

Symptoms.—The nature of the pain in neuralgia is not always the same. In one case, it is dull, heavy, and aching; in another, acute and extremely violent; in a third, it resembles the pain produced by thrusting needles into the tissues; in a fourth, it is pungent, smarting, or burning; in a fifth, it is sharp and darting, like an electric shock, running through the parts with the rapidity of lightning.

The pain, whatever its character may be, is generally attended with more or less soreness and tenderness of the affected parts which sometimes pit on pressure, although they are seldom discolored. Finally, the pain may be concentrated, or diffused; that is, it may be strictly localized, or limited to one particular spot, and that perhaps a very small one; or it may be extended over the greater portion of a nerve, or even over its entire length.

It is important to bear in mind that the pain often breaks out at a point very remote from the one upon which the impression provoking the attack is made. Thus, supra-orbital neuralgia is often produced by disorder of the stomach, or of the stomach and bowels; a carious tooth has been known to give rise to neuralgia of the hip; and spinal irritation not unfrequently occasions neuralgia of the leg, heel, and foot. A very singular case has been reported where a severe attack of neuralgia of the left forearm could always be instantly excited by touching the meatus of the right ear.

Neuralgia is sometimes associated with rheumatism, and it is to this form of the disease that the term rheumatico-neuralgic is usually applied by nosologists. The combination is most generally met with in persons of an arthritic predisposition, commonly affects the muscles, especially the intercostal and spinal, and is often exceedingly intractable, rendering the patient miserable for life, and at length wearing him out by the constancy of his pains.

Neuralgia often exists simultaneously in different parts of the body, and when it is once fairly established it is easily excited by the most trivial circumstances. Its progress is variable. In many cases it readily yields to treatment, or disappears even spontaneously; on the other hand, it is sometimes a most intractable disease, worrying and fretting the patient, undermining his general health, and disqualifying him for business and enjoyment. In its worst forms the suffering is almost constant; whereas, in the milder, there are not unfrequently long intervals of complete, or nearly complete, exemption from pain. When the affection is contracted early in life, and proves rebellious, it is seldom entirely got rid of, whatever means may be adopted for its relief.

Pathology.—The pathology of neuralgia is not understood. It has generally been supposed to consist in a mere exaltation of the sensibility of the nervous tissue, but if this were so it would, probably, not be so intractable a disease as it often is. The explanation may, perhaps, hold good in those cases in which the disorder is very transient, or of malarial origin. In general, however, there is some degree of inflammation either in the nerve-pulp, or in the neurilemma, or in both, as is proved by the fact that the parts supplied by the affected nerves are commonly more or less tender, œdematous, and even somewhat discolored; phenomena clearly indicative of an engorged and incited state of the capillary vessels with a tendency to effusion. In other cases, again, it may consist in a

diversion of the nervous fluid, as when a nerve is compressed by interpositions, or by causes acting upon its periphery, thereby interrupting the passage across the seat of the obstruction.

Prognosis.—The prognosis of this disease may be gathered from what has stated in the preceding paragraphs. It seldom proves fatal. Its course is variable. It may last for months, years, a lifetime, the patient finally dying of some other disease. The most dangerous form is visceral neuralgia, which sometimes causes death by the constancy and violence of the attendant pains.

Treatment.—The treatment of neuralgia must be deduced, in great degree, from the nature of the exciting cause, which should, therefore, always receive particular attention, removing it where this is practicable, or modifying it where it is not, so as to render it as harmless and inoperative as possible. In neuralgia of the face, for example, it will often be found that the cause of the trouble is a diseased tooth, upon extracting which the pain instantly vanishes. Neuralgia dependent upon the presence of an old, callous cicatrice, can only be successfully treated by the excision of the offending tissues. Vermifuge medicines are indicated when it is caused by worms; antacids, when it is excited by vitiated contents of the stomach; purgatives, when it is occasioned by an overloaded condition of the bowels. Thus, it will be perceived that no single remedy, or class of remedies, is adapted to all cases; a fact which strongly suggests, in every case, the importance of a most thorough and critical examination of the state of the part and system, with a view to the institution of a rational therapeutics. It must not be expected, however, that the disease will always disappear upon the removal of the exciting cause. Generally, indeed, it will, and that very speedily and effectually; but there are cases where it is inclined to linger, with little or no mitigation, for an indefinite period, the affected parts being seemingly unable to recover their natural functions, either because they have become habituated to the morbid action, or because they have experienced some organic change which no medication can reach.

The treatment of neuralgia is general and local, except when the cause is entirely of a purely local character, when general means may usually be dispensed with. Purgatives, a proper regulation of the diet, and antineuralgic remedies, as they are named, constitute the more important constitutional measures, while embrocations, leeches, vesicants, the endermic use of morphia, and the application of the affected nerves comprise the more efficient and reliable topical

There are few cases of neuralgia which are not benefited by the use of purgatives; sometimes, indeed, the disease promptly disappears under a few brisk evacuations. Their exhibition is particularly indicated when there is a coated tongue, disorder of the stomach, a vitiated condition of the secretions, headache, pain and aching in the limbs, or an overloaded condition of the system.

The best articles are blue mass, colocynth, and jalap, or the compound cathartic pill, repeated every other night until there is a decided improvement in general health. Emetics may often be advantageously exhibited, especially when there is evidence of biliary and gastric derangement. The pain is generally relieved by their action, and sometimes completely removed, the moment they manifest their specific effect.

The diet must be plain and simple, easy of digestion, and adapted, in regard to nutritive qualities, to the exigencies of each particular case. The plethoric will be benefited by abstinence; the pale and anemic, by good living. When the general health is much impaired, tonics, as quinine and iron, a generous wine, brandy, porter, and ale, with exercise in the open air, will be of great service.

Sometimes a sea voyage, or a residence near the sea shore, is salutary. There are several articles of the materia medica which may be considered as possessing, in some degree, a specific influence over neuralgic affections, and which have received the name of antineuralgic remedies. To this class belong

arsenic, strychnia, aconite, and morphia, along with some other analogous remedies, and the different preparations of iron.

Quinine, the great antiperiodic in intermittent fever, is entitled to the highest

rank in the treatment of neuralgia, particularly in that variety in which the paroxysms observe a regular diurnal relapse, with an interval of entire freedom from suffering. It may be administered by itself or in union with an opiate, and a few efficient doses are almost sure to break up the attack promptly and effectually. In my own practice, I seldom give less than ten grains at a dose, repeated every six or eight hours, until the affection is either vanquished, or the specific effects of the medicine are rendered apparent by the aural and cephalic distress. Some practitioners prefer smaller doses, but experience has shown me that they are less trustworthy, and that, at all events, a much longer time elapses before they put a stop to the disease. Quinine is sometimes very beneficial when the affection is not of malarial origin, but in general its effects are much less apparent.

In chronic neuralgia, or in acute but obstinate attacks, *arsenious acid* is generally found to be one of the best remedies, given in doses varying from the eighth to the twentieth of a grain, three times a day, in union with an anodyne, or an anodyne and tonic. There are few cases of the disease, however obstinate, that will not be materially benefited by the use of this article, if administered with proper judgment and perseverance. The acid is far preferable, in every respect, as an antiperiodic, to Fowler's solution, as it is much less liable to cause nausea and anasarca.

With the value of *strychnia*, as an antineuralgic, every practitioner is familiar. I have used it, as such, for many years, and its effects have rarely entirely disappointed my expectations. The dose recommended in the books is much too large. I rarely give more than the twentieth or twenty-fifth of a grain, thrice in the twenty-four hours. Extract of *nux vomica* is also employed for the same purpose, but is seldom productive of any decided benefit.

Aconite and *Indian hemp* are valuable articles in the treatment of neuralgia, although their efficacy has, I think, been greatly overrated. They may be exhibited in the form of extract, in doses varying from half a grain to a grain every six or eight hours, either alone or conjoined with other articles.

The use of *morphia* is absolutely indispensable in the treatment of neuralgic complaints, not so much as a curative agent, as for the purpose of controlling the excessive pain and inducing sleep. There are cases, however, which are radically cured by the persevering exhibition of this remedy, but then it is generally necessary to give it in large and sustained doses. Protracted narcotism has occasionally vanquished the disease after all other means had failed to afford even temporary relief. Several examples of this kind have fallen under my own immediate observation, and others have been mentioned to me by professional friends. For ordinary purposes the quantity need not exceed a fourth or a third of a grain, and, in chronic or subacute cases, I rarely give more than the tenth, twelfth, or fifteenth of a grain, repeated thrice a day.

For many years past I have been in the habit of employing, with very happy effects, in a great variety of cases of neuralgia, a combination of some or all of the above articles, giving them in pill form three or four times in the twenty-four hours. The subjoined will serve as a type of such a formula.¹ It need hardly be added that the effects of the prescription should be carefully watched, as several of the articles are of a potent and even a poisonous character. If the system be anemic, two grains of sulphate of iron or of the valerianate of that salt may be incorporated with each pill. Carbonate of iron I never use, as it has always disappointed my expectations, even when I have administered it in large doses and for a long time, and my experience, in this respect, is, I believe, fully corroborated by the results of the observations of other practitioners. When the attack depends upon the presence of a redundancy of vitiated gastric acid, the solution of valerianate of ammonia will be found a highly efficient

Mix, and make xxx pills ; one to be given three or four times a day.

remedy, administered in the dose of a drachm every two or three hours until relief is afforded. Iodide of potassium has been much lauded as an antineuralgic; but, although I have used it in many cases, I cannot recall to my mind a solitary one where it seemed to be really of any material service. If it ever does any good in this disease, it is when it partakes of a syphilitic nature.

When the attack is of a rheumatico-neuralgic type, *colchicum* will be required, and will generally act more kindly and promptly than any other article. My invariable plan, however, is to give it in union with a full dose of morphia, as one grain of the salt with one drachm of the wine of colchicum, every night at bedtime, which will be found to be a much better practice than administering these substances in smaller and more frequently repeated quantities.

The *topical remedies* which particularly claim attention on account of their real or imputed virtues are counter-irritants, leeches, morphia, and the steam of hot water, either simple or medicated.

The only counter-irritants that, in my judgment, are at all admissible, in the treatment of this disease, are blisters, ammonia, and iodine. Setons and issues are out of the question, except in deep-seated obstinate visceral neuralgia, when the latter occasionally prove beneficial, especially if made with the hot iron, directly over the seat of the pain, so as to afford a free and protracted discharge. The moxa, formerly so much used, has of late years fallen into disrepute. Blisters are particularly valuable in inflammatory neuralgia; they should be retained until the epidermis is well raised, and they are the more desirable because the raw surface thus made may be advantageously employed for the topical application of morphia. Temporary relief, but nothing more, occasionally follows the use of ammonia in the form of liniment, or of Granville's lotion, frictions with ointment of veratria, and painting the parts with tincture of iodine. Leeching is sometimes useful, by relieving congestion, and thus removing one cause of compression of the nerve-pulp; the operation being performed as near as possible to the seat of the disease.

The endermic application of morphia has been found highly beneficial in neuralgia, chiefly, however, in mitigating pain. It may, as already stated, be simply sprinkled upon a blistered surface, be inoculated, or, what I greatly prefer, be injected subcutaneously. In the latter case, some care is necessary in regard to the quantity of the morphia used, as it occasionally evinces its narcotic effects in a very rapid and decisive manner. The operation which, I believe, I was one of the first to perform, but which has since been generalized by Mr. Wood, is executed with a small syringe, fig. 201, having a very slender nozzle, which is

Fig. 201.

inserted into a small puncture previously made in the skin of the affected parts, the subcutaneous cellular tissue being torn up with a common probe to make room for the reception of a drachm of solution of morphia, holding in suspension from a quarter of a grain to half a grain of the salt, according to the exigencies of the case. The operation may be repeated once in the twenty-four hours, or oftener, if deemed necessary. In the ordinary endermic application, the morphia does not penetrate to a sufficient depth; while inoculation is still more uncertain, and is by no means free from pain. I believe that the subcutaneous injection of morphia will be found highly serviceable in many cases, especially when the disease is distinctly localized, and rebellious to other remedies.

Hot applications are generally beneficial in putting a prompt stop to the severity of the pain, especially if they are medicated with laudanum, or some other anodyne preparation. They may be used in the form of clothes wrung out of water, and covered with oiled silk, to prevent evaporation; or in that of

steam conveyed directly to the part by means of a tube connected with a tea-kettle placed over a spirit lamp near the bed.

Section and excision of the affected nerve have often been practised for the cure of neuralgia, with results, however, by no means always satisfactory. Indeed, there is reason to believe, from the facts that have been published upon the subject by various surgeons, that both operations have generally proved unsuccessful; in many cases temporary relief ensued, but in nearly all the disease ultimately recurred with its former violence. I have myself performed a number of these operations, sometimes merely cutting the affected nerve across, at other times excising a considerable portion of it, but the effect has nearly always disappointed me. Surgeons have not hesitated to remove sections of some of the larger nervous trunks, as, for example, the sciatic.

In facial neuralgia, where resection of the affected nerve is more frequently practised than elsewhere, the operation has lately been pushed to a most extraordinary extent by several American surgeons, Professor Carnochan having led the way. The results of his cases, three in number, will be found in an interesting paper on the subject in the *American Journal of the Medical Sciences* for January, 1858. The procedure consisted in exsecting the trunk of the second branch of the fifth pair of nerves, beyond the ganglion of Meckel, on account of severe neuralgia of the face. The portion of nerve removed, in two of the cases, was two inches in length, and in another an inch and three-quarters. The effect in all was most gratifying. Should the success of Dr. Carnochan be equally great in the hands of other surgeons, he will have conferred, by the boldness of his operation, an inestimable boon upon a class of patients heretofore considered as almost beyond the reach of relief.

The operation of exposing the second branch of the fifth pair, as performed by Dr. Carnochan, is severe and complicated, and requires, besides chisels and bone-nippers, two trephines, one three-quarters of an inch in diameter, and the other half an inch; the latter being intended for perforating the posterior wall of the antrum. The patient, placed under the influence of chloroform, lies upon a table, with the head well supported by pillows, and firmly held by an assistant. The infra-orbital foramen is then laid bare by two incisions, commencing above, near the inner and outer angles of the eye, at the inferior edge of the orbit, and terminating at a sharp point, about an inch below, opposite the furrow on the lower portion of the ala of the nose, the flap thus formed representing the shape of a V. The lip being now everted, is next detached from the upper jaw, when it is completely divided, along with the cheek, by a vertical incision, extending from the inferior extremity of the V incision through its free border. By dissecting up the two large flaps thus marked out, turning one outward and the other inward, the whole of the front wall of the antrum, together with the trunk of the infra-orbital nerve, is completely laid bare. The crown of the large trephine is now applied immediately below the foramen, and an irregular disk of bone removed, so as to expose the cavity of the antrum. The lower wall of the infra-orbital canal is cut away with the pliers and chisel, while the posterior wall of the antrum is perforated with the smaller trephine. The trunk of the nerve is then isolated from the other tissues in the sphenomaxillary fossa, and carefully traced beyond the ganglion of Meckel, behind which, close to the round foramen in the sphenoid bone, it is divided from below upwards with a pair of blunt-pointed scissors, curved on the flat. The hemorrhage is slight, and the flow from the branches of the internal maxillary artery, in the sphenomaxillary fossa, is easily controlled with compressed sponge.

In performing this operation upon the dead subject, I have found it quite easy to obtain a sufficiency of room for exposing the nerve, in its entire length, by carrying a curvilinear incision, from an inch and a quarter to an inch and a half in extent, across the cheek, beginning a short distance below the inner angle of the eye, descending towards the level of the ala of the nose, and terminating a little beyond and below the outer angle of the eye. Whatever plan of incision be adopted, care must be taken not to inflict any unnecessary injury upon the osseous tissues, or to expose too freely the structures of the orbit.

The inferior branch of the fifth pair of nerves may be exposed by perforating the ramus of the lower jaw about three-quarters of an inch behind the large grinder, five-eighths of an inch above the angle of the bone, and an inch and a quarter below the zygomatic process of the temporal bone. A curvilinear incision, with the convexity downwards, is carried over the ramus, about two inches and a half in length, and, the flap thus made being dissected up, and held out of the way, a disk of bone, half an inch in diameter, is removed with the trephine. The nerve is then hooked up with a blunt tenaculum, and as much as can easily be got at removed with the scissors. Some hemorrhage necessarily follows the division of the dental artery, but this is usually readily arrested by the ligature or by compression.

The inferior dental nerve, at its exit from the jaw, will be found opposite the first bicuspid tooth, midway between the inferior border of the bone and its alveolar margin, and may be easily exposed by raising a semilunar flap of integument, with the convexity towards the neck. Should it be deemed advisable to follow the nerve into the dental canal, this can readily be done by the use of the trephine.

I do not consider it necessary to give plans and rules for exposing nerves in other parts of the body. Few Surgeons, at the present day, will be so rash as to exsect any of the larger trunks of the extremities, and the smaller branches may generally be easily found and divided, or portions of them removed, by attention to the anatomy of the parts concerned.

SECT. IV.—PARALYTIC AFFECTIONS.

1. WASTING PALSY

A peculiar affection of the muscles, consisting essentially in atrophy and fatty degeneration of their fibres, has recently been described under the name of wasting palsy, from the fact that wasting and loss of power of these structures are its most prominent features. The disease, first accurately delineated by Cruveilhier, has been studied with great care by several European observers, especially Aran, Duchenne, Wachsmuth, Eisenmann, Meryon, and Dr. William Roberts, the latter of whom has embodied all that was then known respecting it in an admirable monograph, published at London in 1858.

Wasting palsy presents itself under two varieties of form, the partial and general; the first, as the name implies, being limited to particular muscles, or sets of muscles; whereas the other involves nearly all the voluntary muscles, those of mastication and those of the eyeball, including the elevator of the upper lid, being the only ones exempt from its ravages. The involuntary muscles, however, remain altogether untouched, even in the worst cases and in the most advanced stages of the disease. Hence, the reason why the general health is usually so perfect amidst this wreck of the active agents of locomotion.

Of the causes of atrophy and palsy of the muscles, our information is too limited to permit us to speak positively. If their development has occasionally been clearly traced to the effects of cold, to rheumatism, or to excessive and long-continued fatigue, such as attends various mechanical pursuits, it is equally certain that, in the great majority of instances, no plausible reason can be assigned for their occurrence. Now and then the lesion appears to have a syphilitic or strumous origin.

The time of life at which this disease occurs is variable; it has been noticed in young children, and, on the other hand, occasionally in old subjects; but the most obnoxious period would seem to be between twenty-five and thirty-five. Thus, in eighty-eight cases, analyzed by Dr. Roberts, the average period was thirty years and six months. General atrophy is not limited to any particular age, but attacks indiscriminately children, adults, and old persons; whereas the partial form rarely shows itself before puberty and after fifty. Both sexes are liable to it, but males suffer much oftener than females. The lesion has occasionally been observed in several members of the same family, and also in the offspring

of persons who had themselves been its victims, thus exhibiting a sort of hereditary tendency.

The muscles that are most liable to suffer in this affection are those of the extremities, especially the upper. The wasting generally begins at one particular part of a limb, from which it gradually extends to another; but now and then cases are met with in which it attacks several points simultaneously.

It has been noticed that there is usually a tendency in certain muscles to suffer together, as if they were united by a very close fellow feeling; thus it has been found that, whenever wasting palsy occurs in the muscles of the hand, it is extremely liable to affect those of the forearm also; a similar disposition has been remarked in reference to the muscles of the shoulder and those of the arm. Moreover, experience has shown that when one limb is invaded its fellow is very apt to share the same fate.

The most important *symptoms* of this disease are wasting of the muscles and loss of contractile power, generally coming on in a slow, gradual, and stealthy manner. In the great majority of cases, indeed, the person is unconscious of the mischief that is taking place, until his attention is accidentally directed to the subject by a failure of the power of one of his limbs, especially the hand and foot. "The tailor discovers," says Dr. Roberts, "that he cannot hold his needle; the shoemaker wonders he cannot thrust his awl; the mason finds his hammer, formerly a plaything in his hand, now too heavy for his utmost strength; the gentleman feels an awkwardness in handling his pen, in pulling out his pocket handkerchief, or in putting on his hat. One man discovered his ailment in thrusting on a horse's collar; another, a sportsman, in bringing the fowling-piece to his shoulder." The wasting, at first very slight, progressively increases until the affected muscles are rendered perfectly soft and flaccid, and their substance is so much wasted that they are hardly one-fifth of the natural bulk; they are, in fact, completely withered, as if they had been starved, and deprived of all nervous influence. The loss of power is generally in proportion to the wasted condition of the muscles, proceeding gradually from bad to worse, until the parts are entirely disabled and useless, no effort of the will being capable of exciting the slightest action.

Besides the above more prominent symptoms, there are others of a minor and subsidiary character. These are fibrillary tremors, cramps and twitches, pain, and a remarkable susceptibility to cold.

Fibrillary tremors, or convulsive twitchings, are very common, especially in the earlier stages of the complaint; they are dependent upon irregular contraction of individual muscular fibres, and are, consequently, always absent when the disease has reached its full development. They generally occur without the consciousness of the patient, and may usually be readily excited by exposure of the affected parts to a current of cold air or water. Cramps are also very frequent; they come on at various intervals, and often constitute a source of real suffering, especially when they are accompanied with pain, which is present in about one-fourth of the cases. The pain may be slight and wandering, severe and fixed, or sharp and neuralgic, shooting about in different directions with the rapidity of lightning. In some instances it occurs in different parts of the muscular system, more or less remote from the seat of the disease, and is then apparently of a rheumatic character. Wasting palsy causes a remarkable sensibility to cold, especially to a cold, humid atmosphere, so that the patient requires an uncommon amount of clothing to keep himself warm and comfortable. Finally, the galvanic excitability of the muscles regularly diminishes with their decay, but is not wholly annihilated until they have completely lost their primitive structure.

It is remarkable that, amidst all this wear and ruin of the muscular system, the general health should uniformly remain unimpaired, even in the worst forms of the disease. The appetite and sleep are excellent; digestion is well performed; the bowels move with their accustomed regularity; and the functions of the kidneys are perfectly normal. The intellect is clear to the last, and the senses retain their wonted vigor. The only trouble which the patient occasionally experiences is difficulty of respiration, from involvement of the diaphragm.

The *progress* of the disease is generally slow, the muscles steadily decaying, until they are at length completely changed in their character; for months and even years they retain some contractile power, and are even susceptible of restoration. General atrophy is always a gradual affection; it seemingly begins in the partial form of the lesion, and is probably merely an aggravated state of it. When the disease has reached this crisis, the patient may be unable to use any of the muscles, excepting, as already mentioned, those of mastication and those of the eye.

The appearances revealed on *dissection* are characteristic. The muscles, as might be expected, are wasted in various degrees; some slightly, others very much, and others, again, so completely as to be hardly recognizable, consisting merely of cellulo-fibrous vestiges, with no distinct trace of the original structure. The color of those that still remain is much faded, being pale red, rose, buff, or yellowish, according to the extent of the atrophy; and in all, or nearly all, there are well-marked evidences of granular and fatty degeneration, the former generally preceding the latter, although occasionally they exist independently of each other. Sometimes these changes are confined to one particular part of a muscle, as one-half or two-thirds of its belly, while the other portion retains its natural hue and consistence. Under the microscope, the striped primitive fibres are observed to have vanished, their place being supplied by granular matter and oil globules, and their investing tunic broken down and disintegrated.

The nervous system has been closely scrutinized in many of the reported cases of wasting palsy, but, thus far, nothing of a very satisfactory nature has been thereby elicited. It appears, however, to be well established that the lesions of the nervous system are of much less frequent occurrence than had been imagined. In some of the cases, indeed, there has been no perceptible change of any kind whatever; in others, there was softening or other disease of the spinal cord, either alone, or in conjunction with atrophy of the roots of the spinal nerves and of their peripheral branches. In an instance, described by Schneevogt, the great sympathetic with several of its ganglia was extensively wasted and converted into fatty matter.

In what does this disease essentially consist? It was very natural, before our knowledge of the affection was strengthened by the light of dissection, to refer its origin to lesion of the spinal cord, or of the cerebro-spinal axis, such as softening, or chronic inflammation; and from the fact that traces of this description have been observed in several cases, a number of pathologists have been induced to adopt this view. Others, however, maintain, and, as it seems to me, with a better show of reason, that the primordial cause resides in the peripheral nerves, which, becoming affected in a manner that has not yet been determined, undergo atrophy, or atrophy and fatty degeneration, so as to prevent them from conveying a sufficient amount of nervous fluid to the muscles to which they are distributed, and which thus, in their turn, fall into a similar condition. The principal reasons for this conclusion are, first, that in quite a number of the reported cases of this affection the spinal cord was found to be perfectly intact; and, secondly, that, as has been stated elsewhere, the affected muscles sometimes retain, in certain portions of their extent, their natural color and consistence, which could hardly happen if their degeneration depended upon disorganization of the great nervous centres. It may be assumed, then, that wasting palsy is essentially a local disease, originating in some lesion of the nerves of the muscles, and capable, occasionally, of involving the spinal cord secondarily.

The *prognosis* of this affection is generally unfavorable; the partial form is occasionally recovered from, the complete never. In the latter case death, which sometimes does not occur under several years, is usually preceded by great difficulty of respiration, in a paroxysm of which the patient suddenly expires. In partial atrophy, the disabled muscles, after having struggled on for many months, perhaps neither sensibly advancing nor receding, gradually awake from their torpor, and ultimately regain some contractile power, though never their full vigor.

The *treatment* of wasting palsy has hitherto been conducted too much upon

empirical principles; a fact not surprising when we consider the unsettled views that still prevail in regard to its pathology. If it be assumed that it is essentially a local affection, unconnected with any lesion of the spinal cord, it is evident that our remedies should be directed mainly to the seat of the disease. This is accordingly what should be done. If there is any disorder of the general health, it should promptly be corrected. If the lesion can be clearly traced to a syphilitic or strumous taint of the system, as it has been in some of the reported cases, the proper treatment will be iodide of potassium with bichloride of mercury; or, when a tonic effect is required, potassium with iodide of iron. Gentle purgatives will be useful when there is constipation with derangement of the secretions. The diet must be plain, simple, and unirritant.

The best *local remedy*, in the early stage of the disease, is a blister sufficiently large to cover the whole of the affected muscles, and retained long enough to produce thorough vesication. If decided improvement do not follow in a week or ten days, the application should be repeated. I have often obtained excellent effects from this remedy, and can therefore strongly recommend it as worthy of trial. The hot douche, immediately followed by the cold, will also be found serviceable, but to prove efficacious it should be aided by frictions with some stimulating embrocation, as spirits of camphor, or alcohol and ammonia. The cold douche alone is objectionable, on account of its depressing tendencies. Shampooing will be found useful, and should be practised several times a day. Galvanism has been highly extolled by Duchenne, Meyer, Gros, and others, and there can be no doubt that it has occasionally rendered good service. The current should be passed rapidly over the disabled muscles, taking care to return to each several times during the same sitting; it should be strong in proportion to the obtuseness of the parts, but be gradually diminished as the sensibility augments, otherwise over-stimulation may occur, and thus do harm instead of good. The application may be repeated at first every twenty-four hours, and afterwards twice a day.

The treatment, whatever it may be, should be combined with gentle exercise of the affected parts, to recall them, as it were, to a sense of their duty. They should, in fact, be re-educated by a system of careful training; but to do this to advantage, the efforts must be steadily and perseveringly continued for many months, if not for several years. Conducted in this way, great confidence may be entertained of ultimate benefit.

2. INFANTILE PALSY.

There is a variety of paralysis which may be briefly mentioned in connection with the preceding; occurring in young children, generally during the period of dentition, and which, in point of obstinacy and incurableness, is, if possible, still more deplorable. It may be called infantile palsy. Its attacks are usually sudden and unaccountable. The child goes to bed in the evening, perhaps to all appearance perfectly well; during the night, however, he becomes feverish and restless, and in the morning, on attempting to walk, he is unable to stand or use his legs. The limbs soon lose their round, plump appearance, the muscles are rendered soft and flaccid, the feet trail the floor, and the surface feels cold and numb, though sensibility is seldom entirely destroyed in any case, however extensive.

The seizure is much more common in the lower extremities than in the upper; very often it is confined to one thigh and one leg, but occasionally both limbs, or even all four are involved, the child being perfectly helpless, and in the most pitiable condition. The paralysis is generally complete, but cases occur in which the little sufferer is still able to use certain muscles, although not with anything at all like their natural freedom and strength. When the upper extremity is attacked, the deltoid muscle is very liable to be affected, becoming remarkably soft and wasted, so that the patient finds it impossible to elevate the arm or lift the smallest weight.

The cause of this variety of palsy is not always very evident; in general,

However, it depends upon disease of the spinal cord, or of the cord and its membranes; probably inflammation, followed by effusion of lymph and serum, or thinning of the nervous tissue. However this may be, the idea of such an occurrence is countenanced by the suddenness of the attack, by the paralysis of the muscles, not of a portion of them, as in wasting palsy, properly so termed, and by the remarkable obstinacy of the disease, most persons remaining crippled during the rest of their lives. If occasionally a recovery takes place, it is to be viewed rather as a rare exception than as a general law.

The general health is seldom impaired in infantile palsy; the mind acts with accustomed vigor, and all the bodily functions are well executed. As the child advances in years, all the limbs, excepting the disabled ones, increase in size and strength, but the latter remain stationary, or dwindle away still farther, and thus form a striking contrast with the sound.

The *treatment* of infantile palsy must mainly be directed, in the first instance, to the spinal cord, by whose disease it has been provoked. For this purpose cupping, cupping, rubefacients, and blistering should be employed as soon as possible after the occurrence of the paralysis; and these should be followed, if the case is likely to prove obstinate, by a seton, or, what is preferable, because more efficient, by an issue with the actual cautery, applied, as nearly as may be, opposite the seat of the lesion, and made to furnish a copious supply of pus. If nothing can reach such a case, it is active and long-continued counter-irritation. Meanwhile, the muscles themselves must be rubbed and shampooed, and subjected upon a course of careful training, as advised under the head of wasting palsy. If the general health is suffering, alterants and tonics are prescribed; the child is carried about in the open air, and special attention is paid to the bowels and secretions. As recovery advances, strychnia may be of service; but no benefit will be likely to accrue from its exhibition in the earlier stages of the complaint. Mercury has been strongly recommended in this disease, given in minute doses several times a day for several successive months; but, although such a plan of treatment is extremely plausible, I cannot say that it has ever been attended with any material benefit in the large number of cases in which I have employed it.

The use of iodide of potassium has, in my hands, been equally unavailing. The contraction of the tendons, consequent upon this variety of palsy, must be relieved by appropriate apparatus, aided, in obstinate cases, by tenotomy.

3. PARTIAL PALSY.

Besides the above forms of palsy there are some others, to which the term partial, transient, or anomalous may be applied, such, for instance, as loss of motion of one side of the face, one eyelid, one side of the tongue, or of the hand, arm, or shoulder, or even of the entire superior extremity. The subsequent facts will serve as illustrations of its character.

Pressure upon the nerves is liable to be followed by interruption of their functions, at one time temporary, at another permanent. A case recently came under observation in which a man, aged thirty-five, suffered from partial palsy of the forearm and hand from having rested for two hours with his head upon the elbow as he lay asleep upon the floor.

In another case, which came under my notice several years ago, temporary paralysis of the left upper extremity was produced by the arm, thrown across the back of a chair, being compressed by the head while the man was asleep. Pressure of the head of a crutch upon the axillary plexus of nerves will occasionally lead to weakness, numbness, and prickling pain in the arm, hand, and fingers. Recently a youth of fifteen was under my charge on account of paralysis of the left arm, consequent upon a fall on the shoulder from a railroad car, two months previously. The limb was instantly deprived of motion and sensation, and so continued up to the time of his visit. The head of the humerus had been thrown violently forwards against the coracoid process, but it exerted no perceptible pressure upon the brachial plexus of nerves.

Paralysis of one side of the face from injury of the portio dura is not infrequent;

more generally the affection is caused by suppression of the cutaneous perspiration, from exposure to cold and wet; and an instance is occasionally met with in which it is produced by disease of the petrous portion of the temporal bone. The subjoined case affords a good illustration of a very common form of facial palsy.

David Shepard, aged 15 years, blacksmith, of temperate habits, came under my treatment, in 1856, for paralysis of the left side of the face. The attack had occurred suddenly three days previously, without any apparent cause, soon after eating a moderately hearty dinner. He had been subject to frequent and severe paroxysms of headache, preceded by dizziness and vertigo. On the morning, however, on which he was seized with palsy he had felt uncommonly well. His appetite and sleep had always been good, and his bowels regular. The palsy was characterized by loss of motion in the muscles of the left side of the face, and by inability to close the left eyelids, accompanied with a want of sensibility of the integuments. The tongue, when protruded, inclined to the right side, and was deprived of feeling and taste, a lump of sugar, held in the mouth, making no impression on the affected side of the organ. The general health at the time was excellent.

In the *treatment* of these paralytic affections, special attention must be directed to the improvement of the general health, which is often seriously impaired, by the use of purgatives, alterants, and a proper regulation of the diet. In obstinate cases, a mild mercurial course is sometimes serviceable, especially when the lesion is dependent upon organic disease of the brain, or of the cerebro-spinal axis. The principal local remedies are leeches, blisters, stimulating embrocations, veratria ointment and the hot and cold douches, followed by dry friction. Occasionally electricity proves beneficial.

CHAPTER IV.

DISEASES OF THE LYMPHATIC VESSELS AND GANGLIONS.

THE pathologist can certainly not boast of his knowledge of the diseases of the lymphatic vessels; he knows, it is true, that they are liable to inflammation, but of the manner in which it is produced, and of the effects to which it gives rise, he is, in great measure, ignorant. That these vessels play an important part in various affections is extremely probable; but such are their excessive tenuity and the great delicacy of their structure that no one has yet been able to point out the character and amount of their participation. It has been supposed that at least one form of cutaneous disease, namely, erysipelas, essentially consists in inflammation of the absorbents, and it must be confessed that the opinion, although insusceptible of demonstration, is highly plausible.

SECT. I.—LYMPHATIC VESSELS.

Inflammation of these vessels, technically called *angeioleucitis* or *lymphatitis*, has hitherto been studied to most advantage in connection with external injuries, particularly punctured and poisoned wounds, of which it is by no means an infrequent consequence. Doubtless, the disease is sometimes idiopathic, or dependent upon internal causes, such as give rise to erysipelas and other bad forms of inflammation in the cutaneous and other tissues. When arising as a consequence of an abrasion, or the prick of a needle, as in sewing up a dead body, the affected vessels can be easily traced, as they pass beneath the skin, as

small reddish cords, tense, nodulated, and painful to the touch, accompanying the principal veins, and extending as far as the nearest ganglions, in which they appear to terminate. The number of these reddish lines is variable; sometimes there are only two or three, while at other times there are as many as six, ten, or a dozen, forming a kind of band, from half an inch to an inch in width. Whenever the number is considerable, there is always a good deal of concomitant swelling; and the parts, feeling stiff, sore, and tender, readily pit on pressure, owing to the effusion of sero-plastic matter. In the more severe attacks of *angeioleucitis*, as those consequent upon inoculation with putrid or poisonous matter, the tumefaction soon becomes general, spreading rapidly over the whole limb, and the discoloration, losing its striated appearance, so characteristic of the disease in its earlier stages, also assumes a diffusive disposition. Arrived at this point, it is usually impossible to distinguish this affection from ordinary *erysipelas*, so closely do the two lesions resemble each other.

Occasionally the inflammation seems to take its rise in the deeper layers of vessels, and then the discoloration is generally preceded by considerable induration of the subcutaneous areolar tissue, giving the part a kind of brawny sensation; by and by, however, red streaks appear in the skin, and then the disease follows pretty much the same course as when it begins in the superficial vessels.

However originating, the affection nearly always involves the neighboring lymphatic ganglions, causing them to enlarge, and to become tender, red, and painful. In some of the worst forms of *angeioleucitis*, the glands manifest signs of being diseased before the absorbents themselves are apparently implicated. Such an occurrence, although uncommon, is occasionally met with in inflammation of these vessels consequent upon dissection wounds.

Angeioleucitis no doubt sometimes passes into suppuration, and, perhaps, even into gangrene; but of these occurrences, as pure, uncomplicated affections, our knowledge is too imperfect to justify a positive opinion.

The *symptoms* ushering in an attack of *angeioleucitis* are usually such as are denotive of constitutional depression, following pretty closely upon the injury sustained by the affected vessels. The patient, after having felt indisposed for some hours, seldom more than from twelve to twenty-four, is seized with chilly sensations, accompanied with flushes of heat, a disposition to yawn, headache, pain in different parts of the body, and a dry and contracted state of the skin. Sometimes the attack is announced by violent rigors, rapidly succeeded by high fever, and delirium. If the local affection is at all severe, the symptoms soon assume a typhoid character, the pulse becoming weak and frequent, the surface hot and dry, and the tongue covered with a brownish fur. The local distress, meanwhile, increasing, abscesses form in different portions of the limb, the matter being of a foul, unhealthy character, and disposed to spread extensively among the surrounding structures, in the same manner as in *erysipelas* and other bad forms of inflammation.

Angeioleucitis may be confounded with other diseases, particularly *erysipelas* and *phlebitis*, and the distinction is by no means always so easy as might at first sight appear. In fact, it can only be made out satisfactorily in the earlier stages of the complaint, the principal source of diagnosis being the red striated appearance of the affected surface, reaching from the seat of the injury up to the nearest lymphatic ganglions. In *phlebitis*, the discoloration is also linear, but the cords are much larger, firmer, more knotty, and more deeply seated; they are also less numerous, and there is not nearly so much involvement of the lymphatic glands. In *erysipelas*, the inflammation usually begins as a circumscribed affection, with diffuse, uniform redness, not striated, as in *angeioleucitis*, or in *phlebitis*.

In the *treatment* of this disease, the same general principles are to be observed as in the treatment of *erysipelas* and *phlebitis*, to which it bears so close a resemblance. The exciting cause being removed, such local and general means are to be employed as may seem to be best adapted to the exigencies of each particular case. Bearing in mind that, if the disease is at all severe, the symptoms will be likely soon to assume a typhoid character, the surgeon will take care not to deplete much, especially with the lancet and purgatives, lest he be instru-

mental in inducing fatal exhaustion, of which the danger may be already sufficiently great in consequence of the progress of the morbid action. Leeches may be applied along the course of the affected vessels, but not directly over them, if the disease is in its earlier stages, and the patient is robust and in the prime of life. They should be employed in considerable numbers, and be succeeded by warm fomentations, the whole limb being enveloped in flannel cloths wrung out of a strong solution of acetate of lead and opium, and kept constantly wet. The application of iodine will also be found advantageous; also, a long, narrow blister, stretched along the course of the affected vessels, and retained for a sufficient length of time to produce thorough vesication. If matter form, or great tension and throbbing exist, suitable incisions must be made.

The constitutional treatment must be regulated by the character of the general symptoms. Purgatives, to clear out the bowels and correct the secretions; iron, or iron and quinine, to improve the tone of the system and the state of the blood; and anodynes, to allay pain and induce sleep, with a properly regulated diet, will constitute the most reliable and efficient means. If marked debility arise, brandy, wine, or porter, with nutritious broths, will be required. When the disease proves obstinate, or becomes chronic, a mild mercurial course will be beneficial.

Varicose enlargement of the lymphatic vessels has occasionally been noticed, although the occurrence is extremely uncommon. In a case mentioned by Carswell, of a young man, twenty-six years old, a tumor nearly as large as an orange existed in each groin, for which he had worn a double truss from his boyhood, under the supposition that he had hernia. On dissection, however, each tumor was found to consist of enormously dilated absorbent vessels connected with the inguinal ganglions. When cut into, instead of presenting a solid, compact structure, it had the appearance of a coarse sponge, most of the vessels being from one to three lines in diameter. The same phenomenon was witnessed, only in a more striking degree, in the lymphatics of the pelvic and lumbar regions. The spongy and elastic character of such a swelling ought to prevent any serious error of diagnosis. Hardly any treatment would be necessary in such a case. Excision might prove dangerous, and should not be practised without due deliberation.

In wounds of these vessels there is occasionally a real lymphorrhœa or a discharge of thin, pale, whitish fluid, standing like drops of sweat upon the affected surface. The exudation has been known to continue for a considerable length of time, and to interfere perplexingly with the healing process. Vidal and Lebert have each described a case in which small transparent vesicles, filled with lactescent fluid, formed upon the thigh and scrotum. In the case detailed by the latter, the vesicles, after having obtained a certain bulk, broke, and discharged their contents, which, on analysis, were found to contain sugar of milk and minute clots. The patient, aged twenty-one years, was affected with hypertrophy of the scrotum.

When a wound with such a discharge is slow in healing it may at length degenerate in a troublesome *fistule*, difficult to cure, and the seat of a constant exudation of milky fluid, mixed with pus. The remedies most likely to afford relief in such a case are systematic compression and the application of the solid nitrate of silver. Should these fail, recourse should be had to the knife, Vienna paste, or the actual cautery.

SECT. II.—LYMPHATIC GANGLIONS.

The lymphatic ganglions are liable to inflammation, chronic enlargement or hypertrophy, carcinoma, tubercle, earthy degeneration, and fibro-plastic tumors.

Inflammation of these bodies, technically called adenitis, may show itself either as an acute or a chronic affection, and is of such remarkable frequency as to demand special consideration. In whatever form it occurs, it is most common in young children of a strumous predisposition, and is generally brought on by attacks of cold, or by some local irritation implicating the afferent lymphatic vessels. The disease, moreover, may be common or specific, of the latter of which illustrations

are afforded in syphilitic bubo, in the bubo of plague, and in the swelling of the lymphatic ganglions of the axilla consequent upon dissection wounds and malignant pustule.

1. *Acute adenitis* is most common in the ganglions of the neck, jaw, and supra-clavicular region; it is also occasionally met with in those of the groin and axilla. The disease may be limited to one of these bodies, or, as is more generally the case, affect a considerable number of them; beginning as a hard, painful knot, exquisitely tender to the touch, and rapidly increasing in size, until, in some instances, it attains the volume of an almond or a pullet's egg. The increase in the size of the tumor is sometimes exceedingly rapid, as we often see in adenitis of the neck from exposure to cold, where a body of this kind, scarcely perceptible in the natural state, may, in the course of a few hours, acquire the size of a filbert or a small marble. As the disease advances, the swelling extends to the connecting areolar tissue, the skin becomes red and inflamed, and the parts pit on pressure. The discoloration is not unfrequently of an erysipelatous character. When the inflammation is fully developed, the local distress is usually very severe, and the constitution actively sympathizes with the suffering textures, the patient being feverish, deprived of appetite and sleep, and affected with constipation.

Dissection shows the affected ganglions to be of a deep reddish or brownish color, infiltrated with sero-plastic fluid, softened, lacerable, or easily crushed with the finger; the cellular tissue around is also abnormally vascular and infiltrated, and, in many cases, it seems to be the principal seat of the morbid action.

Adenitis may end in delitescence or resolution, pass into suppuration, or assume a chronic character. The occurrence of gangrene is very uncommon.

Adenitis sometimes vanishes in a few hours, either spontaneously, or under mild treatment. We often see enlarged and inflamed ganglions of the neck, or at the angle of the jaw, most rapidly disappear under frictions with ammoniated liniment, aided by hot drinks and immersion of the feet in hot water, or simply warming the feet near the fire. When the inflammation is more severe, an active purgative will be necessary, followed by a gentle diaphoretic, as one-fourth of a grain of morphia with one-half that quantity of tartar emetic. The diet must be light, and the part and system must be kept perfectly at rest. If the inflammation threaten to prove troublesome, or to pass into suppuration, leeches and medicated fomentations must be employed. In many cases the dilute tincture of iodine will be beneficial in cutting short the disease.

When adenitis passes into *suppuration*, matter generally begins to form from the fifth to the tenth day, sooner or later, according to circumstances, the event being generally most rapidly excited in young, weakly, or scrofulous children, with an impoverished state of the blood. The pus is not always situated in the enlarged ganglions; in many cases, in fact, it is limited, in great degree, if not entirely, to the neighboring areolar tissue. It is of a light yellowish color verging on greenish, thick, and often very copious; occasionally it is mixed with blood, and with the debris of the affected ganglions. Finally, the matter may occur as an infiltration, or as a distinct abscess. The microscopical characters of pus from a lymphatic ganglion are seen in fig. 202.

Fig. 202.

Scrofulous pus from a lymphatic gland. 250 diameters.

The occurrence of suppuration is announced by increased heat, pain, redness, and swelling, along with a sense of throbbing, and by high constitutional disturbance, attended by chilly feelings, or even rigors, followed by fever and perspiration.

The *treatment* is strictly antiphlogistic. If the phenomena are clearly denotive of the existence of pus, an early incision is made, free and dependent, to favor thorough evacuation and prevention of reaccumulation. The operation is followed by warm water-dressing or an emollient cataplasm. The use of a tent will occasionally be required to maintain patency of the puncture.

2. *Chronic adenitis* is a very common occurrence; it generally succeeds to

the acute variety of the disease, but there are cases in which it is seemingly, although not in reality, a primitive affection. However this may be, its effect is gradually to produce enlargement and induration of the affected bodies, until, in

Fig. 203.

Hypertrophied lymphatic glands.

many cases, there is complete subversion of the natural structure. In the earlier stages of the disease, the gland is of a reddish, brownish, mottled hue, considerably increased in size, and of a firm, fleshy consistence; by and by, however, it assumes a grayish or whitish aspect, becoming almost homogeneous, and cutting very much like an unripe apple or pear; in some cases it is quite soft and lacerable. When the transformation is very great, the hardness of the gland may be equal to that of scirrhus, with which it is then liable to be confounded.

A distinct capsule, composed of dense cellular substance, generally surrounds the enlarged body, which is capable, under such circumstances, of attaining the volume of a small orange. When a number of such ganglions are agglomerated together, a large tumor is formed, of a hard, firm consistence, more or less adherent to the neighboring parts, and of an irregularly lobulated appearance, as in fig. 203, copied from one of my preparations.

Chronically enlarged or hypertrophied lymphatic ganglions may occur in any part of the body; but they are most commonly met with in the neck, or about the lower jaw. In the internal cavities they are most frequently seen in the mesentery and pelvis, and at the root of the lungs. The effect which these bodies exert upon the structures among which they are situated, is principally of a mechanical character; compressing them, and so interfering more or less with the exercise of their functions. Thus, in the neck they may cause injurious pressure upon the trachea, vessels, and nerves; in the pelvis they may interfere with parturition by preventing the descent of the child's head; while in the lungs they may occasion suffocation by obstructing the entrance of air into the bronchial tubes.

Various causes may give rise to this affection; some of a local, others of a purely constitutional nature. In the neck, it is often occasioned by cold, or by disease of the jaw, teeth, gum, or tonsil; in the groin, by ulceration of the penis; in the axilla, by disorder of the mammary gland; in the mesentery, by irritation of the small bowel. The most efficient general cause is a strumous state of the system; but there is reason to believe that the lesion may be produced by anything that has a tendency to derange the general health, or to impoverish the fluids and solids.

Chronic enlargement of the lymphatic ganglions often continues for years, now advancing, then stationary, and now, perhaps, receding; in general, however, the disease is obstinate, especially when the structure of these bodies has undergone serious organic changes, in which case it is often extremely difficult, if not impossible, to reclaim them by any mode of medication of which we have any knowledge.

The *treatment* of chronic adenitis is both constitutional and local. In the first place, the exciting cause is looked for, and, if possible, removed; the carious tooth is extracted, the ulcer on the penis healed. The general health is improved by attention to the bowels and secretions, and by a strict observance of the laws of hygiene. When plethora exists, detraction of blood, and the antimonial and saline mixture will be of service; under opposite circumstances, the proper remedies will be a nutritious diet, and alterant tonics, consisting of iodide of iron and quinine, bichloride of mercury, iodide of potassium, and cod-liver oil. When there is no contra-indication, minute doses of mercury in Huxham's tinc-

ture of bark will often be highly efficacious, but care should be taken not to carry it to profuse ptyalism. Tartar emetic also, given in small doses, as the tenth or twelfth of a grain, three times a day, will frequently prove eminently beneficial. In most cases a regular system of purgation should be maintained. The German practitioners are fond in this disease of the use of hydrochlorate of ammonia, administered in doses of from five to ten grains three times in the twenty-four hours. The article is a powerful sorbefacient, and is therefore worthy of trial, especially in cases refusing obedience to the more ordinary measures.

Among the more important topical remedies are leeches, and sorbefacient liniments, unguents, and embrocations, assisted by systematic and steady compression. These means must be employed with great caution and judgment, otherwise they will be sure to be productive of harm instead of benefit. All sorbefacient applications should, in the first instance, be of a mild character, their strength being gradually increased as the parts become more tolerant of their impression, and their peculiar effects are rendered more and more apparent. When the enlarged ganglions are favorably situated, compression will often be found to be a most admirable remedy; it may be applied with the pad of a truss, as in hypertrophy of the inguinal glands, or with a compress and bandage when it affects the glands of the neck, care being taken not to interfere with respiration. In obstinate cases, the application of a blister occasionally exerts a salutary influence, relieving the enlarged structures of engorgement, and stimulating the absorbent vessels so as to induce them to remove morbid deposits. The electric current has sometimes been advantageously used. Subcutaneous division of the enlarged glands, or comminution with the bistoury, has occasionally been practised, but the effects have not been such as to render a repetition of the operation at all desirable.

Finally, when the disease is intractable, our only resource is removal of the morbid mass, provided it is situated favorably for such a procedure. Such a step, however, should not be lightly taken, as it must often involve serious consequences, on account of the deep situation of the tumor, and its connection with important structures. In the cervical region, for example, the excision of a mass of enlarged and indurated lymphatic ganglions not unfrequently proves a most difficult, embarrassing, bloody, and hazardous operation. Removal will be much facilitated, if the knife be kept close to the hypertrophied glands. Sometimes the enlarged and disintegrated structures may be pressed out bodily through a small opening in the integuments. When the diseased mass compresses the trachea or great vessels of the neck, and does not admit of removal, relief must be sought by the subcutaneous section of some of the constricting muscles, especially the sterno-cleido-mastoid.

3. *Carcinomatous disease* of the lymphatic ganglions is occasionally met with as a primary affection, more particularly the encephaloid variety. Scirrhus is extremely uncommon; colloid I have never seen here; and of melanosis I have witnessed only a few instances. As a secondary formation, cancerous disease of the lymphatic ganglions is very frequent.

Primary *encephaloid* is most common in the lymphatic ganglions of the groin, axilla, and neck; it occurs in both sexes, and at various periods of life, in children and adolescents, as well as in subjects after the age of fifty. In general, the disease arises spontaneously, but in some cases its origin may be distinctly traced to external injury, as a blow or kick. Its progress is usually very rapid, few persons surviving its attack longer than from six to twelve months. Beginning commonly in one of these bodies, as a hard, smooth, semi-elastic swelling, it soon extends to those in its immediate vicinity, thus often involving a whole group of ten, fifteen, or even twenty. In consequence of this arrangement, the tumor has generally a knotty, lobulated surface, and not unfrequently acquires a large bulk, equalling, or even exceeding, that of a fist. Soft and elastic at one point, it is hard and firm at another, while at a third it is occasionally almost of a fluid consistence. As it progresses it contracts firm adhesions to the surrounding parts, the skin becomes attenuated and discolored, and the subcutaneous veins assume that peculiar varicose disposition so common in encephaloid in

other parts of the body. By degrees, the morbid mass breaks through its confines, ulcerating and fungating, and destroying life either by hemorrhage or by hectic irritation.

Examined after removal, the morbid mass is found to consist of a soft, brain-like substance, inclosed in thick, strong membranous cysts, representing the original capsules of the affected ganglions, but greatly condensed by the pressure of the contained matter. In addition to these cysts, there is generally a large quantity of filamentous tissue, intersecting the parts in different directions. A grumous looking, semi-organized substance often occurs in these tumors, and there are cases in which they contain serous cysts. In an instance of encephaloid of the axillary ganglions, which I observed in a man fifty-six years of age, there was a cavity of this kind which distinctly fluctuated under the finger, and gave vent, on being punctured, to upwards of eight ounces of sero-sanguinolent fluid.

The diagnosis of encephaloid of the lymphatic ganglions is easily made; the only affections with which it is liable to be confounded being chronic enlargement and tubercular disease, from both of which it may be distinguished by the history of the case, and the rapid growth and soft consistence of the tumor. In chronic enlargement, the swelling is hard, and often involves a whole chain of ganglions; in tubercular disease the swelling, also very firm, generally manifests a disposition to suppuration, and is nearly always associated with other marks of the tubercular dyscrasia.

The proper remedy is early extirpation, although the disease will be certain to recur, and ere long prove fatal. Such a result will generally occur much sooner in young than in elderly individuals, and it has, therefore, been a question whether they should ever be subjected to operation.

Primary *scirrhus* of the lymphatic ganglions is extremely uncommon; in the few cases in which it has hitherto been observed it occurred in the cervical, inguinal, and axillary regions of elderly persons. The disease is comparatively tardy in its progress, and the tumor, which is distinguished by its great hardness, seldom acquires any considerable bulk. My opinion is that what is usually considered as scirrhus of these bodies is nothing but fibro-plastic disease.

Melanosis of the lymphatic ganglions may occur as a primary affection; generally, however, it is associated with melanosis in other parts of the body. I have noticed it in a few instances in the lymphatic ganglions of the groin and axilla, which, I believe, are its most frequent seats. It shows itself either as an infiltration, as in fig. 204, from a specimen in my cabinet, or as an irregular tumor, solid, inelastic, and of variable size and shape.

Tubercular disease of these bodies is met with chiefly in young subjects, before and soon after the age of puberty; most generally in children. Now and then it occurs in elderly persons, but this is very uncommon. Surgically considered, it is most frequent in the ganglions of the neck and jaw, and may be limited to one of these bodies, or, as is most generally the case, affect a large number of them, either simultaneously or successively. It often coexists with tubercular disease of the lungs, joints, and other parts. As this subject, however, has already been discussed in the chapters on scrofula and tumors, any further remarks respecting it here would be superfluous.

The lymphatic ganglions occasionally undergo the *earthy degeneration*, as in fig. 205, being converted into a soft, whitish substance, not unlike chalk. Such an occurrence is most common in the bronchial and mesenteric ganglions, but is also sometimes seen in those of the neck. Not long ago I met with a case in which not less than five of the cervical ganglions had become completely calci-

Fig. 204.

Melanosis of a lymphatic gland.

Fig. 205.

Earthy degeneration of the lymphatic glands.

fied; they were of stone-like solidity, of a light brownish color, rounded, and from the size of a pea to that of a hazel-nut. The patient was a middle-aged, strumous female, and the ganglions, which formed a chain along the inner edge of the sterno-cleido-mastoid muscle, on the right side, had been affected from early youth. Their character was obvious on the slightest touch. Excision was easily effected. Such tumors need not be interfered with, unless they become a source of annoyance by their situation.

The *fibro-plastic* tumor is sometimes found in these bodies, the proper tissue of which is replaced by a whitish, dense, solid substance, which, to the naked eye, as well as under the microscope, presents all the characteristic features of this morbid growth. The tumor generally occurs in young subjects, after the age of puberty, and is capable of acquiring a bulk varying from that of an orange to that of a fist. It is easily recognized by its firmness and slow but steady progress, and by the absence of pain and constitutional involvement. The proper remedy is excision.

CHAPTER V.

DISEASES AND INJURIES OF THE ARTERIES.

SECT. I.—WOUNDS AND HEMORRHAGE.

THERE can be no more terrible and appalling sight to a patient and his friends than hemorrhage from a divided artery, especially when the blood is gushing out in a full and angry torrent, threatening every moment to put an end to existence. There is something indescribably sickening and distressing in such a scene, from which every sensitive mind shrinks with dismay and bewilderment. The horror of the scene is increased a hundred-fold, when we are unable to afford the requisite relief. But the sight of blood is not disagreeable only to the common observer; there are few surgeons, however heroic, or well disciplined, who do not, at times, participate in this feeling. If it were not for the frightful hemorrhage which so frequently attends them, operations would be robbed of nearly all their terror, and few men would shrink from their performance. Fortunately, or unfortunately, however—for it is not easy to determine which—this is not the case; the slightest incision is often followed by profuse bleeding, and in the extirpation of tumors, in the removal of limbs, and in various other proceedings, the patient has reason, in many cases, to congratulate himself if he do not perish from the loss of blood. Some of the more serious accidents, as incised, gunshot, and punctured wounds, often prove instantly fatal from hemorrhage; or, if syncope should, luckily, ensue, and thus temporarily arrest the bleeding, death may occur subsequently, but not less certainly, from the same cause. It is for these reasons that hemorrhage has always been a source of so much anxiety to the surgeon, and that its study has engaged so large a share of his attention from the earliest ages of medical science down to the present time. It is, indeed, impossible for him to be too well acquainted with the subject, or too thoroughly prepared to meet its various, trying, and painful emergencies. The reflection, which must often arise, under such circumstances, that possibly all was not done that might have been done, if greater skill had been exercised, is well calculated to overwhelm the sensitive and conscientious surgeon, and to induce a degree of distress which no one, who has not himself experienced it, can possibly appreciate. I do not envy that man his feelings who, through ignorance, inattention, or indecision, allows his patient to perish from loss of blood when he ought to have saved him.

The characteristics of arterial hemorrhage are, first, the scarlet color of the blood, and, secondly, the peculiar manner in which it issues from the injured vessel; it spirts out in jets, synchronously with the contraction of the left ventricle, and not in a steady, continuous stream, as when it comes from a vein. This, however, is true only of the larger arteries; for, when the smaller branches are severed, their contents escape very much like those of a vein, only more forcibly, the fluid even then often projecting to a distance of several feet. When one of the principal trunks is divided, the blood is frequently sent with great violence to the ceiling, or far across the room, to the horror and dismay of every one present. The effects of hemorrhage vary very much, and are by no means always in proportion to the extent of the injury. When proceeding from a large artery, or a considerable number of small ones, it may prove almost instantly fatal, or, at all events, in a few minutes. In general, however, the case does not progress in this manner. The patient, after the bleeding has continued for some time, is seized with syncope, and now, the heart's action being greatly depressed, an opportunity is afforded for the formation of a clot both within and around the artery, followed by an arrest of hemorrhage. By degrees reaction takes place, color returns to the cheek, the extremities become warm, and the pulse reappears at the wrist. With these phenomena recurs the danger of bleeding. As the heart's action augments, the blood is again vigorously propelled through the body, and, presently, the temporary clot being washed away, the wound is reopened nearly, if not quite, to its original extent. Again fainting occurs, a new plug is formed, and for a time life is once more free from immediate risk; but this truce, like the first, is of short duration; the same scene is re-enacted a second and a third time, until at last, by the repeated drain, the heart and the brain are no longer capable of supporting each other in the fearful struggle, and the patient sinks completely exhausted.

A person dying from repeated losses of blood, consequent upon the division of a large vessel, presents a fearful picture. His countenance is ghastly pale; his pupils are widely dilated; he pants and sighs for breath; his ideas are vague and confused; he is sick at the stomach and vomits; the extremities are icy cold; and the whole surface is covered with a profuse, clammy perspiration. The thirst is usually intense and unquenchable, the largest quantity of water failing to satisfy the urgent wants of the system; excessive restlessness and jactitation succeed; the patient calls loudly for cold air; paroxysm after paroxysm of swooning recurs; the pulse has, perhaps, already been long absent from the wrist; the eyes assume a glazed and fixed expression; the respiration grows more and more feeble; and death often steals on so imperceptibly as to render it difficult to determine the precise moment of its occurrence. During

all this time, whether it embraces only a few minutes or hours, or whether it extends through several days, there is generally an entire absence of pain, the loss of blood operating as an anæsthetic.

If we inquire into the nature of wounds of the arteries, we shall find that they do not differ, as it respects the weapons with which they are inflicted, from wounds in other tissues. Thus they may be incised, punctured, lacerated, contused, or gunshot, and it would frequently be difficult to determine which class is the worst, or the most certainly and speedily fatal. In regard to their size they present every possible gradation, from the slightest incision to the complete division of the vessel; the wound being either oblique

or transverse in the latter case, but of various shapes when the lesion is partial. Occasionally the wound consists of a mere vertical fissure. The different ap-

pearances here alluded to are well displayed in fig. 206. The extent and character of the wound necessarily exert great influence upon the amount and duration of the hemorrhage, and therefore demand careful study.

When an artery has been completely cut across, there is an instantaneous and impetuous flow of blood, followed immediately by the retraction and contraction of each end of the vessel, as exhibited in fig. 207. The effect of this double action is to diminish the amount and force of the stream, but not to arrest it; instead of this it usually continues until a coagulum has formed upon the orifice of the artery, as well as in the parts immediately around, particularly in the loose cellular tissue constituting its sheath. In this manner a mechanical obstacle is opposed to the effusion of blood, but this would soon be washed away if it were not aided and fortified by the speedy development of a coagulum within the vessel, extending usually as high up as the first large collateral branch. These clots, of which the first bears the name of external, and the other that of internal, fig. 208, are the means which nature employs to put a stop to the hemorrhage; not, however, until, as a general rule, it has proceeded to the extent of syncope, a circumstance always eminently favorable to the coagulation of the blood, and, consequently, also to the formation of the clots now described. But these clots, at this stage of the process, are necessarily very soft, as well as very imperfectly adherent; hence, in order to guard against their detachment, or, what is tantamount to the same thing, against a recurrence of the hemorrhage, it is imperative that plastic matter should speedily be effused, so that all these parts—clots, vessel, and surrounding structures—may become effectually and permanently soldered together. This accordingly soon happens; for within a few hours after the occurrence of the injury inflammation is enkindled, both in the divided artery and its sheath, and this being followed by a deposit of lymph, the parts in question are more firmly fixed in their respective situations, every day adding to their security and stability. Meanwhile, a process of organization is instituted, the first step of which is the removal of the serum and coloring matter of the clots, thereby rendering them more pale and solid; vessels now show themselves, some of them being probably of new formation, while others, and perhaps the greater number, are derived from the divided artery and its sheath, as well as from the surrounding structures.

The two clots now described are, it will be seen, inseparably blended at the orifice of the divided vessel, and their form and arrangement may not inaptly be compared to a glass stopper, closely fitted into the neck of a decanter. The outer clot is rough and irregular, whereas the internal is perfectly smooth and cylindrical, except its cardiac extremity, which is nearly always conical, as in fig. 208. The longer the internal coagulum is the less danger will there generally be of its premature detachment.

The changes above mentioned as occurring in the two clots are generally the work of time; the gluing process is usually effected rapidly, since its intention is to protect the patient against hemorrhage; but the removal of the serum and coloring matter of the blood, and the conversion of this fluid into solid matter,

Fig. 207.

Fig. 208.

Plan of natural hemostatics, in a cut artery. At *a*, the cut end of the arterial tube, conical, by contraction. At *b*, the arterial sheath, vacated by the retracted artery, and occupied by coagulated blood. At *c*, the coagulum projecting from the orifice of the sheath.

take place more slowly, and are often not completed under several months.

Fig. 209.

Change in the shape and structure of an artery after ligation.

Finally, if the parts be examined at a still later period, it will be found that both clots have entirely disappeared, and that the injured vessel, as high up as the first large collateral branch, has been transformed into a dense, strong, fibrous cord, fig. 209, similar to that observed in the umbilical arteries of the infant.

Such, then, is the process which nature employs for arresting the flow of blood from a divided artery. Taking advantage of the exhausted condition of the system consequent upon the shock and loss of blood, she instinctively forms the two clots, having, first of all, drawn away the vessel from the main wound, as well as caused it to diminish its caliber, and then she goes deliberately to work to fasten these clots at points precisely where they are most needed for the purpose. The vessel being thus hermetically sealed, she afterwards busies herself still further in getting rid of these plugs, as they are now no longer required, and, finally, completes the labor by converting the obsolete extremity of the artery into an analogous tissue. These changes, so profoundly curious and interesting, bear, it will be perceived, a very close resemblance to those which take place in the callus of a broken bone.

After the ligation of an artery, the supply of blood in the parts beyond the seat of the obstruction is maintained by what is called the collateral circulation, the vessel above communicating freely with that below, as in fig. 210, by its anastomosing branches.

When an artery is divided only partially, whether transversely, obliquely, or longitudinally, an external clot forms, but this is generally so imperfect as to render it altogether incapable of opposing an effectual barrier to the flow of blood.

Fig. 210.

Diagram of collateral circulation.

What adds to the difficulty is that the edges of the wound have a constant disposition to gape; and hence, although plastic matter may perhaps be deposited in great abundance, yet it is impossible for the parts to contract permanent and satisfactory adhesions to each other. Whenever the circulation is conducted with any degree of vigor, the blood as it sweeps along washes off the clot, and appears upon the exterior of the wound; and thus the hemorrhage usually continues, paroxysm after paroxysm recurring in more or less rapid succession, until it proves fatal.

Although such is the course which the case usually pursues when an artery is divided only in a part of its diameter, it must not be thence inferred that a very small lesion of this kind may not occasionally be susceptible of spontaneous cure. Such an event, which must, however, at best, be extremely rare, may be supposed to be most likely to occur when the wound is oblique or longitudinal; when the opening in the overlying parts is a mere fissure or canal,

offering an imperfect outlet to the contents of the vessel; when the system remains for a long time in a prostrate condition; and when, finally, there is a rapid and abundant deposit of plastic matter in the various structures involved in the injury. I have several times seen small shot wounds of the larger arteries, as the subclavian and femoral, healed in this manner; and there is reason to believe that punctures made accidentally in the brachial, in bleeding at the bend of the arm, are occasionally repaired either by the direct adhesion of their edges, or through the intervention of an external clot. In general, however, all such lesions are followed either by hemorrhage, or aneurism, according to the opportunity, or otherwise, which the blood may have in finding its way to the surface.

It is well known that contused and lacerated wounds of the arteries bleed much less freely than incised. The reason of this has already been explained in the chapter on wounds, and need not, therefore, be reproduced here.

But, although nature may, and, indeed, sometimes does, arrest the hemorrhage from a divided artery, yet no sensible surgeon would intrust her with such an office, when it is in his power to get at the seat of the wound; for it is hardly possible to conceive of a case involving one of the larger trunks where her efforts would be likely to be successful, or where, if ultimately triumphant, the patient would not be brought repeatedly to death's door before she could attain her end. It is only in wounds of the internal arteries, as those of the chest and abdomen, and in the aorta and its larger branches, that we must refrain from direct interference, and limit ourselves to the use of general means calculated to keep down vascular action, especially the liberal use of anodynes and sedatives, as opium, aconite, and acetate of lead, the application of ice over the seat of the injury, exposure of the patient to cold air, and perfect quietude of mind and body. All active exertion must for a long time be avoided, in order that, if a cure should take place, the wound may not be suddenly reopened by the giving way of its edges, in consequence of the imperfect organization of the clots and plasma.

The means employed by art for suppressing hemorrhage are quite numerous, as well as greatly diversified in their nature, and will therefore require to be considered somewhat in detail. The most important of these means are: first, the ligature; secondly, compression; thirdly, styptics; and fourthly, torsion. Besides these there are several others of a subordinate character, meriting merely a passing notice.

1. *Ligature*.—Ligatures are composed of various materials, as silk, linen, and soft leather. Of these, the first is the most unexceptionable, and almost the only one now employed. It should be round, smooth, well twisted, colorless, and so strong as not to break without considerable effort. For the smaller arteries, as the radial, tibial, and temporal, common sewing silk is well adapted; but for the larger trunks, as the femoral, iliac, and carotid, stay silk, a much stouter article, is required. Some practitioners are in the habit of using what is called dentist's silk, no matter what may be the size of the vessel, on the ground that it is much stronger in proportion to its thickness than any similar substance, and, therefore, less liable to excite undue irritation. This thread, which is employed in making fishing lines, is rendered very hard and stiff by means of gum, which, however, is easily removed by boiling it for a few minutes in a slightly alkaline solution. Treated in this way, a piece long enough to tie the iliac artery will hardly weigh the twenty-fifth of a grain. I have not had occasion to use this form of silk, having always had reason to be satisfied with the common article. Linen thread makes an excellent ligature; and in case of emergency, a sensible surgeon will not hesitate to take anything that may happen to come in his way. Whatever substance be employed, it is very important that it should be thoroughly waxed, otherwise it will be difficult, if not impracticable, to draw and tie it with the requisite degree of firmness, to say nothing of the greater tendency of the knot to slip. From eight to ten inches is a good average length for a ligature.

Animal ligatures were first introduced to the notice of the profession by Dr. Physick, early in the present century, and they have ever since been occasionally employed by different practitioners, chiefly American. The late Dr. Jameson,

of Baltimore, used them nearly altogether for many years, under the belief, founded upon numerous experiments and clinical observations, that they were decidedly superior to all others, their presence never causing any of the irritation which sometimes follows the application of the ordinary substances. The article to which he gave the preference was soft buckskin leather, cut into thin, narrow strings, care being taken not to tie them too firmly, lest they should break, and be thus prematurely detached. Other practitioners have recommended the fibres of the sinew of the deer. The advantage of the animal ligature is that, besides approaching more nearly to the living tissues than any other material, the ends may be cut off close to the knot; its disadvantage, that it soon becomes disintegrated, from the imbibition of fluids, thereby rendering it liable to separation before it has accomplished the object for which it was applied. This reason is, I conceive, quite sufficient to induce its rejection; for no conscientious surgeon should ever subject his patient to such a contingency, especially when he has always at hand so reliable a substance as silk.

The wounded artery may very conveniently be drawn out with a pair of spring forceps, fig. 211, an instrument which, indeed, I generally prefer, or with a tena-

Fig. 211.

The spring artery-forceps.

culum, represented in fig. 212. If the vessel is small, it should be seized in its longitudinal axis, but in the horizontal if it is large, since in this way we can

Fig. 212.

Tenaculum.

more effectually occlude its orifice, and thus prevent the loss of blood. It is for this reason, also, that the forceps are generally to be preferred to the tenaculum; the latter instrument, however, possesses an advantage over the former when the artery is cut off very closely, or when it is desired to include some of the surrounding tissues. Care must be taken not to transfix the coats of the vessel, and then tie the ligature below the point of perforation, as this might lead to

Fig. 213.

Sliding-forceps.

secondary hemorrhage. When no good assistant is at hand, the artery forceps, delineated in fig. 213, an instrument with broad, serrated extremities, and a movable slide or catch, to close the blades, will be found convenient. The vessel being pulled gently out, as in fig. 214, is carefully isolated from its connections, either with another pair of forceps, the finger, or the knife, or all three together, as may be most expedient. The propriety of excluding from the ligature the

smallest nervous filament, as well as the most insignificant vein, and every particle of muscular tissue, is too obvious to require any comment. Such a pro-

Fig. 214.

Mode of drawing out and isolating an artery.

ceeding is absolutely necessary, not only to prevent pain and suppuration, but to promote the separation of the ligature. The ligature is applied to a sound portion of the vessel, immediately above the instrument, and tied into a single knot, when it is drawn so firmly as to divide the inner and middle tunics, as in fig. 215, if the artery is large, or even of medium caliber; while in the smaller branches, mere apposition of the opposite surfaces is aimed at. In executing this part of the operation, the extremities of the ligature should be wound round the fore and middle fingers of each hand, while the thumb is extended upon them nearly as far over as the vessel, in order that the force may be exerted in as gentle and equable a manner as possible. Nothing is more unseemly, or more truly reprehensible, in a surgeon or his assistant than to pull a ligature by fits and jerks, or so violently as to break it in pieces, or, perhaps, lacerate and tear off the artery itself. With a little care and gentleness, a comparatively weak ligature may be thrown round a vessel so as to answer the intention most fully. I deem it my duty to dwell upon this point with some degree of emphasis, because it has happened to me to witness quite an unusual number of these Herculean feats with the ligature, the men often pulling as if they had hold of a rope and piece of wood, instead of a delicate thread and artery. Fig. 216 shows the indented appearance of the artery after ligation.

Fig. 215.

Effects of ligation upon the inner coats of the artery.

The tying is completed with a double knot, when one end is cut off close, and the other is afterwards brought out at the nearest angle of the wound. The knot which is thus made is the reef-knot, fig. 217, in which the ends of the thread lie across the artery, as in the lips of the wound in the ordinary interrupted suture. The surgeon's knot, fig. 218, is no longer used for the purpose, as, from the manner of making it, it is very irregular, and, consequently, ill adapted to the object. In tying very small vessels, sometimes only one knot is employed.

The practice of cutting off both ends of the ligature, and of closing the wound over the injured vessel, first suggested towards the latter part of the last century, by Mr. Haire, of England, and subsequently so warmly lauded by Mr. Lawrence and Mr. Hennen, is now universally abandoned, and very justly so, on the ground that the noose, after having performed its duty, creates irritation among the parts with which it lies in contact, leading thus to the development of abscesses, which continue to discharge as long as the foreign substance remains. When

the animal ligature is used, this objection does not obtain, as the noose is soon removed by absorption; but then, as was previously observed, this material ought not to be employed, because of its liability to give way before the vessel is completely occluded.

Fig. 216.

Exterior of an
artery after ligation.

When the arteries are diseased, or abnormally brittle, in consequence of the fibrous, cartilaginous, earthy, or fatty degeneration of their tunics, the ordinary ligature must be dispensed with, and a flat one used in its stead. It may consist of two or more silk threads, carefully waxed, and arranged side by side, or of a piece of soft, narrow braid, and should be drawn so gently round the artery as merely to approximate its serous surfaces. In using the round ligature the object is to divide the inner and middle tunics, as this is most favorable to adhesion; but in this case the

Fig. 217.

Reef-knot.

Fig. 218.

Surgeon's knot.

aim is to preserve their integrity, well knowing that if this is not done the ligature will fall off prematurely, and thus occasion secondary hemorrhage. Instances occur in which the fragility of the arteries is so great as to render them incapable of bearing even this degree of pressure; and then our only resource is to include the vessel with a portion of muscular or aponeurotic substance in a flat ligature. Such a procedure is much more rational than the practice, formerly recommended, of tying the artery over a roll of adhesive plaster, an operation which cannot fail to be followed by mischief.

In regard to the propriety of drawing the ligature so firmly as to divide the inner and middle tunics, no doubt is any longer entertained by enlightened practitioners. In the time of Scarpa much disputation prevailed respecting this point in the ligation of arteries, it having been alleged by this distinguished surgeon, on the strength of numerous experiments, that a cure could be effected quite as rapidly, and, in the end, more safely, simply by placing the serous surfaces gently in contact with each other. It was supposed that the part, treated in this way, would unite by direct adhesion, and that, consequently, when the ligature finally became detached, there would be much less risk of hemorrhage than when the vessel is lacerated and contused by the ruder method of procedure above described. Plausible as this theory may, at first sight, appear, it is found to be wholly unreliable in practice, for the very reason which induced Scarpa and his followers to advocate its adoption, the ligature being not only a much longer time in separating, but the two ends of the artery being much less effectually occluded. When it is recollected that a certain degree of inflammation is necessary, after this operation, in order to afford the requisite amount of plasma, for gluing the inner clot to the surface of the vessel, it is reasonable to suppose that it would be much more easily induced by a partial division of the inner and middle tunics than by the mere approximation of the opposite sides of the tube; and this is precisely what the general experience of the profession has at length established in relation to the subject.

When a considerable portion of neighboring tissue is obliged to be included along with the artery, the best instrument for performing the operation is a sharp tenaculum, with an eye near its point, as seen in fig. 219; a curved needle armed with a ligature; or Physick's artery-forceps, fig. 220.

An artery is sometimes rendered incapable of bearing the ligature in consequence of the softening of its tunics by inflammation. Such an event, which is

Fig. 219.

Tenaculum-needle, armed with a ligature.

Fig. 220.

Physick's artery forceps.

often exceedingly perplexing, is most liable to happen in cases of secondary hemorrhage after wounds and amputations. The remedy is to isolate the vessel a short distance beyond its diseased limits, and to ligate it there in the usual manner; or, this being impracticable, to tie the diseased part along with more or less of the surrounding tissues; or, this also failing, to cut down upon and secure the main trunk of the artery.

In tying an artery in its continuity, whether as a means of arresting hemorrhage, or of curing disease, the ligature is passed round the vessel by means of an aneurism-needle, fig. 221, a kind of blunt tenaculum, with an eye at the free

Fig. 221.

Aneurism-needle, armed with a ligature.

extremity. The point of the instrument is gently carried round the vessel, without including any of the accompanying structures, steady counter-pressure being made with the end of the forefinger, especially as it penetrates the connecting cellular tissue.

The precise situation of an artery is determined by its pulsation, and by its anatomical relations. Sometimes its course may be accurately defined by stretching a line from one point to another. At the commencement of the operation, the limb should be forcibly extended, as the muscles and tendons will then be rendered most prominent; but, as the dissection proceeds, the object will be greatly promoted by flexing the limb in order to relax the soft parts. That the artery may not be wounded, its sheath should be carefully pinched up with the forceps, nicked slightly with the scalpel, and then slit open to the distance of a few lines upon a grooved director. Isolation is best effected with the point of this instrument. The proper sheath must be disturbed as little as possible, as it is intimately connected with the nutrient vessels, the injury of which might occasion softening, ulceration or gangrene of the artery. The muscles are separated with the handle of the scalpel, without any material interference with the integrity

of their fibres; and great care is taken, before commencing the incisions, to ascertain the situation of the superficial veins, by compressing the parts above the seat of the proposed operation, as it is very important that they should not be wounded.

The practice of applying two ligatures, and dividing the artery between them, is now very justly abandoned. The operation, which dates as far back as the time of Aëtius, was revived by Mr. Abernethy, through whose influence it became for a while quite popular. It was soon found, however, that it was liable to be followed by secondary hemorrhage, owing chiefly to the injury inflicted during its execution, and it has, therefore, deservedly fallen into desuetude.

It was also in the Aëtian operation that some of the surgeons of the last century employed what was termed the *reserve ligature*, intended as a ready resource in sudden emergencies. The cord was placed loosely round the artery, to be tied instantly in the event of hemorrhage, from the premature detachment of the original ligature. Experience, however, soon showed that the procedure, instead of answering the design for which it had been intended, had a direct tendency to bring about the mischief, from its liability to produce ulceration of the denuded and tortured vessel. Its evils, indeed, are so palpable that there is no probability that it will ever be revived by any enlightened surgeon.

When an artery is cut completely across in the continuity of a limb, as, for instance, in a sabre wound of the femoral, it is necessary to use two ligatures, one for the cardiac, and the other for the distal, extremity of the vessel. The reason of this is that, however securely the cardiac end may be tied, there will inevitably be more or less hemorrhage from the lower end, unless this be tied also, in consequence of the activity of the recurrent circulation. Every one who has ever had occasion to ligate the brachial artery at the bend of the arm, on account of injury inflicted upon the vessel in bleeding, must have seen that the hemorrhage was only partially controlled by tying its upper extremity. The blood, under such circumstances, wells up from the lower part of the artery as water bubbles up from the bottom of a spring; it does not issue in jets, or in a saltatory manner, as when it proceeds from the upper orifice, but lazily, and of a dark color, the bleeding resembling that of a vein rather than of an artery; and thus the hemorrhage goes on, with little or no interruption, until it is arrested by ligature, or until it proves fatal. The flow may, it is true, be temporarily stopped, during an attack of syncope; but even then seldom perfectly, for the reason, apparently, that the vessel here does not possess the same power of contraction and retraction that it does above, and is, therefore, not capable of forming any efficient clot, either external or internal.

The changes which occur in an artery after the application of a ligature are essentially similar to those which occur when the bleeding is arrested spontaneously. The first thing that happens, after such an operation, is the coagulation of the blood within the artery as high up, generally, as the first considerable collateral branch, thus forming what is named the internal clot. The external clot is, of course, wanting, and this circumstance constitutes the chief point of difference in the two cases. The injured tunics, becoming inflamed, pour out plasma not only into their own substance, but also upon the free surface of the serous membrane, by which the internal clot is firmly and permanently fixed in its situation; the clot is next organized, and, finally, after an indefinite period, it is completely absorbed, the corresponding portion of the artery being converted into a dense, fibro-ligamentous cord.

The changes experienced by the arteries and the blood in their interior, after the application of the ligature, are admirably illustrated in the adjoining sketches. Fig. 222 represents the carotid artery of a dog 48 hours after deligation. At *a* the coats are cut across; lymph is effused around, and a clot is formed on each side of the ligature. Fig. 223 exhibits the artery 96 hours after the operation. The extremities of the vessel are surrounded by a mass of plasma, through which the ends of the ligature are seen protruding. Fig. 224 represents the vessel on the twelfth day after the deligation: at *a* the artery is cut open, to

show its interior; at *b* numerous vessels are seen coming from the exterior, and coursing onwards to enter the clot at *c*.

Fig. 222.

Fig. 223.

Fig. 224.

The period at which a ligature is detached varies with many circumstances, of which the principal are, the size of the cord and the manner in which it is tied, the state of the artery, and the amount of the resulting inflammation. A small ligature will, other things being equal, be separated sooner than a large one, and a firm sooner than a loose one; a sound artery will be longer in throwing it off than a diseased one, simply because it has more power of resistance. A ligature upon the brachial artery will generally be detached in about ten days; upon the femoral, in from twelve to fourteen; upon the external iliac, in sixteen; upon the common iliac, in about twenty-one. To this rule there are, of course, many exceptions. I recollect the case of a man in whom, after an amputation of the leg, the ligature was still firmly adherent to the anterior tibial artery at the end of the fourth month. Dr. Lopez, of Mobile, communicated to me, some years ago, the particulars of a case where the separation was not effected before the end of the eleventh month; and Professor Eve met with one where it did not take place until after the thirteenth month. Such occurrences usually depend either upon the faulty manner in which the operation is performed, or upon the presence of an extraordinary quantity of organized plastic matter, interfering mechanically with the detachment of the thread.

When a ligature is indisposed to come away, gentle traction may be made upon it, repeated once in the twenty-four hours; great care, however, must be exercised in performing the operation, otherwise we may not only inflict severe pain upon the patient, but subject him to the risk of secondary hemorrhage.

The process by which the separation of the ligature is effected is worthy of inquiry. It is generally ascribed to ulcerative action, and this is undoubtedly true; but it is equally true that that portion of the artery immediately embraced by the ligature mortifies, and comes away in the form of a slough. When the cord is drawn very tight, the corresponding part of the artery is strangulated, either at once, or, at any rate, within a few hours; but, in general, the process takes place more tardily, and thus affords the two ends of the vessel time to prepare and fortify themselves for the approaching crisis. If we study the whole subject minutely, it will be found to embrace the following acts:—first, the strangulation and death of the vessel at the site of the ligature; secondly, ulceration and the consequent separation of a part of the artery, thus producing a gap in its continuity; thirdly, the adhesion of the clot to the inner surface of the vessel, speedily followed by its organization; and, lastly, the absorption of the clot and the transformation of each extremity of the tube into a dense fibrous cord. In addition to these changes, there is occasionally slight suppuration, the matter usually presenting itself in the form of a little abscess.

The discovery of the use of the ligature is due to Ambrose Paré, in the sixteenth century, prior to whose time surgeons were in the habit of stanching hemorrhage with the actual cautery, hot pitch, and all kinds of styptics, of the most cruel and barbarous nature. “For the good of mankind,” says this great man, “and the improvement and honor of surgery, I was inspired by God with this good thought.” Paré himself fully appreciated the utility of his invention, but his contemporaries spared no pains to undervalue it, and to revile and persecute its author, subjecting him to the humiliation of searching the writings of the ancient fathers of medicine for traces of the use of the ligature as a justification of his practice. Gourmelen, the jealous and malignant President of the College of Physicians of Paris, made himself particularly conspicuous on the occasion, and thus earned an infamous reputation; for the only act by which he is now remembered is his bitter and unrelenting persecution of Paré, rendered immortal by his great achievements.

2. *Acupressure*.—Acupressure, as a means of arresting hemorrhage, was devised by Professor Simpson, who published an account of it in January, 1860. Since that period the operation has attracted much attention, having been performed by different surgeons both in Europe and this country with results generally of a highly gratifying character. What its ultimate fate, however, may be, time alone can determine. That it is destined entirely to supersede the use of the ligature is not at all likely; on the contrary, indeed, highly improbable, inasmuch as the instrument with which the pressure is made can be applied only in certain regions of the body.

The advantages claimed for this operation over that of the ligature are, first, that it is more easy, simple, and expeditious of execution; secondly, that the acupressure needle does not, like the ligature, provoke irritation, much less suppuration, ulceration, or mortification at the seat of the constriction; thirdly, that the instrument may generally be removed, even when an artery of large size, as, for example, the femoral, is concerned, at the end of the second or third day; fourthly, that the wound will, other things being equal, be more liable to unite by the first intention; and, lastly, that there will be much less risk of erysipelas, pyemia, phlebitis, abscesses, traumatic fever, and secondary hemorrhage.

The only instrument required for this operation is a steel pin, sharp at one end and provided at the other with a glass-head, of a rounded shape, sufficiently stiff to prevent it from bending, perfectly smooth, and coated with silver, zinc, or gold, although this is not at all essential. The length of the pin should vary, according to the caliber of the vessel and the diameter of the limb in which it is situated, from two and a half to six inches. In ordinary cases the lady's bonnet pin, or the pin worn by gentlemen in their shawls, will answer every purpose. In regard to the isolation of the artery from the surrounding structures, the same rules are applicable as in the use of the ligature. There is, however, less danger from the inclusion of the accompanying veins, and hence these vessels may with great propriety be embraced along with the artery in the event of their being

disposed to bleed unduly, as they occasionally are in amputations, resections, and the extirpation of large tumors.

In performing the operation, the pin, previously oiled, is passed from without inwards through the skin, and thence on through the muscles and other structures down to, and underneath, the artery, in such a manner as to obliterate completely its caliber by bringing together its opposite surfaces. The instrument is then pushed through the tissues on the other side from within outwards, so that, when the transmission is effected, the extremities shall rest upon the skin, while the middle shall firmly embrace the artery. If the constriction is not sufficient to arrest the flow of blood, a ligature may be thrown tightly round the pin, as in the operation for hare-lip; but this will seldom be necessary, especially if the precaution be taken of inserting the compressor close to the vessel, or at a rather acute angle. The point of compression for the larger arteries should be at least six lines from the open orifice, and about half that distance for those of smaller size. The pin should be left entirely free during the application of the dressings, and in withdrawing it the parts must be well supported in order to avoid the risk of hemorrhage.

The annexed sketches, from Erichsen, will serve to show, at a glance, the application of acupressure. Fig. 225 exhibits the extremities of the pin as they project through the skin, while fig. 226 displays the manner in which the instru-

Fig. 225.

Acupressure, showing the manner in which the ends of the pin project across the skin.

Fig. 226.

Position of the artery and pin in acupressure.

ment embraces and constricts the artery. A good idea of it may also be formed by the manner in which the stalk of a flower is fastened to the lapel of a coat by transfixing the cloth with a pin.

3. *Compression.*—Although the ligature is the most certain means of arresting hemorrhage, yet cases occur to which it is either not at all adapted, or where, from the great depth and narrowness of the wound, it is impracticable. It is then that compression becomes available; an agent often hardly less valuable than ligation itself. It is particularly serviceable when the injured vessel lies upon a bone, as in injury of the brachial and temporal arteries; in wounds penetrating deep cavities, as the thoracic and abdominal; and, lastly, when the blood issues from a considerable number of small vessels instead of escaping from one large one.

The compression may be temporary or permanent, according to the exigencies of the case. When temporary, it is made with the hand, finger, tourniquet, or compress and bandage, and is kept up only until the injured artery can be ligated, or secured in some other effectual way. In permanent compression, the application is continued until the vessel is completely obliterated, whether the time is short or long.

Fig. 227.

Tourniquet applied to the femoral artery.

Temporary compression is necessary chiefly in cases of sudden emergency, as, for example, when an individual is stabbed in the femoral artery, and the surgeon cannot obtain any person to assist him in tying the vessel. In such an event an attempt is made to arrest the hemorrhage with a tourniquet, fig. 227, or with a graduated compress and bandage; the former being placed directly over the course of the artery from which the bleeding proceeds, or, if this is impracticable, over the main trunk of the limb, and the latter directly over the wound as well as for some distance above it, along the track of the vessel. In either case, it is to be borne in mind that the compression, even if it is maintained only for a few hours, may become a source not only of excessive pain, but also of mortification. The greatest possible vigilance should therefore be exercised in its employment.

When the ordinary tourniquet is not at hand, very efficient compression may be made by tying a piece of bandage, a cravat, or a handkerchief loosely round the limb, and then twisting it over a thick compress, to the requisite extent, by means of a stick, fig. 228, or the hilt of a sword, fig. 229, inserted underneath it. This contrivance, usually called the field-tourniquet, because it was originally

Fig. 228.

Field tourniquet; handkerchief and stick.

Fig. 229.

Field tourniquet; handkerchief and sword.

employed on the field of battle, may be resorted to with great advantage when a surgeon is obliged to amputate an extremity without having a sufficient number of intelligent assistants, although it labors under the inconvenience of not always concentrating the pressure upon the spot where it is most needed. For this reason the common tourniquet is always to be preferred.

For arresting hemorrhage in gunshot and other wounds on the field of battle, the most effective tourniquet is that of Mr. Lambert, of Peekskill, consisting of two concavo-convex pads of tin plate, connected by a non-elastic ribbon, nearly two feet in length by an inch and a half in width. When the instrument is applied, one of the pads rests upon the main artery of the limb, and the other upon a point directly opposite, without the slightest intermediate constriction, and, consequently, without any embarrassment whatever of the venous circulation.

Compression with the hand may often be advantageously employed for the arrest of accidental hemorrhage, until the surgeon has time to apply a ligature; and it is also occasionally resorted to for the purpose of controlling the circula-

tion in the main artery of a limb during amputation. In the upper extremity it is generally applied to the brachial artery, as it courses along the inner border of the flexor muscle; and in the lower, to the femoral artery where this vessel lies upon the pubic bone beneath Poupart's ligament. The annexed drawings, fig. 230 and fig. 231, are illustrative of the subject.

Fig. 230.

Digital compression of the humeral artery.

Fig. 231.

Digital compression of the femoral artery.

In *permanent compression* the force is applied in one of two ways, either directly or indirectly. The former method is particularly adapted to the suppression of hemorrhage from deep wounds, as in the lateral operation of lithotomy; in wounds of the rectum, whether accidental or wilful; in bleeding of the nose and uterus; in the removal of tumors from the maxillary sinus; in the extraction of teeth; in the extirpation of the eye; and, finally, in wounds of the middle artery of the dura mater, as well as in a number of injuries in other regions of the body.

The great objection to this mode of compression is its liability to become deranged and produce severe pain and inflammation, the latter of which is often sufficient to cause profuse suppuration. It should, therefore, never be employed with a view of arresting hemorrhage from a large artery, or even from a small deep-seated one, if it is practicable to apply a ligature, as this is, of course, always the most certain and efficient means; but this objection does not obtain when the blood proceeds from a bleeding cavity, or when it oozes from the bottom of a recent wound. In such a case, indeed, compression must be used at all hazard, for there is frequently no other way by which the flow can be arrested.

The compression may be made with a graduated compress and roller, or by means of sponge, cotton, wool, patent lint, or any other porous substance. *Whatever article is employed, the bleeding surface must pre-*

Fig. 232.

Plan of a graduated compress. *a*. The artery wounded. *b, b*. The graduated compress, arranged so that the apex of the cone is in immediate contact with the bleeding orifice, while its mass occupies the general wound, and projects somewhat above the integumental level.

viously be freed from coagula, in order that the compress may be placed directly in contact with the orifices of the vessel, as exhibited in fig. 232. When the blood proceeds from a large artery, the circulation must be controlled, during this part of the proceeding, with the finger or tourniquet applied some distance above the wound. The compress is then thrust gently but firmly into the breach, the smallest piece being placed directly upon the mouth of the vessel, the next above this, and so on until a sufficient number have been applied, when the operation is completed by bandaging the limb from its distal extremity upwards, care being taken that the pressure is made in as equable and uniform a manner as possible. The part is then put at rest, in an elevated position, and action moderated by the use of cold water, anodynes, and other suitable means. The dressings are frequently examined, but not disturbed under four or five days, unless they become displaced, or offensive from the discharges.

When the hemorrhage proceeds from a wound, as, for example, from that made in the lateral operation of lithotomy, the part must be plugged with a sponge, or a piece of patent lint, the hollow of which is filled up with similar matter, or raw cotton, an instrument having previously been introduced through the foreign substance for the purpose of conducting off the urine. A like plan is pursued in bleeding of the rectum. In hemorrhage of the uterus, the vagina is plugged, while in epistaxis both nostrils are closed.

In injuries of the bones, the surgeon is sometimes obliged to use a plug of soft wood, as a piece of pine. In compound fracture of the skull, attended with lesion of the middle meningeal artery, running in an osseous canal, such an expedient is often the only one which can be successfully opposed to the hemorrhage. Bleeding of the nutrient artery of the long bones is sometimes stopped in a similar manner.

In some cases the tissues of the part whence the hemorrhage proceeds are employed as the compressing agents. In the operation for hare-lip, for example, the simple approximation of the edges of the fissure by the twisted suture effectually arrests the flow of blood from the coronary artery.

The compression is said to be indirect or lateral, when it is applied to the track of the injured vessel, and not to its orifice. It is, in general, a more eligible way of arresting hemorrhage, being free from the objections that have been urged against direct compression, with which, however, it is occasionally combined. The best mode of effecting it is to place a long and rather narrow compress over the course of the artery, extending from the neighborhood of the wound some distance above, and to confine it by means of a roller, commencing at the distal portion of the limb, and carried upwards in such a manner as to afford equable support at every point. In other respects, the treatment is to be conducted as in direct compression. This mode of management is often employed, with the happiest effects, in wounds of the brachial artery, at the bend of the arm, caused by venesection.

4. *Styptics*.—Styptics are remedies which arrest hemorrhage by their direct influence upon the blood, and the arteries furnishing it. They comprise a long and varied catalogue of articles, some of which produce merely an astringent effect; others act apparently mechanically; and others, again, are escharotic, destroying both the vessels and the connecting tissues.

The most powerful, and, at the same time, the least objectionable styptic at present known is the *persulphate of iron*, or Monsel's salt, as it is generally called. It is applied either in substance, or, what is preferable, in strong solution, and possesses the property of instantaneously coagulating the blood, converting it into a very dense, insoluble clot, which continues to increase and to harden for several hours afterwards. What adds greatly to the value of this remedy is its entire freedom from causticity. It is particularly adapted to hemorrhage of the nose, mouth, throat, and uterus, as well as of other parts of the body where it is impossible to ligate the bleeding vessels, on account of the great depth at which they are situated. It has also been used for the cure of vascular tumors of the skin and subcutaneous cellular tissue, in the form of solution injected by means of a delicate syringe.

A very convenient and efficient mode of using this salt has been introduced to the notice of surgeons by Mr. Henry Johnson, of Chester, Pennsylvania. It consists of cotton thoroughly steeped in a saturated solution of the persulphate, and then dried and rolled up for use. Previously to applying it, the wound should be well wiped, when it should be covered with a thick layer, supported by a compress and a roller.

The *perchloride of iron* also possesses remarkable coagulating powers, but it creates so much irritation as almost inevitably to lead to suppurative inflammation, if not to destruction of the tissues. A similar remark is applicable to the tincture of the chloride of iron.

Among the minor and less reliable styptics are alum, sulphate of copper, creasote, and matico. Of these the first is by far the most valuable. It may be applied in saturated solution, or in powder, upon patent lint, directly to the bleeding surface, previously freed of clots, and generally produces a powerful astringent effect, causing speedy coagulation of the blood, and marked contraction of the vessels, without necessarily provoking suppuration. Sulphate of copper may be used in a similar manner, or in the form of a stick, held firmly for some minutes upon the oozing capillaries. Creasote possesses none of the hemostatic qualities formerly ascribed to it, and is now seldom applied with such a view. Of matico, as a styptic, I have not made sufficient trial to enable me to form a correct opinion, but there is no doubt that its virtues, in this respect, have been greatly overrated.

Some surgeons, especially the French, place a good deal of reliance upon the styptic fluid of Pagliari. It consists of a strong watery solution of benzoin and alum, is of a limpid appearance and aromatic odor, and causes instantaneous coagulation of the blood. The clot, however, is less firm than that produced by persulphate of iron, and I have myself very little confidence in its efficiency as a hemostatic.

Cold is a powerful styptic, and may be used in various ways. A current of cold air will often promptly and effectually stop capillary hemorrhage, or even hemorrhage produced by the division of a small artery, as is exemplified in operations upon the tonsils and anus, or ano-rectal region, as well as upon other parts of the body. To prove beneficial, the air must have free access to the part, and it may often be usefully directed by means of the fan, which has the additional advantage of rendering it more cool.

Cold water, refrigerating lotions, pounded ice in bladders, or lumps of ice rolled up in cloths and applied to the bleeding surface, or in its immediate vicinity, occasionally promptly arrest hemorrhage. These applications are particularly valuable in deep-seated hemorrhage, or in hemorrhage of the internal organs and cavities; they must, however, be used with a certain degree of caution, as their protracted continuance may be followed by injurious reaction, and even by mortification of the part. When the wound is situated externally, but too deeply to render the injured vessels accessible to the ligature, the bleeding may often be speedily and effectually checked by a full stream of iced water, directed upon the part, and maintained steadily for some time, from a large syringe.

The *actual cautery* can hardly be considered as a genuine styptic, although it is usually classed under this head. Its effect is not to constrict the vessels, but to destroy them, by producing an eschar, by which their mouths are, for the time, hermetically sealed. Upon the separation of the slough, however, there is frequently a reproduction of the hemorrhage, especially if the wounded vessels are at all large, owing to the imperfect coagulation of their contents. The cases to which the cautery is mainly applicable are those in which the hemorrhage proceeds from a deep and narrow osseous cavity, and in wounds of the tonsils, uterus, and rectum. The instrument, which may be of a conical form, should be heated to a black or slightly red heat, and used in such a manner as not to injure the structures around the seat of the affected vessels. When the artery is very diminutive, the object may sometimes be attained with a hot knitting-needle, a wire, or a probe.

5. *Torsion*.—Torsion is an old procedure, reintroduced to the notice of the profession by Thierry, Amussat, Velpeau, and others: at one time pointedly condemned, at another immeasurably lauded: opinion being still at variance, although decidedly preponderating against it. In the enthusiasm of the moment much was said and written in its favor: it was even alleged that the larger arteries might be occluded in this way, and a German surgeon, Dr. Koch, of Munich, actually published some cases of amputation of the thigh, in which he trusted entirely to torsion as a hemostatic. No other practitioner, however, has, I believe, had the hardihood to imitate him, and the operation is now entirely limited to the smallest arterial twigs. The procedure, which is said to answer admirably in the inferior animals, serving as a substitute for the ligature, is executed with two pairs of forceps, as shown in fig. 233: a small one for draw-

Fig. 233.

Torsion-forceps.

ing out the artery by grasping it horizontally, and a long, stout one provided with a slide and serrated blades, for twisting it in its longitudinal axis; from six to eight turns being required, according to the size of the vessel, to lacerate and bruise its tunics so as to intercept and coagulate its contents. I have rarely found torsion of any service even in the smallest arteries.

General Means.—Whatever mode of procedure be adopted for arresting the bleeding, it is an object of primary importance to place the affected part perfectly at rest, in an easy and elevated position: the slightest motion might be injurious, especially when no ligature has been used, and should therefore be sedulously guarded against. Repose of the body is equally necessary with that of the part, and it is hardly needful to add that mental tranquillity is also of the greatest moment. Cardiac action, too, must be maintained in the most perfect quietude, as any perturbing agency of this kind cannot fail to favor a return of the hemorrhage and exhaust the system. With a view of inducing this result a full anodyne should be administered early in the disease, the dose being repeated from time to time as occasion may seem to require the soothing and sustaining influence of the remedy. Too much stress cannot be laid upon the use of opiates in the management of arterial hemorrhage, and it is surprising that the remedy is not more generally employed than it seems to be. To allow the heart to go riot, or to move and toss about tumultuously, as it is so liable to do after serious loss of blood, while we take every local precaution for the suppression of the bleeding, is assuredly a strange inconsistency, and one altogether irreconcilable with experience and common sense.

The diet should be perfectly bland, and just sufficient in quantity to supply the wants of the body. To give less might cause irritability of the system; to give more, over-stimulation. The drink must be cold and acidulated, and not taken so freely as to oppress the stomach, as it will be sure to do if the quantity is not carefully restricted, as the thirst is always urgent after the loss even of a comparatively small portion of blood. Lumps of ice, or pounded ice, held in the mouth, and gradually swallowed, often prove most grateful and beneficial. The air of the apartment must be kept perfectly cool; in short, every effort must be made to maintain the tranquillity of the circulation.

Secondary Hemorrhage.—Secondary hemorrhage occurs at variable periods;

sometimes in a few hours, at other times not under several days or weeks. It is not necessarily preceded by primary hemorrhage, but may come on where the loss of blood in the first instance was perhaps altogether insignificant, and where everything, so far as this event is concerned, gave promise of a most favorable issue. The bleeding often supervenes without any assignable cause, generally suddenly and unexpectedly; hence it often makes great progress before an opportunity is afforded to arrest it. When proceeding from a large vessel, it may prove fatal in a few minutes, in the same manner as when the bleeding is primary. The scarlet hue of the blood always denotes its source.

The causes of secondary hemorrhage are various, but the most important are the following:—1st. A faulty application of the ligature; 2d. A diseased state of the arteries; 3d. Morbid changes in the clot; 4th. Improper traction upon the ligature; 5th. Tight dressing, or too great dependency of the part; 6th. Want of retraction in the vessels; and 7th. A hemorrhagic diathesis.

1. When a ligature is properly applied it simply divides the inner and middle tunics, leaving the outer intact; this too, however, may be cut, not completely, but partially, and therefore the more insidiously, in consequence of the force used in tying the ligature; or, the deligation may not have been sufficiently firm, the opposite surfaces being only slightly approximated, and the resulting adhesion, therefore, inadequate to effect hermetic closure of the artery on detachment of the cord; or, lastly, the fault may have existed in the ligature itself, on account of the rottenness of its substance, or the imperfect tightening of the knot. Whatever the cause may be, the proper remedy is more efficient ligation.

2. The hemorrhage may arise from disease of the *artery*, either from undue inflammation, or degeneration of its coats, rendering them incapable of supporting the ligature until the clot has contracted firm adhesions. The mode of procedure is obvious; a more healthy portion of the vessel must be sought for, and the ligation effected with more caution; or, this failing, the hemorrhage may be arrested by tying the main trunk of the limb, some distance from the seat of the injury.

3. Morbid changes in the *clot*, commencing in a process of softening and disintegration, occasionally occur after ligation, leading to its premature detachment, perhaps several weeks after the operation. Such changes, which are well illustrated in fig. 234, are most frequent in cases of pyemia and diffuse erysipelas, consequent upon some injuries and amputations, eventuating in a tendency to suppurative inflammation. The only remedy, under such circumstances, is the ligation of a healthy portion of the artery.

4. Young and inexperienced surgeons sometimes bring on hemorrhage by improper traction of the *ligature*, with a view to the promotion of its separation; forgetting that they may thus tear the artery, or, at all events, break up important adhesions. Such a procedure cannot, as stated elsewhere, be too severely censured. Re-ligation is obviously the remedy in such a case.

5. *Tight dressing*, causing unequal constriction of the part, or improper dependency, favoring undue afflux of blood, may induce this form of hemorrhage. The result will be most likely to happen when a number of small arteries have been divided, without any attempt having been made to secure them with the ligature. Bleeding having ceased, the dressings are applied, but too firmly, or the part is placed too low, and presently blood begins to appear, issuing, perhaps, with great freedom. The treatment consists in the removal and readjustment of the dressings, with strict attention to posture.

6. Secondary hemorrhage occasionally comes on after operations for the relief of anal, perineal, and other fistules, chronic abscesses, and old ulcers, from an inability of the vessels to retract in consequence of the indurated condition of the divided

Fig. 234.

Partial absorption of the clot, in the femoral artery, a fortnight after amputation.

parts. Exposure of the surface to cold air, the application of ice, direct compression, or styptics, constitute the best means of relief. In some cases the actual cautery may be required.

7. Finally, the cause may be the *hemorrhagic diathesis*, an affection which, as will be stated elsewhere, may occur at any period of life, and which it is often found extremely difficult to control by any mode of treatment, however judiciously conducted.

SECT. II.—SUBCUTANEOUS HEMORRHAGE.

There is a form of arterial hemorrhage to which, from its situation, the term subcutaneous is very properly applicable. It takes place when, from any cause, an artery is laid freely open, and its contents, instead of escaping externally, are extensively extravasated among the surrounding structures. In ordinary hemorrhage, the blood issues directly from the injured vessel, because the outer wound is sufficiently capacious to admit of its free and unrestrained passage, and the consequence, generally, is that it continues until the patient faints, and the bleeding orifice is closed by coagula. In the variety of hemorrhage, however, under consideration, the opening in the integuments is so small as to prevent the blood from appearing externally, and it therefore accumulates beneath the skin, in the subcutaneous cellular tissue, when the artery lies superficially, or in the subcutaneous and intermuscular cellular tissue, when it is deep-seated. The accident which usually causes this hemorrhage is a puncture, such as that inflicted in venesection at the bend of the arm, where, in civil practice, it is most commonly met with. It may, however, in consequence of a stab, a bayonet wound, or the laceration occasioned by the sharp end of a broken bone, occur in any part of the body, and is sometimes most profuse, its extent being regulated chiefly by the size of the affected vessel, and the quantity and laxity of the connective substance. In the superior extremity, the extravasated fluid often reaches nearly as high up, on the one hand, as the axilla, and, on the other, as low down as the inferior third of the forearm, extensively separating the muscles from each other by breaking up their cellular attachments, and forming a large, ill-shaped, and confused swelling, attended with violent pain, numbness and œdema of the whole limb, and discoloration of the integuments. More or less pulsation is generally present, especially in the earlier stages of the case, and, upon applying the ear over the site of the wound, a well-marked bruit can frequently be recognized, attended occasionally with a peculiar thrill, or a whirring noise, and a vibratory sensation. It is for these reasons that this affection has usually been described as a variety of aneurism; and, as the blood is always widely extravasated, the prefix diffuse is commonly added to that term, as particularly expressive of its more important attributes. Strictly speaking, however, there is no aneurism here; there is simply a subcutaneous accumulation of blood, the consequence of external injury, without any dilatation of the vessel, or degeneration of its tunics; and, although there frequently is, as just stated, more or less concomitant pulsation in the part, yet this does not any more entitle it to be regarded as an aneurism than it would if the effused fluid were so much pus or serum.

The blood that is effused in this accident usually promptly coagulates, and, exerting injurious compression upon the parts with which it is in contact, soon excites severe inflammation, which, especially in persons of an irritable constitution, is liable to assume an erysipelatous character, and to terminate in suppuration, ulceration, and even gangrene. The pain is often intense, depriving the patient of appetite and sleep, and making rapid inroads upon the system. I have witnessed cases where, from the excessive distress thus produced, hectic fever soon came on, and life was placed in imminent peril.

The *treatment* of this lesion is precisely similar to that which is necessary when there is an open wound; that is, the artery must be secured promptly and at all hazard, and the coagulated blood thoroughly evacuated. The operation is often one of great embarrassment, owing to the confused and displaced condition of the parts, and the difficulty experienced in finding the injured vessel, which is not unfrequently lost in the midst of the coagulated blood. A large incision is

generally required, and two ligatures must be applied, one above and the other below the wound in the vessel, precisely as in ordinary cases, the object being the prevention of hemorrhage by the recurrent circulation. As a preliminary step, the injured artery is compressed by the finger or tourniquet, and, after the operation is over, the limb is wrapped up in warm water-dressing, medicated with laudanum and acetate of lead, or laudanum and alcohol, to favor the reduction of inflammation.

SECT. III.—COLLATERAL CIRCULATION.

Among the more interesting phenomena that occur after the deligation of the larger arteries, not the least curious and important is the manner in which the circulation is carried on and maintained in the structures beyond the seat of the ligature. A long time elapsed after the discovery of the ligature before surgeons could be induced to believe that such an operation could be performed in the continuity of a limb without endangering the parts below by gangrene, in consequence of the sudden abstraction of their accustomed supply of blood. Chance gradually led to the correction of this apprehension, which, however, is not without some foundation, as is proved by the fact that the procedure is occasionally followed, even at the present day, in the hands of the most scientific surgeons, by loss of limb and life. Cases had been observed, from time to time, of the obliteration of the largest arterial trunks by fibrinous concretions, and yet it was perfectly certain that the structures in the distal portions of the extremity had retained their normal growth, no difference being discoverable between them and those of the opposite side. Such a result, it was obvious, could only have been brought about by an enlargement of the collateral vessels, thus enabling them to keep up the normal supply of blood, after the obstruction of the main artery. A number of instances had been noticed of complete closure of the aorta, both in its thoracic and abdominal divisions, without any apparent detriment of any kind, either proximate or remote. These facts, the fruits of the cultivation of morbid anatomy, were eminently suggestive, and we accordingly find that they gradually paved the way for some of the most daring feats in surgery. The original trials with the ligature upon the principal arteries in the continuity of the limbs were highly gratifying, as tending to show that, although the distal structures were temporarily deprived of their accustomed supply of blood, this occurrence did not sufficiently interfere with their vitality to cause gangrene, the circulation being speedily re-established through the collateral routes. The process employed by nature in effecting this object has been demonstrated, in repeated instances, by dissection of the parts at variable periods after they had been subjected to operation.

The moment a large artery, as, for example, the femoral, is tied, the blood is obliged to seek new channels for its transmission to the distal portion of the limb. For this purpose it passes on in all directions, entering every vessel, both large and small, into which it can find access. This, however, does not occur all at once, but gradually; for as the arteries which are to carry on this collateral circulation, as this arrangement is termed, are comparatively small, some time is necessary to prepare them for the reception and accommodation of the increased flow of blood. In fact, they are compelled to submit to a species of preliminary dilatation, their tonicity being such as rather to resent its encroachment than to yield to its effects. This is the case both with the branches that are detached from the sides of the vessel above the seat of the ligature and with the capillaries of the various tissues entering into the composition of the limb, which, immediately after such an event, always play an important part in maintaining the distal circulation. Hence, for some time after the operation, the quantity of blood below the point of obstruction is necessarily considerably less than in the normal state, as is demonstrated by the cold and pallid state of the integuments, the defective sensibility, and the loss of muscular power, which is occasionally so great as to deprive the patient of motion in the affected member. The diminution of temperature is liable to a good deal of variation, but in general it amounts to several degrees, and the surgeon is, therefore, often obliged to employ

artificial heat. Gradually, however, as the circulation increases in vigor, the temperature returns to the natural standard, and in many cases even exceeds it, owing to the enlargement and inordinate activity of the cutaneous capillaries, although such an occurrence is usually of short duration.

An instance occasionally occurs in which there is either no change of temperature at all from this cause, or where it is so very slight as to be hardly perceptible. Such a phenomenon is most apt to happen in old aneurisms, where, owing to the obstruction in the artery connected with the tumor, the anastomosing vessels have had time to become enlarged prior to the application of the ligature, so that the operation exerts little, if any influence, upon the circulation in the distal portion of the limb, as it necessarily must in recent cases of that disease, and also in wounds of the arteries, in which no such opportunity is afforded for an increase in the size of the collateral channels.

Coincident with this effort on the part of the affected structures to establish the collateral circulation, there is generally a feeling of uneasiness, if not of actual pain, of a burning or tingling character, obviously occasioned by the compression which the enlarged and distended vessels exert upon the neighboring nerves. Usually, however, this effect is of short duration, as the nerves soon accommodate themselves to their new relations. After some time, the parts gradually recover their natural functions, all disagreeable sensations vanish, the muscles increase in vigor, and the process of nutrition proceeds apparently as well as it did prior to the deligation of the vessel.

Although such is the ordinary course of events after the main artery of a limb has been tied, important exceptions are occasionally met with. Thus, it now and then happens that the circulation remains extremely languid for an unusual length of time, perhaps for a number of days, if not several weeks, the anastomosing branches being seemingly incapable of enlarging to a sufficient extent to convey an adequate supply of blood to the affected structures; the extremity is, consequently, cold, heavy, numb, and of a reddish or purplish hue, from passive congestion of the capillaries, and is moved with pain and difficulty. A struggle is evidently going on between nature and disease, in which the latter but too often comes off victoriously; the limb either falling into gangrene without the occurrence of reaction, or, reaction taking place, it is overpowered by the resulting inflammation. Finally, cases occur, although, fortunately, very unfrequently, in which the parts remain permanently weak and crippled; the muscles are soft and flaccid, the adipose tissue is absorbed, and the integuments are habitually cold and congested; the circulation having never attained the normal standard after the operation.

It is worthy of notice that gangrene, from defective circulation, is much less liable to occur after the ligation of an artery, in the continuity of a limb, in wounds than in aneurism. This fact, at all events, is clearly deducible from the statistical tables of Dr. Norris, from which it appears that in seventeen cases in which the femoral artery was secured on account of recent injuries and different tumors, gangrene did not occur in a single one, whereas this result was witnessed in thirty-one cases out of two hundred and four in which the operation was performed for the cure of aneurism. May not the cause of this disparity be the compression which the tumor in this disease exerts upon the neighboring structures, thereby obstructing the circulation in the distal portion of the limb, and at the same time seriously embarrassing the functions of the nerves? I presume that this result is very materially influenced by the nature of the wound, necessitating the deligation of the artery. If, for example, the parts are extensively divided transversely, or very obliquely, so as to destroy the continuity of a large number of its more important branches in the immediate vicinity of the wound, gangrene will be much more likely to occur than under opposite circumstances, in which, the neighboring vessels being but little injured, the blood will easily find its way into the distal structures, thus affording them the requisite supply not only for the preservation of their vitality but also for the maintenance of their nutrition.

Although the capillaries are greatly instrumental in carrying on the circulation

in the distal portion of the limb, immediately after the deligation of its main artery, their agency is really merely of a temporary character, ceasing with the establishment of the collateral circulation, properly so called, as developed by the larger arterial branches in the vicinity of the ligature. These arterial branches are occasionally given off by the affected artery itself, but most commonly they arise from some neighboring trunks. Thus, when the superficial femoral is tied high up, the collateral circulation is established through the agency mainly of the profunda, whose branches anastomose with the articular, which are offsets of the popliteal. In ligation of the brachial, the blood is transmitted to the forearm and hand by the communications naturally existing between the anastomotic and profunda arteries, branches of the affected vessel, and the recurrent branches of the radial and ulnar, in which the brachial terminates. In ligation, on the contrary, of the common carotid, the circulation of the corresponding side of the head and neck is kept up mainly by the communications between the occipital and deep cervical arteries.

It has been noticed, as an interesting physiological fact, that the anastomotic arteries, before they unite with each other, separate into several branches, often as many as three or four, so as to form a kind of circle, as if nature were particularly anxious to guard against any risk that might otherwise occur to the collateral circulation from accident or disease.

However established, the collateral vessels gradually augment in size, until, at length, their united capacity is fully equal to that of the obliterated trunk, as in fig. 235, whatever may have been its size. There are, of course, as already stated, exceptions, but they are, probably, much less frequent than is generally imagined. A highly interesting case, beautifully illustrative of the present topic, occurred, some years ago, to Dr. Francis West, of this city, in a stout, athletic man, aged thirty-two, who died suddenly from rupture of an aneurism of the thoracic aorta. On dissection, this vessel was found to be entirely obliterated, just beyond the remains of the arterial duct, its coats having a constricted appearance, as if they had been embraced by a tightly-drawn ligature. Everywhere else, excepting at the place of aneurism, the aorta was perfectly natural. All the branches of the subclavian arteries were much increased in size; and the internal mammary and epigastric, which served to keep up the connection of the circulation above and below the seat of the stricture, were fully as large as the external iliac, the former having coursed along the walls of the chest in a very tortuous manner. As no tumor was discovered at the seat of the obliteration, it could not be determined whether the disease had been the result of accident or of a congenital vice. Be this as it may, the case affords an admirable example of the manner in which the collateral circulation is carried on after the interruption of the column of blood in such an immense vessel as the aorta.

The collateral circulation is not developed with equal facility at all periods of life, or under all circumstances; it is most readily established in young subjects, in whom the arteries, besides being very active, enjoy a high degree of elasticity and pliancy, well adapted for such an enterprise. In old persons, on the contrary, the functional activity of these vessels is often much impaired, many of the small branches are obliterated, and their coats are extremely liable to earthy deposits, converting them into firm, rigid tubes, ill qualified for the discharge of their duties. In

Fig. 235.

Collateral circulation shown in the thigh. At *a*, the femoral artery has been obliterated by ligature.

many cases, loss of blood, ill-health, or defective vital power, seriously interferes with the development of the collateral circulation.

Finally, the collateral circulation may be too active. Such an event is not likely to happen when the main artery of a limb is tied on account of hemorrhage from a wound, but its occurrence is by no means uncommon in aneurism, and is then apt to be followed by a return of the circulation and pulsation in the tumor, in consequence of the activity of the anastomosing branches, which thus continue to feed the sac, and perhaps effectually oppose the cure.

SECT. IV.—HEMORRHAGIC DIATHESIS.

The hemorrhagic diathesis is that peculiar state of the system in which, generally from some slight traumatic cause, there is a strong tendency to an inordinate discharge of blood. Persons laboring under this constitutional infirmity are often placed in imminent jeopardy by the most insignificant scratch, puncture, or incision, which, under ordinary circumstances, would hardly emit more than a few drops of blood. Occasionally the cause of the bleeding is the accidental rupture of some of the smaller vessels of the mucous membrane of the nose, lungs, rectum, or urinary bladder. The extraction of a tooth is sometimes followed by this form of hemorrhage. I recollect one case in which death was produced in this way; and another where the bleeding, having persisted for nearly four days, gave rise to severe exhaustion and great apprehension respecting the safety of the patient. Many years ago I lost a child, six months old, from hemorrhage consequent upon lancing the gums over the upper central incisors, which were nearly ready to protrude; he was affected at the time with cholera, but previously to that he had always been remarkably healthy. The bleeding commenced in less than twenty-four hours after the operation, and continued, despite all that could be done for his relief, until the end of the fifth day, when he died completely exhausted. A short time before he expired, hemorrhagic spots appeared on different parts of the body, and blood began to be discharged from the bowels. In 1857, I operated for strabismus upon a young gentleman who possessed this peculiarity; the division of the internal straight muscle was followed by an oozing of blood, which continued, nearly constantly, for the greater part of a fortnight, when, the wound being almost healed, the bleeding ceased.

The blood in this variety of hemorrhage oozes from the injured part, as water oozes from a sponge; it does not spirt out in jets, as when it comes from an artery, or in a continuous stream, as when it proceeds from a vein. Its color is neither scarlet nor black, but intermediate between the two; it generally partially coagulates when it is received into a vessel, but rarely while it is in contact with the living surface.

This affection has occasionally been noticed in several members of the same family. In a remarkable case, reported by the late Dr. John A. Swett, of New York, it existed in all the children, eighteen in number. All, except one, had died from this cause, and he was suffering under profuse hemorrhage of the nose and rectum. Twelve sisters died before the age of twelve from bleeding of the uterus; two of the brothers had fallen victims to traumatic hemorrhage.

Mr. Wardrop has reported a curious case in which this peculiarity was hereditary. The patient was a boy, in whom the hemorrhagic tendency displayed itself when he was scarcely two months old. On several occasions, he nearly lost his life from the most insignificant wounds. His brother, twenty-two years old, was frequently afflicted in a similar manner. Of his five uncles, not one was free from this predisposition, three having died from the division of the frænum of the tongue, and one from the extraction of a tooth; while the other, although he suffered from the same disease, finally died from some other cause. His two aunts exhibited no signs of this diathesis; but all the male branches of their families, excepting one, were thus affected.

A still more remarkable case has been described by Dr. Hughes, of Kentucky. The predisposition here was associated with the rheumatic diathesis, and was

satisfactorily traced as far back as five generations. It was confined exclusively to the male branches of the different families; but the females, nevertheless, invariably transmitted it to their offspring. Many of the individuals died in infancy and childhood, death resulting, in some, from the cut of the lancet; in some, from accidental wounds; in some, from internal hemorrhage; and in two, simply from the application of blisters, the vesicles being filled with blood instead of water.

Of the remote *causes* of the hemorrhagic diathesis nothing is known. Whatever they may be, it is evident that they are deeply engrafted in the constitution, as is proved by the fact, first, that the affection generally shows itself at a very early age; secondly, that it often occurs in several members of the same family; and, thirdly, that it is sometimes hereditary. The immediate causes seem to be two: first, want of coagulability in the fibrin of the blood, and, secondly, an imperfectly organized state of the capillary vessels, the immediate seat of the hemorrhage.

If one were inclined to speculate in regard to the cause of this defective coagulating property of the blood, it would be easy to find it in an insufficient supply of nervous power, upon the presence of which, as is well known, the vitality of this fluid essentially depends. Whatever has the effect of weakening this influence, proportionately interferes with the concretion of the blood, both as it circulates through the body and after its removal by venesection. The fact that the blood remains fluid in sudden death from lightning has long been familiar to practitioners. Similar phenomena occur when a person is killed by a blow on the stomach, by prussic acid, the poison of the rattlesnake, excessive bodily fatigue, or violent agitation of the mind. Certain diseases, as Asiatic cholera, plague, and malignant fevers, produce analogous effects. It has been satisfactorily ascertained that, when the pneumogastric nerves are tied in animals, the blood loses its property of coagulating, the coloring matter at the same time separating from the fibrin, and assuming an unusually black color.

But in all these cases, the loss of nervous power is sudden, and hence it is easy to perceive how it should influence the coagulation of the blood. In persons laboring under the hemorrhagic diathesis, on the contrary, the blood is generally habitually indisposed to coagulate, so that they are more or less liable to bleeding whenever they experience any injury, however slight. The analogy, then, between these different states of the system is exceedingly remote, and can, indeed, hardly be said to be established. Its force, moreover, is weakened by the fact that the subjects of the hemorrhagic diathesis generally enjoy as good health, and as much vigor of constitution, as those who are free from it. To say that such persons are constantly laboring under a want of nervous fluid, is to affirm that they are imperfectly organized, and, consequently, deficient in life-power; circumstances which, if true, remain to be proved. I am not aware that any experiments have been made tending to show that the blood in the hemorrhagic diathesis is deficient in fibrin; such observations might easily be instituted, and they could hardly fail to throw important light upon the pathology of this singular affection.

The other appreciable element in the pathology of the hemorrhagic diathesis is a want of contractility in the capillary vessels. It has been supposed that this is due to the absence of the middle tunic of these vessels; but such a deficiency must necessarily be a matter of inference rather than of observation, and I am not aware that any one, whose opinion is entitled to much weight, any longer holds such a view. That there is a want of tone in the capillaries is certain, but how this is brought about, or in what it consists, is still a subject of conjecture.

The *prognosis* of this form of hemorrhage is generally not very favorable, particularly when it is of a hereditary nature, in which event it is extremely liable to prove fatal. In the case related by Swett, seventeen out of eighteen members of a family thus affected had perished, and the survivor himself had repeatedly suffered from severe bleeding in different parts of the body. In the case of Hughes, in which the diathesis prevailed in not less than five generations, nearly every individual died from hemorrhage; many of them in infancy and childhood.

collected into small abscesses between the inner and middle tunics. Arteritis is much less liable to terminate in suppuration than phlebitis, in which respect the one resembles inflammation of the serous membranes, the other of the mucous.

Fig. 236.

Plastic deposits in the aorta.

Fig. 237.

Plastic plug occluding the axillary artery

The arteries are almost insusceptible of *gangrene*. Their conservative powers are certainly very great, as is evinced by the fact that they often escape destruction in the midst of parts that are perfectly deprived of vitality. In such cases, their outer surface is incrustated, at an early period of the disease, with a thin layer of fibrin; and, long before the sloughs begin to separate, the blood coagulates in their interior, thus opposing an effectual barrier to the occurrence of hemorrhage.

Softening of the arteries is a common occurrence, especially in the smaller branches. It is often witnessed in organic diseases of the principal viscera, and is a frequent attendant upon acute inflammation, cancerous affections, and the application of the ligature. The lesion is characterized, as the name indicates, by a diminution of the cohesive power of the vessels, the coats of which are rendered friable, spongy, and inelastic. It is generally accompanied with slight-tumefaction, engorgement of the capillary vessels, and effusion of serosity, or sanguinolent fluid, into the interstitial cellular tissue.

The *symptoms* of acute arteritis are generally so obscure as to render it extremely difficult to distinguish it, especially when it occurs in the more deep-seated vessels. In the majority of cases, the attack strongly resembles one of rheumatism. The most reliable phenomena, in a diagnostic point of view, are excessive pain and tenderness along the course of the affected arteries, increased by pressure, cough, and change of posture, and accompanied by violent and tumultuous throbbing, which is sometimes felt over the greater portion of the body, and may often be easily perceived at a considerable distance. The action of the heart is much increased in force and frequency, the pulse is hard, wiry and thrilling, and the system is disturbed by irritative fever, which rapidly assumes an asthenic type. When the disease is at all extensive, the patient soon succumbs under its influence, the immediate cause of death being either

tion from the violence of the inflammation, or from the formation of the osseous concretions in the larger arteries, thereby arresting the circulation in some of the more important organs.

There are no symptoms denotive of suppuration, ulceration, or softening of the arteries, apart from those of acute or chronic inflammation. The formation of an abscess would probably be ushered in by rigors, followed by copious sweats, great irritation, and excessive prostration, but the occurrence would hardly be marked in a nature as to serve any diagnostic purpose.

Treatment of acute arteritis must be conducted by the lancet, purgatives, and antimonials, if the patient is young and plethoric, or by a conservative regimen, if he is weak, decrepit, or exhausted by previous suffering, intemperance, or dissipation. Aconite, veratrum, or colchicum will usually form valuable additions to the other means, especially if they be combined with morphia, which is necessary to allay pain and quiet the heart's action. If the disease is connected with the rheumatic diathesis, calomel must be given, in full and frequently repeated doses, with a view to early but gentle ptyalism. Colchicum will then prove useful. The most suitable topical remedies, when the affected arteries are superficial, are leeches, iodine, and saturnine lotions, in union with laudanum.

2. CHRONIC AFFECTIONS.

The most common chronic affections of the arteries are the fibrous, earthy, and calcareous transformations, which, although of frequent occurrence, are chiefly interesting in relation to the influence which they exert upon the production of aortic aneurism. It is for this reason, therefore, that they should be carefully studied. These transformations, notwithstanding that they widely differ from each other in their physical and chemical properties, possess several characteristics in common, of which the most important are, first, that they are met with exclusively in elderly subjects; secondly, that they render the coats of the vessels brittle, and, consequently, prone to rupture; thirdly, that they nearly always occur in association with each other; and, lastly, that they usually begin in the cellular tissue, between the inner and middle tunics, which, however, in general, participate in the morbid action.

Fibrous transformation is characterized by the appearance of small, hard, whitish patches beneath the serous layer of the arteries, usually isolated, but sometimes grouped, of no definite shape, thin, and of a whitish, grayish, or pale yellowish aspect. When the patches are numerous or unusually large, they convert the affected arteries into firm, inelastic tubes. The matter which gives rise to this transformation is originally deposited in the form of fibrin, which ultimately assumes the properties here assigned to it.

Earthy degeneration is most common in old subjects after the sixtieth year, but it usually, however, begins to form as early as the forty-fifth, and cases of it have been observed in very young children. Although it may take place in all the arteries, it is most generally met with in the aorta and its larger branches, as the iliac, femoral, popliteal and innominate. What is remarkable, in the present state of the science, altogether inexplicable, is, that, while the femur of the thigh is so frequently ossified, the humeral artery is seldom affected. Another fact, not less singular, is that this transformation is comparatively rare in the female; a fact which satisfactorily accounts for the difference in the relative frequency of spontaneous aneurism in the two sexes. An instance has occasionally occurred in which there is a strong ossific diathesis, or tendency to ossification, nearly all the arteries in the body being converted into rigid tubes. The earthy matter is deposited in an amorphous form, and is destitute of bone corpuscles; consisting essentially of phosphate and carbonate of lime in combination with a small quantity of albumen, which apparently serves as a matrix.

Calcareous matter exists in various forms; sometimes in small grains and scales, now in scales, plates, and patches, and now in complete rings, which, by encircling the vessel, convert it into a firm, rigid, inflexible tube, completely

Fig. 238.

Calcareous
deposits.

destitute of its natural attributes, as seen in fig. 238. The inevitable effect of these changes, which are always most conspicuous in the inner coat, is to render the artery abnormally brittle, and, therefore, ill able to withstand the pressure of its contents.

The starting point of this deposit is the subserous cellular tissue, whence it gradually extends to the substance of the inner and middle tunics, both of which are sometimes completely transformed by it. It is rare that the outer coat suffers from it; such a change, however, is not impossible, and I have seen specimens in which the deposit was apparently entirely restricted to it. The exciting cause of the calcareous transformation is chronic inflammation. That this is the case is rendered clearly manifest by the fact that it is invariably accompanied by more or less thickening and induration of the arterial tunics, independently of those produced by the deposit itself.

The *atheromatous* deposit, fig. 239, now usually denominated

Fig. 239.

Atheromatous deposits.

the *fatty degeneration*, is, I believe, very rare among our native inhabitants, although it appears to be sufficiently common in our immigrants, especially the Irish and English. In Europe, it is said to be more prevalent in Great Britain than in any other country; a fact which accounts for the remarkable frequency of aneurism in that part of the world. However this may be, the

deposit always begins in the subserous cellular substance, generally in minute, isolated points, not larger than the head of a pin, of a pale yellowish, whitish, or brownish color, somewhat greasy to the touch, and of a semi-concrete, friable consistence. In time, many of these points, or dots, coalesce, and so form irregular-shaped patches, which, pushing the lining membrane before them, may involve the whole circumference of the tube, and extend several lines or even inches up and down in the direction of its length. Having remained stationary for an indefinite period, the deposit manifests a disposition to softening and disintegration, and is ultimately converted into a curdy, friable, or, more properly speaking, a pap-like substance, possessing, apparently, all the properties of scrofulous pus. At this stage of the disease, the lining membrane is often elevated into small pustules, or little abscesses, which, bursting, discharge their contents into the blood, thus leaving a corresponding number of ragged and irregular ulcers, the base of which is formed by the middle tunic.

The fatty deposit is most common in the aorta, particularly its thoracic portion, near the origin of the great cervical trunks. Its occurrence is almost peculiar to the aged. What the causes are, under whose influence it is devel-

oped, has not been ascertained. That it is occasionally connected with imperfect alimentation, and the inordinate use of ardent spirits, is unquestionable, but that these circumstances are essential to its production, as some pathologists contend, cannot be admitted; because the disease, as is well known, has frequently been witnessed in the stoutest and most temperate subjects, a fact which is entirely at variance with such a conclusion.

Under the microscope the atheromatous matter is observed to consist of albuminous and earthy particles, of crystalline plates of cholesterine, of an imperfect fibrous texture, and of oil globules. The amount of fatty substance is frequently so great that it imparts a greasy stain to paper when dried on it by heat. The minute appearances of this deposit are well shown in fig. 240.

In regard to the different transformations now described, there are no remedies, which, so far as is at present known, are capable of exerting any influence over their development. What treatment might accomplish, if their diagnosis could be satisfactorily established, is an interesting problem for future inquiry to solve. To speak of administering remedies for their removal when we are unable to determine the fact of their existence is one of those practical refinements which are more befitting the transcendentalist and the idle speculator than the man of sound sense.

Ulceration, as a consequence of arteritis, whether acute or chronic, is seldom witnessed. Manifesting a peculiar predilection for the larger trunks, it commonly commences in the serous membrane, from which it gradually extends to the middle and outer tunics until it leads to complete perforation. Such a termination, however, is extremely rare. The ulcers, which are very irregular in their form, vary much in size, number, and general character. At times they are very small, scarcely exceeding the diameter of a mustard-seed; but they may be as large as a split pea, a five cent piece, or even a guinea, according to the caliber of the affected tube. Their margins are usually ragged, irregular, and considerably elevated, but seldom injected; their bottom, which is rough and uneven, is commonly formed by the middle tunic, the fibres of which frequently present a shreddy, lacerated appearance. In many instances, the erosions look like so many fissures, cracks, or chaps, with sharp, prominent, and irregular borders. This form of the disease is ordinarily dependent upon the presence of calcareous matter. The number of ulcers is seldom considerable, though in a few rare cases the inner surface of the larger trunks has been found completely checkered with them. When confined to the internal tunic they sometimes admit of cicatrization.

3. INTRA-PARIETAL SEPARATION OR DISSECTING ANEURISM.

There is an affection of the arteries, occurring exclusively in old persons, more particularly in women, to which the term *dissecting aneurism* has been applied; it is not, however, in reality, an aneurism at all, but merely a separation of the lamellæ of the middle tunic, as has been satisfactorily established by the investigations of Dr. Pennock, and by an examination by myself of nearly all the reported cases of the disease. A more appropriate name would be *intra-parietal separation*. The lesion, which presents nothing of any practical interest, inasmuch as it is always fatal, is entirely limited to the aorta and the larger trunks more immediately connected with it, and is always dependent upon organic disease of the coats of the arteries, rendering them lacerable, and, consequently, incapable of resisting the impulse of the blood. The manner in which the affection takes place is easily understood. In the natural state the different coats are

Fig. 241.

extremity of the aorta to the other, being perhaps prolonged at the same time into the carotid, subclavian, and iliac arteries.

4. VARICOSE ENLARGEMENT.

The arteries are liable to a dilated and nodulated condition, similar to that of the veins, and hence very frequently termed varicose enlargement. The affection has also been described under the name of varicose aneurism and of arterial varix. Its general features are well illustrated in fig. 242. The lesions,

Fig. 242.

Varicose enlargement.

which is exceedingly rare, is met with chiefly in the superficial arteries, particularly in those about the hand, forearm, leg, and foot; and consists in a remarkably tortuous, elongated, and convoluted state of these vessels, evidently

so intimately connected together that it is almost impossible, even by the nicest dissection, to detach them from each other; but when they are altered by disease, or by some of the degenerations to which they are so liable, the connecting cellular tissue is rendered soft and friable, and their separation may then be effected with the greatest facility. In this condition, moreover, the tunics themselves are frequently very much changed, so that they are scarcely able to resist the slightest impulse. Now, if under these circumstances the lining membrane gives way, whether from ulceration, erosion, or rupture, the blood will insinuate itself into the accidental opening, which is thus gradually enlarged, at the same time that the fluid is forced on between the layers of the weakened middle tunic, dissecting them from each other as with a knife, and forming thus either a blind pouch or a distinct canal, open at both extremities, or at some intermediate point.

The separation is not of the same extent in all cases. It rarely embraces more than one-fourth, one-half, or two-thirds of the circumference of the tube, while in length it may vary from six, eight, or ten lines to as many inches. Occasionally it reaches nearly from one

dependent upon the effects of inflammatory action, as is shown by the fact that their coats are always abnormally thickened, either uniformly, or alternately thickened and attenuated. In elderly subjects it is generally associated with the fibro-cartilaginous, earthy, or fatty degeneration. The dilatation and varicosity sometimes affect an entire artery, but more commonly they are limited to particular portions of it; it may be restricted to one vessel, or occur simultaneously in several. When the diseased artery is superficial, the character of the lesion is rendered sufficiently clear by the tortuous and nodulated course of the vessel beneath the surface; but there are no pathognomonic signs when it is deep-seated.

This affection rarely requires any treatment; for, even when the enlargement is considerable, it is rather an inconvenience than an actual disease. In ordinary cases, the vessels may be supported by the constant use of a well-applied bandage, or of an apparatus constructed upon the principle of the laced stocking. During the forming stage, much may be done in the way of repressing development by astringent and soothing lotions, along with rest and elevation of the parts, and the occasional abstraction of blood, provided the patient is plethoric, in order to moderate the momentum of the circulation. When the disease proves troublesome, by causing pain and functional disorder, the only effectual remedy is ligation of the offending vessels, at the cardiac side of the enlargement.

SECT. VI.—ANEURISM.

An aneurism is a pulsating tumor, occupied by blood, and communicating with an artery deprived, either partly or completely, of its integrity.

The subject of aneurism has been encumbered by too many divisions and subdivisions, and the consequence is that several lesions have been included under it which do not, properly speaking, appertain to it. The effect of this over-refinement has been to embarrass the study of this disease, and to invest it with difficulties which are altogether foreign to it. The distinction of aneurism into true and false is one of great importance, and should, therefore, be retained. The same may be said in regard to spontaneous and traumatic aneurism. The term dissecting aneurism, introduced by Laennec, and adopted by most modern authors, should be discarded, inasmuch as the affection which it serves to designate has nothing whatever in common with aneurism; it is, in fact, as already stated, merely a separation of the coats of the arteries, without any tumor or symptoms denotive of that lesion. Then, again, as to the term varicose, which I have myself employed, along with others, in my writings, to designate a peculiar form of arterial lesion, it is obviously improper when we come to make a practical application of it. A varicose artery is, in reality, no more an aneurism than a varicose vein; both affections consist essentially in a dilated and tortuous state of these two classes of vessels, and not, as an aneurism, in a pulsating tumor, caused by the destruction, partial or complete, of the tunics of an artery. An anastomotic aneurism is a pulsating tumor formed by hypertrophy of the arterial and venous capillaries of a part; critically speaking, therefore, the term aneurism is not applicable to it, and yet, as it has been fully engrafted upon our surgical nomenclature, it is difficult to dispense with it, or to substitute one of a more expressive and appropriate character.

The term true is applied to that species of aneurism in which one or more of the arterial tunics, without being necessarily perfect, form a part of the tumor. A false aneurism, on the contrary, is one in which all the coats have given way, the sac being composed of the surrounding cellular tissue in a state of condensation. It was formerly supposed, chiefly through the influence of the writings of Scarpa, that there was no such disease as a true aneurism, but that in every instance, whatever may be the size, form, or site of the affection, there was a complete absence of the arterial tunics at the situation of the tumor. This opinion, however, has become obsolete, experience having shown that there are cases, although they are confessedly rare, in which the aneurism clearly consists of at least one, if not more, of the coats of the artery from which it springs. Each of these

Fig. 241.

The so-called dissecting aneurism. *a* Semilunar valves, *b*. External vessel laid open in its entire extent, so as to expose the aorta at *c*; *d* Valvular opening in the coats of the aorta, showing the communication of this vessel with the artificial channel, *e*; the probe *e* passed through the abnormal opening. *f* exhibits the foramina between the aorta and the outer canal.

extremity of the aorta to the other, being perhaps prolonged at the same time into the carotid, subclavian, and iliac arteries.

so intimately connected together that it is almost impossible, even by the most dissection, to detach them from each other; but when they are altered by disease, or by some of the degenerations to which they are so liable, the connecting cellular tissue is rendered soft and friable, and their separation may then be effected with the greatest facility. In this condition, moreover, the tunics themselves are frequently very much changed, so that they are scarcely able to resist the slightest impulse. Now, if under these circumstances the lining membrane gives way, whether from ulceration, erosion, or rupture, the blood will insinuate itself into the accidental opening, which is then gradually enlarged, at the same time that the fluid is forced on between the layers of the weakened middle tunic, dissecting them from each other as with a knife, and forming thus either a blind pouch or a distinct canal, open at both extremities, or at some intermediate point.

The separation is not of the same extent in all cases. It rarely extends more than one-fourth, one-half, or two-thirds of the circumference of the tube, while in length it may vary from six, eight, or ten lines to as many inches. Occasionally it reaches nearly from one

4. VARICOSE ENLARGEMENT.

The arteries are liable to a dilated and nodulated condition, similar to that of the veins, and hence very frequently termed varicose enlargement. The affection has also been described under the name of varicose aneurism and arterial varix. Its general features are well illustrated in fig. 242. The lesion

which is exceedingly rare, is met with chiefly in the superficial arteries, particularly in those about the hand, forearm, leg, and foot; and consists in a remarkably tortuous, elongated, and convoluted state of these vessels, evident

portion, particularly its anterior and right side, suffers more than other part, and it is here that the blood exerts its greatest pressure, coming up from the left ventricle. The popliteal artery, which is the center of involvement, is subjected, in a degree beyond that of the other extremities, to a similar influence during the flexed con-

dition, inasmuch as it is liable that some influence is also due to the weakness which exists at the origin of their larger branches. The fibres of the artery are separated here, in consequence of which they are unable to withstand the shock of the blood as it is directed against them. Experience teaches that aneurism is peculiarly liable to

be produced in a position which may be supposed to favor the production of aneurism, inasmuch as the arteries are subjected, especially during exertion. Such an influence must be particularly felt by the thoracic aorta during bodily and mental excitement, and by the various muscular exertions of the lower extremity.

If these causes alone is capable of producing aneurism is a conjecture. Without degeneration of the arterial tunics, a very little influence, while under opposite circumstances

Indeed, it is very questionable whether aneurism would be as common as it is, if the arteries were altogether exempt from atheromatous deposits; nay, we may go further, and assert, that if atheromatous deposits could be prevented, spontaneous aneurism would

aneurism would seem to be influenced by climate or locality. In the case of aneurism in the inhabitants of the southwestern States of America. In a practice in Ohio and Kentucky of twenty-five years, I witnessed almost every surgical disease incident to the human system, and I never occurred to me to meet with an example of spontaneous aneurism. In this respect, is fully sustained by that of Dr. J. C. Bush, whose practice embraced a wide field, which has since been sustained by Professor Bush, of Transylvania University. I assured me, some years ago, that this affection had been observed in a very small range of their observation. Professor T. G. Richardson, superintended, while Demonstrator of Anatomy in the University, the dissection of several hundred bodies, and yet he never observed the malady. The testimony of Dr. Bayless, who occupied the same position, is precisely to the same effect. To what extent aneurism is due, we have no means of determining. The population of the United States is a mixed and laborious one, and the habits of the civilized world, and pursuing all kinds of occupations, from the most delicate and refined to the most rude and vigorous, and yet aneurism, in any class of its citizens, is absolutely an exception. The opinion is that the disease is equally uncommon in our north; but upon this subject it is necessary to speak with some reserve, as there are no positive data to guide us.

The prevalence of aneurism in our larger towns and cities, our knowledge is very imperfect. Professor Gibson, formerly of the University of Pennsylvania, states that the disease is quite infrequent in Philadelphia, and I believe to be the fact from the results of my own inquiries. On the contrary, it would seem, according to the statement of Dr. J. C. Bush, a circumstance which is, perhaps, not surprising, that the heterogeneous character of the people of that city, and, of its commerce, and the numerous accidents incident to its population, is, however, is, that nearly all the cases met with by the surgeon, during a period of upwards of forty years, occurred in the Eastern States. In opposition to this fact, the authority of Dr. John Watson and others, of New York—

great divisions comprises several varieties, founded principally upon the form and volume of the tumor. Thus, an aneurism is

Fig. 243.

Fig. 244.

Fig. 245.

Fig. 246.

said to be sacculated when it consists of a distinct bag, as so often happens in aneurism of the aorta and the principal branches given off from it; the term cylindroid is used when the swelling affects the artery uniformly in its entire circumference, while the tapering tumor is known by the appellation of fusiform. The words circumscribed and diffused refer mainly to the dimensions of the aneurism.

The annexed sketches afford a good idea of the arrangement of the tunics of the arteries in the principal varieties of spontaneous aneurism. In fig. 243 the tumor is formed by the expansion of all the coats of the vessel, an extremely rare event; in fig. 244 the middle tunic has given way, the inner and outer being

preserved; in fig. 245 the aneurism is formed by the external tunic alone; in fig. 246 the two outer membranes have been ruptured, the inner projecting through the crevice thus left, in the form of a hernia. This variety is very uncommon, but cases of it have been reported by different authors, especially by Haller, Laennec, Dupuytren, and Dubois. It can occur only when the inner coat of the artery has been thickened and fortified by interstitial and surfacial deposits.

Finally, aneurisms are divided into internal and external, the former expression being used chiefly in reference to the aorta and to the arteries of the viscera, the latter in relation to the vessels of the head, neck, and extremities. The words spontaneous and traumatic sufficiently explain themselves.

1. LOCALITY, PREVALENCE, AGE, SEX, AND CAUSES.

Spontaneous aneurism does not occur with equal frequency in all parts of the body; on the contrary, there are a number of arteries which are almost entirely exempt from it, or which, at all events, so seldom suffer as to be scarcely entitled to notice. The vessel which is most frequently involved is the aorta; first in its ascending portion, then in the thoracic, and, lastly, in the abdominal. Next in point of liability to the disease are the popliteal artery, the femoral, common carotid, subclavian, innominate, axillary, and external iliac. The arteries of the leg and foot, hand, forearm, and arm, face, upper part of the neck, and of the viscera, together with the common and internal iliac, rarely suffer in this wise. Traumatic aneurism may occur in any of the arteries, but is most common in those that are most exposed to external injury.

If we attempt to inquire into the causes which induce spontaneous aneurism more frequently in one artery than in another, we shall be met by difficulties. Several circumstances, however, may be assigned as affording at least a plausible explanation of the circumstance.

1st. It is well known that certain arteries are peculiarly prone to the calcareous and atheromatous degenerations, while others, on the contrary, are almost entirely exempt from them, whatever may be the condition of the rest of the arterial system, or the age of the patient. Now, dissection has shown that those vessels which are most frequently diseased in this way are also those which are most frequently affected with aneurism, and conversely. Spontaneous aneurism of the arm and forearm is among the rarest occurrences, and everybody knows how free their vessels are from the degenerations in question. In the aorta and popliteal artery, on the other hand, they are extremely common, and it is here, as already seen, that spontaneous aneurism is most frequent.

2d. In the next place, some influence is no doubt due, in the production of this difference, to the force with which the blood impinges against the walls of the vessels. Thus, in the aorta, which is more prone to aneurism than any other

artery, the ascending portion, particularly its anterior and right side, suffers more frequently than any other part, and it is here that the blood exerts its greatest force, as it is pumped up from the left ventricle. The popliteal artery, which comes next in the order of involvement, is subjected, in a degree beyond that of any other vessel in the extremities, to a similar influence during the flexed condition of the limb.

3d. It is not improbable that some influence is also due to the weakness which the arteries experience at the origin of their larger branches. The fibres of the middle tunic suffer a species of separation here, in consequence of which they are less capable of withstanding the shock of the blood as it is directed against them. However this may be, experience teaches that aneurism is peculiarly liable to occur at these points.

4th. Another circumstance which may be supposed to favor the production of aneurism is the motion to which the arteries are subjected, especially during sudden and violent efforts. Such an influence must be particularly felt by the ascending portion of the aorta during bodily and mental excitement, and by the popliteal artery in the various muscular exertions of the lower extremity.

How far any one of these causes alone is capable of producing aneurism is altogether a matter of conjecture. Without degeneration of the arterial tunics, they would probably exert but little influence, while under opposite circumstances it must be very great. Indeed, it is very questionable whether aneurism would be one-twentieth part as common as it is, if the arteries were altogether exempt from the earthy and atheromatous deposits; nay, we may go further, and assert, positively, that if these deposits could be prevented, spontaneous aneurism would almost cease to exist.

The occurrence of aneurism would seem to be influenced by climate or *locality*. The infrequency of the lesion in the inhabitants of the southwestern States of North America, is proverbial. In a practice in Ohio and Kentucky of twenty-three years, in which I witnessed almost every surgical disease incident to the human frame, it rarely occurred to me to meet with an example of spontaneous aneurism. My experience, in this respect, is fully sustained by that of Dr. Dudley, of Lexington, whose practice embraced a wide field, which has since been so successfully cultivated by Professor Bush, of Transylvania University. Both these gentlemen assured me, some years ago, that this affection had been extremely rare within the range of their observation. Professor T. G. Richardson, now of New Orleans, superintended, while Demonstrator of Anatomy in the University of Louisville, the dissection of several hundred bodies, and yet he hardly met with an instance of the malady. The testimony of Dr. Bayless, who formerly occupied the same position, is precisely to the same effect. To what this extraordinary immunity is due, we have no means of determining. The population of that region of the United States is a mixed and laborious one, made up from all parts of the civilized world, and pursuing all kinds of occupations, from the most delicate and refined to the most rude and vigorous, and yet a case of spontaneous aneurism, in any class of its citizens, is absolutely an anomaly. My impression is that the disease is equally uncommon in our northern and middle States; but upon this subject it is necessary to speak with some degree of reserve, as there are no positive data to guide us.

In regard to the prevalence of aneurism in our larger towns and cities, our information is also very imperfect. Professor Gibson, formerly of the University of Pennsylvania, asserts that the disease is quite infrequent in Philadelphia, and this I am inclined to believe to be the fact from the results of my own inquiries. In New York, on the contrary, it would seem, according to the statement of Dr. Mott, to be quite frequent; a circumstance which is, perhaps, not surprising, when we consider the heterogeneous character of the people of that city, and, above all, the extent of its commerce, and the numerous accidents incident to its pursuits. What is remarkable, however, is, that nearly all the cases met with by this distinguished surgeon, during a period of upwards of forty years, occurred among native-born citizens of the United States. In opposition to this fact, however, I have the authority of Dr. John Watson and others, of New York—

as communicated to me by Dr. Lente—for stating that the great majority of cases of aneurism in that city, especially in hospital practice, are met with among those of foreign birth. Its negroes would also seem to be particularly obnoxious to the disease.

Aneurism is uncommon in the East and West Indies, in the British Provinces of North America, and on the continent of Europe, especially France, Italy, and Germany. In Great Britain, on the contrary, it is sufficiently frequent; more so, perhaps, than in any other part of the globe. According to the report of the registrar-general, it appears that the number of deaths from aneurism, in England and Wales alone, during a period of five years—namely, from 1838 to 1842—was 593; being an annual average of one in about 131,000 of the inhabitants. The various hospitals of London receive every year a large number of cases of this disease. The people of Ireland are said to suffer more frequently from aneurism than any other race.

The *causes* of aneurism are divisible into predisposing and exciting. Of the former, the most constant, and, therefore, the most important, is a diseased condition of the arterial tissues, usually presenting itself in the form of the earthy and atheromatous degenerations. These degenerations, by rendering the coats of these vessels preternaturally brittle and lacerable, cause them to yield more readily under the impulse of the blood and the various extraneous circumstances which have a tendency to stretch and twist them. I have already expressed the belief that, but for these alterations, spontaneous aneurism would be almost unknown. The influence of age and climate in the production of this disease, is adverted to in the preceding paragraphs. All laborious pursuits, involving sudden and violent muscular exertion, powerfully predispose to its occurrence. Hence, it is more common among sailors, and those who are much accustomed to athletic exercises, than among any other class of individuals. Soldiers suffer much less frequently than was formerly supposed. Men engaged in agricultural pursuits, although their labor is often severe, are, in great measure, free from the disease, owing, doubtless, to the want of liability of their arteries to abnormal deposits. Protracted courses of mercury, a syphilitic taint of the system, and the constant and inordinate use of ardent spirits, are supposed to predispose to the formation of aneurism; but how far, or in what degree, remains to be demonstrated.

The immediate cause of aneurism is rupture of the coats of the arteries, in consequence of severe muscular exertion unduly stretching these vessels, or, as in the case of the aorta and its larger offsets, an inordinate impulse of the blood, during the sudden and violent contraction of the left ventricle of the heart. The vessels, weakened by the degeneration of their tissues, and deprived of their elasticity, readily yield to the forces thus applied, commonly at a particular point, which is afterwards converted into a distinct pulsating tumor, generally composed, in great measure, if not exclusively, of the external tunic of the artery along with more or less of the circumjacent cellular tissue. Sometimes the exciting cause of the disease is ulceration, but such an occurrence is comparatively rare, especially as an affection unconnected with the earthy and atheromatous deposits. This process, as stated in a previous section, should not be confounded with the cracks or fissures which so often follow these deposits, inasmuch as the latter are usually the result, not of a vital action, as in true ulceration, but of a mere mechanical one, gradually effected under the impulse of the blood, as it rushes over the inner coat of the diseased vessel.

Aneurism occasionally exists simultaneously in several arteries. Thus, it is by no means uncommon for a patient to have one tumor of this kind in the aorta and another in the carotid, subclavian, popliteal, femoral, or external iliac artery. I have seen several instances of the coexistence of popliteal aneurism in the same individual. When the disease affects a considerable number of arteries, it constitutes what is termed the *aneurismal diathesis*; a circumstance which imperatively contraindicates surgical interference, however favorably the external tumor may be situated for operation. Weak, sickly persons, of depraved constitution, and intemperate habits, are the most common subjects of this diathesis. *Sermon*

remarkable examples of this predisposition to the formation of aneurism are upon record. Pelletan gives one in which the number of tumors was upwards of sixty, and in another, related by J. Cloquet, there were more than two hundred, the patient being a man fifty years of age. The aneurisms, in this instance, affected nearly all the arteries in the body, but they were most numerous in those of the extremities, the axillary, humeral, radial, ulnar, femoral, popliteal, tibial, and peroneal being all closely studded with them.

It has long been known that the formation of aneurism is influenced, in a remarkable degree, by *age*. Prior to the thirtieth year, the disease is extremely rare, and up to the period of puberty it is almost unknown, even in the aorta, which is so much more frequently affected than the other vessels. The greatest number of cases, by far, occur between the thirty-fifth and fiftieth year; a good many cases are also met with during the next decennial period and a half, but after that time the malady is very rare; probably not that the predisposition to it ceases, but because, as it seems to me, in the first place, the number of subjects is comparatively small; and, secondly, because persons at this age are much less exposed to violent muscular and mental excitement than during the meridian of life. That this supposition is true is rendered highly probable by the fact that the earthy and atheromatous deposits generally exist in greatest abundance in advanced life. The absence of these deposits in young subjects readily explains the non-occurrence of aneurism in children and adolescents. An instance of spontaneous popliteal aneurism in a boy only nine years old occurred in the practice of Mr. Syme, of Edinburgh, in 1844, and is probably the only case at this early age upon record.

Males suffer from aneurism more frequently than females, but in what precise proportion has not been determined. The question has hitherto engaged but little attention, and it is obvious that it can be decided only by the analysis of a much larger number of cases than have yet been adduced for the purpose. It has been alleged that the relative frequency of carotid aneurism in the two sexes is nearly equal, and the occurrence has been attempted to be accounted for on the supposition that the arteries of the neck of the female are nearly as much exposed to all kinds of violence and muscular exertion as those of the male. Little confidence, however, can be placed in such opinions; for, before we can receive them as true, we must be satisfied that the disease is as common in women as in men, which I am very certain it is not. Mr. Crisp, in his excellent work on the diseases of the arteries, states that of 551 cases of aneurism of all kinds, more than seven-eighths occurred in men.

Having long been impressed with the belief, founded upon numerous dissections, that the difference in the relative frequency of aneurism in the two sexes was due, not to any difference in their occupation, but to the difference in the relative frequency of the earthy and fatty degenerations of the arteries, I was induced to institute special inquiry into the subject, and am gratified to be able to say that my views are fully confirmed by the statements of Dr. D. Hayes Agnew, Dr. C. E. Isaacs, Professor T. G. Richardson, and Professor J. B. S. Jackson. The testimony of these teachers, who are all well known as able and experienced practical anatomists, tends to show, indisputably, that females are much less subject to chronic disease of the arteries of every description than males. Neither their information, however, nor my own, is such as to enable me to determine the relative proportion of these degenerations in the two sexes, in a given number of cases. That it corresponds very closely with the difference in the number of cases of aneurism is what may readily be believed, and what future observation will, no doubt, abundantly verify.

If we assume what is here said to be true, it follows that the opinion which ascribes the greater frequency of spontaneous aneurism in males than in females to their more laborious occupation, their more intemperate habits, and their greater exposure to all kinds of disease, is entirely untenable, and, therefore, unworthy of confidence. Women, it is true, are not sailors, carpenters, blacksmiths, or hod-carriers, but in many parts of the world they are tillers of the soil, and engaged in almost every variety of pursuit calculated to rupture the arterial

tunics if they were in a serious state of disease, such as we so often meet with in the other sex.

2. VARIETIES OF ANEURISM.

True aneurism presents itself under two varieties of form, differing from each other materially in their appearance and mode of formation, although their essential symptoms and effects are usually perfectly similar, if not identical. These two varieties are the tubular and the sacciform, terms which are sufficiently expressive of their general conformation.

Fig. 247.

Sacculated aneurism.

Each consists of one or more of the arterial tunics, and forms a tumor, which, in time, is capable of exerting the most injurious effects upon the neighboring structures, and of causing the death of the patient.

The *sacciform variety*, fig. 247, is by far the more common of the two. It essentially consists, as the name denotes, in the formation of a pouch, bag, or sac, connected with the side of the affected artery. In the tubular variety the tumor is formed at the expense of the entire circumference of the vessel; in this, on the contrary, it occupies only a limited portion of it. The arteries most liable to sacciform aneurism are the aorta, particularly its thoracic division, the popliteal, femoral, innominate, carotid, and subclavian. The number of tumors is subject to considerable diversity; cases have been reported in which there were so many as to constitute

a genuine aneurismal diathesis, nearly all the principal arteries in the body being more or less implicated. In general, however, there is only one, although others may be developed during its progress. Thus, it occasionally happens in popliteal aneurism that an aneurism forms in the aorta, the carotid, or in the popliteal artery of the opposite side.

The sacciform aneurism is capable of assuming a great variety of forms; the most common is the globular, or ovoidal; in rare cases it is conical, elongated, or irregularly flattened, like a shot-pouch. Much diversity also obtains in regard to its dimensions; thus, while in some instances it is hardly the volume of a hazelnut, in others it is as large as a fist, or the head of the patient; in general, however, it does not exceed a hen's egg, or a medium-sized orange. The largest aneurisms of this kind are usually found in the aorta and in the popliteal, iliac, and innominate arteries. The attachment of the tumor to the

artery is commonly effected by a narrow footstalk; but cases occur in which it takes place by a broad and extended base, and it is then not unusual for the artery to suffer serious compression during the progress of the disease.

Fig. 248.

Aneurism of the aorta, the greater part of the cyst being filled with clots, and the aperture of communication being small.

The orifice of communication, fig. 248, between the sac and the artery varies in different preparations. When the tumor arises by a narrow footstalk the opening is usually proportionately small, with smooth and well-defined margins. When, on the other hand, it is attached by a broad base, the aperture is always much larger, and its edges are also more irregular, sometimes, indeed, quite shreddy and ragged, as if they had been torn. The situation of the orifice is commonly

and ragged, as if they had been torn.

towards the centre of the sac, but it may be at one side, or even at one of its extremities. The form of the opening is extremely variable, and admits of no specific description. In the early stage of the disease, and in nearly all cases where the tumor is small, the orifice is of a rounded or circular configuration, while in cases of an opposite character it is generally more or less irregular. The internal and middle tunics may terminate abruptly at the margins of the opening of communication, or they may extend into the cavity of the sac, and thus serve to give it a partial lining.

The sac generally consists simply of the external tunic, the inner and middle having given way either prior to, or during, the development of the disease. The first thing, in fact, that commonly happens, in all such cases, is the destruction, by ulceration or some other disorder, first, of the internal, and, soon after, of the middle layer of the artery, leaving thus a kind of crevice, which gradually enlarges under the influence of the impelling column of blood, and thus permits the corresponding portion of the vessel, now of course greatly weakened, to be converted into a pouch. This pouch, usually called the aneurismal sac, is then originally composed exclusively of the external coat of the affected vessel, the other strata terminating abruptly at the margin of the opening of communication, neither of them being prolonged into its interior. But this pouch would be very weak, and, consequently, ill adapted to withstand the shock of the blood as it rushes into its interior, if it were not strengthened by adventitious aid, derived from interstitial deposits in the surrounding cellular tissue. We accordingly find that nature, ever on the alert to save the part and system, is prompt in supplying the required relief by setting up inflammation and pouring out plastic matter, both in the substance of the sac and in the neighboring structures, thereby thoroughly gluing them together, at the same time that they are greatly increased in thickness and density, and thus enabled more effectually to resist the effects of the ever-beating, dashing, and tumultuous sanguineous current within. Such aid, then, is wise and needful, and, fortunately, always comes in play at an early stage of the disease, the laceration of the inner and middle tunics of the artery, and the pressure of the blood against the tumor, being sufficient causes of inflammation. When the periosteum contributes to the formation of the sac, as it occasionally does in aneurism of the thoracic aorta, the walls of the tumor may be partially earthy or osseous.

Although the sac is generally composed of the outer tunic alone, cases, nevertheless, occasionally occur where it consists, in the first instance, exclusively of the inner coat, the other two having given way. That such an arrangement is exceedingly infrequent, is proved by the fact that many surgeons of large experience have warmly contested the possibility of its existence. Haller and his cotemporaries, however, met with undoubted cases of it, and, in more recent times, it has been witnessed by Breschet, Dupuytren, and other observers, who have given particular descriptions of it. One ground for assuming that this form of aneurism cannot occur is, that it has never followed the numerous attempts that have been made to produce it in the inferior animals, by exposing the carotid artery and dissecting off its outer and middle tunics. In every experiment of this kind, the denuded membrane maintained its integrity, and the breach was speedily repaired by a free deposit of plastic matter. There is, however, no analogy between a sound and a diseased artery, and this fact should be borne in mind in the discussion of the subject. When the outer and middle tunics are destroyed by ulceration, as they always must be in such a case, not rapidly, but slowly, it is not difficult to suppose that the inner membrane may, at the injured and weakened part of the vessel, be made to bulge across the opening, in the form of a thin, translucent cyst. Interstitial deposits would soon aid in strengthening the cyst, although ere long, and before it has acquired any considerable bulk, it would be obliged to yield to the resistless impulse of the blood within. Haller has described this variety of aneurism under the term *hernia of the inner coat of the arteries*.

Cases in which the sac consists of the outer and inner coats of the artery, the middle having been destroyed, although also exceedingly infrequent, are more

common than those in which it consists of the internal tunic alone. Such an arrangement is occasionally observed in aneurism of the carotid, femoral, and popliteal arteries; but, in time, the lining membrane is sure to give way, leaving thus the cyst composed of the outer coat and the surrounding tissues, as in the ordinary form of sacculated aneurism.

The sac varies in thickness in different cases and under different circumstances, from the fourth of a line to the fourth of an inch. It is often remarkably tough, and, in cases of long standing, it is generally composed of several

Fig. 249.

Sacciform aneurism of the aorta ready to give way.

distinct strata, of a grayish, whitish, or drab-colored aspect, consisting of fibres which intersect each other in every conceivable direction. The outer surface of the tumor is rough and shreddy; the internal, on the contrary, is smooth and polished, only, however, as a general rule, in its earlier stages, for in time it also becomes rough, and is finally incrustated with fibrinous matter. Notwithstanding the thickness of the aneurismal sac, and the efforts which nature makes to strengthen it, it gradually dilates, as in fig. 249, under the impulse of the inflowing column of blood, and at length, after the lapse perhaps of several months, manifests a disposition to yield at one or more points, very much as an abscess, the activity of the absorbent vessels exceeding that of the capillary.

The sacciform aneurism always contains, even at an early period after its formation, *fibrinous concretions*, the presence of which constitutes one of its most interesting and important features, as they are evidently designed not only to strengthen the tumor, but to aid in its obliteration,

and, consequently, in the production of a permanent cure, although such an event is extremely rare. In their arrangement, these clots are always concentric, not unlike the layers of an onion, one being piled upon, and closely connected to, another. Their color and density vary according to the period of their formation, the older being usually of a pale, yellowish appearance, and of a firm, fibrous consistence, while those that are of a comparatively recent date exhibit very much the aspect and consistence of a common heart clot. Their thickness ranges from the fourth of a line to that of a sheet of paper; and their number is often immense, thousands existing in a tumor perhaps not larger than an ordinary fist. That these concretions are organized, at least in many cases, is evinced by their intimate adhesion, not only to each other, but also to the inner surface of the sac, by their extraordinary density, and by their yellowish hue, which contrasts most strikingly with that of recently deposited fibrin and coagulated blood. These circumstances show that these lamellæ undergo most important changes after they have been deposited; that absorbent vessels are busily engaged in carrying away the serum and coloring matter of the blood, and in solidifying the fibrin after it has been extricated from the general mass; while the successive development of concretions clearly denotes that the process is as much a vital as a mechanical one. No arteries and veins have, I believe, yet been demonstrated in them; but that such vessels are always present—often, indeed, in great numbers—in cases of long standing, does not admit of any reasonable doubt. We may, therefore, look upon these clots as exceedingly interesting structures, capable, after a certain period, of maintaining a kind of independent existence. Their primary object evidently is to strengthen the aneurismal sac, and, under favorable circumstances, to fill it up, so as to effect a radical cure. What adds to the force of this conclusion is the fact that, when a cure of this description has been effected, the tumor is gradually brought under the influence of the absorbent vessels, by which it ultimately entirely disappears, with the exception, perhaps, of a little

module, not larger than a pea, and just sufficient to indicate the former site of the disease. It is proper to state that the recently-formed strata of an aneurismal sac are, in general, very imperfectly, if at all, organized; they are certainly not vascularized and furnished with absorbents.

How are these aneurismal concretions formed? Upon this subject there still exists some contrariety of sentiment. Most pathologists, however, suppose, and very correctly, as I think, that they are deposited from the blood as it sweeps over the inner surface of the sac, during which more or less of its fibrin is disengaged, while the other elements of the fluid are sent forward to mingle with the current in the affected artery. This opinion derives plausibility from the fact that the development of these strata always proceeds most rapidly when there is a comparatively small orifice of communication, with a languid state of the systemic and aneurismal circulation. It has been conjectured that the clots had their origin in an effusion of plastic matter, such as occurs in injuries and ordinary inflammation; but for such a view I can myself perceive no just ground, as it is impossible to discover the slightest similarity between the two processes. The act of formation, as stated in the preceding paragraph, is both a mechanical and a vital one; mechanical, as far as the mere separation of the fibrin from the blood is concerned; vital, as it respects the decolorization, condensation, and intimate adhesion of the concretions.

The *tubular aneurism* is extremely rare; it is observed principally in the aorta and its larger branches, especially the innominate, carotid, and iliac, and consists in a uniform dilatation of the vessel, usually composed of all its tunics in varying degrees of alteration. In its shape, the tumor is commonly somewhat spindle-like, and hence it is often described under the name of fusiform aneurism; the term cylindroid has also been applied to it, as its conformation occasionally partakes strongly of that character. The word tubular, however, is more expressive of its appearance, and I therefore adopt it in preference to any other. The annexed drawing, fig. 250, from a specimen in my collection, affords a good idea of this variety of the disease.

The size of the tubular aneurism varies from slight increase of the normal diameter of the vessel to a tumor capable of receiving a large fist. When it occupies the arch of the aorta, it often projects up into the neck so as to form a prominent swelling above the sternum, admitting of satisfactory examination, both by touch and auscultation. The distance between the roots of the carotid arteries is greatly increased, and the aneurism generally encroaches sensibly upon the heart. In nearly every instance its length considerably exceeds its diameter. The dilatation of which it consists seldom terminates abruptly, but is lost by insensible degrees in the vessel above and below, thus giving the tumor the appearance of two cones united at their bases. In the smaller arteries, as, for example, the innominate, the aneurism sometimes involves the whole length of the vessel.

The structure of the tubular aneurism is usually made up of all the tunics of the affected artery, in a notable state of alteration, of which hypertrophy constitutes the most striking feature. In two remarkable

Fig. 250.

Tubular aneurism of the aorta.

specimens in my collection, the different tunics are immensely thickened, and increased in strength and density, the effect, evidently, of long continued interstitial deposits; they both occupied the arch of the aorta, extending as far as the root of that vessel, and were taken from male subjects upwards of fifty years of age. The lining membrane has lost its white and glossy appearance, and has been replaced by a thick, opaque, and rugose structure, having none of the properties of the original texture. The middle coat is at least ten times as thick as natural, very strong, elastic, and deprived of its yellowish hue; the outer one is also greatly changed in its appearance, being remarkably strong, thick, and firm. No evidence whatever exists in any of the tunics of the earthy, atheromatous, or fatty degeneration.

From a careful examination of this form of aneurism, it appears to me to consist essentially in a dilatation of the caliber of the artery with hypertrophy of its different tunics. The first step, probably, in its formation is chronic inflammation, causing weakness of the walls of the vessel, and uniform enlargement of its diameter. By and by, however, as the dilatation increases, the coats become strengthened in every direction by interstitial deposits, and it is thus that a tumor is at length formed capable of offering great resistance to the impulse of the blood. It is owing to this superaddition of matter that the tubular aneurism so seldom gives way by rupture; a circumstance in which, as well as in several others, it differs remarkably from the sacciform variety of the disease.

It is not to be supposed, from what precedes, that this form of aneurism always consists of the different tunics of the affected artery; this is unquestionably true in most cases, but we now and then meet with an instance in which the lining membrane, and perhaps, also, the middle layer, are partially deficient, thus

causing irregularity in the dilatation, unless, as occasionally happens, the defect is atoned for by plastic deposits. Indeed, the retention of all the tunics would seem to be an essential condition to the formation of the true tubular aneurism; if the inner and middle lamellæ be destroyed, even to a small extent, the blood will dilate the vessel unequally, and inevitably give rise to a sacculated tumor. It is in this way that we may explain the occasional co-existence of the two forms of the malady.

The tubular aneurism is remarkable, besides some of the characters already pointed out, for the absence of fibrinous concretions, which are so common in the sacciform; and the circumstance may be employed as an additional evidence of the correctness of the view, so long and so generally entertained, that the formation of these substances takes place directly from the circulating fluid, and not as an effect of the deposition of plastic matter, consequent upon inflammation, as some have conjectured. If the development arose in the latter way, it ought to be of frequent, if not of constant, occurrence, inasmuch as the inner coat of the affected artery is seldom entirely free from inflammation, and would thus afford a large surface for the effusion of fibrin; but every one who has ever examined a specimen of tubular aneurism, knows how extremely rare it is to find its walls incrustated with anything. In the annexed sketch, fig. 251, from Hodgson, a tubular aneurism is seen occupied by con-

Fig. 251.

Aneurism, by dilatation. The abnormal space is almost entirely filled up by fibrin; the arterial canal remaining clear. Spontaneous cure exists in an advanced stage.

cretions, with a central canal, which preserved the continuity of the vessel, and thus maintained the circulation. The stratification appears to have been very perfect.

3. SYMPTOMS OF ANEURISM.

The symptoms of aneurism exhibit, as might be supposed, much diversity, the principal circumstances which influence them being the nature, seat, and age of the tumor. Hence, in order to comprehend the subject thoroughly, it must be studied with special reference to these points.

In spontaneous aneurism, which usually depends upon rupture of the coats of an artery, the patient is often apprised of the commencement of the disease by the occurrence of a sharp pain, not unlike that produced by an electrical shock; he feels as if he had received a smart blow, and perhaps turns round to see who inflicted it. Occasionally, also, he is conscious of something having suddenly given way—he may even have heard a slight noise—and on examining the part a small pulsating tumor is found. Upon being interrogated as to the cause of the accident, he will usually state that it took place while he was engaged in some severe bodily exertion, as leaping, running, lifting, or coughing. But the origin of the disease is not generally thus marked; in the majority of cases, in fact, the patient has no distinct perception of its occurrence, and he is only apprised of its existence by degrees; not, perhaps, until it has already made serious progress. Such an event will be particularly apt to happen when the lesion consists essentially in a dilated condition of the arterial tunics, unattended with rupture, as it is then often extremely stealthy in its mode of invasion. In traumatic aneurism, on the contrary, the characteristic symptoms ordinarily show themselves immediately after the receipt of the injury of the vessel upon which the disease is situated.

The aneurismal tumor is usually quite small at its commencement, not exceeding, perhaps, the volume of a filbert, a small hickory-nut, or an almond; by degrees, however, it increases in size, and may ultimately acquire a bulk equal to that of a man's fist, or even of an adult's head. In its form it may be globular, elongated, ovoidal, conical, fusiform, or cylindrical; or so irregular as to defy description. However this may be, it is a living, beating tumor, rising and expanding synchronously with the contraction of the left ventricle of the heart. Its pulsations are often perceptible at the distance of a number of feet, especially in strong, plethoric subjects, and are always increased in force and frequency by whatever has a tendency to excite the general circulation. It imparts a distinct impulse to the hand, rising and falling as the blood enters and passes out; it is soft and elastic, and in its earlier stages permits itself to be emptied by steady and uniform pressure. Upon applying the ear to the tumor a peculiar noise is perceived, differing very much in its character and intensity. In general, it is a kind of sawing, rasping, or bellows sound, so loud as to be heard with great distinctness at a distance of several inches; occasionally it is of a peculiar whizzing, whirring, or purring nature, and cases occur, although they are rare, in which it strongly resembles the buzzing of a fly in a bottle. The immediate cause of the sound is the manner in which the blood rushes into the tumor; its pitch is always greatest, other things being equal, when there is a comparatively small opening of communication, and when the sac, containing but little solid matter, is seated superficially.

The phenomena now described are, in general, susceptible of great modification by pressure applied to the artery above and below the tumor. In the former case, the size of the swelling is notably diminished, and all motion and noise disappear; in the latter, it is sensibly augmented, the tumor heaves and rises under the resistance, and the blood, rushing violently against the inner surface of the sac, at each systole of the heart, produces great tumult, with a corresponding increase in the intensity of the different sounds. Considerable changes in the aneurismal sounds are sometimes occasioned by the rugose condition of the margins of the orifice of communication, and by partially detached clots, or projecting filaments, *within the sac, intercepting the column of blood, and causing various*

murmurs and vibrations, together with a tremulous shaking of the tumor, isochronous with its pulsations.

The pain attendant upon aneurism is constant, but subject to variation in its intensity; slight early in the disease, and while the swelling is still small; more severe and harassing as it progresses and encroaches upon the surrounding parts. Diversified in its character, it is generally dull, aching, and throbbing, as if matter were about to form; in some cases it is sharp and darting, in others dull, heavy, or gnawing. Occasionally it is of a neuralgic nature, coming in fits and starts, or, as sometimes happens, in regular paroxysms, once or twice in the twenty-four hours. The immediate causes of the pain are, inflammation of the sac and the pressure of this upon the neighboring structures; hence it is always greatest, as a general rule, in large and old aneurisms, and in those parts of the body which are most abundantly supplied with nerves.

For the same reason that the pressure of the tumor causes pain, the distal parts usually suffer from numbness, and a sense of aching and weariness. Their temperature is diminished, and they are weak and crippled. Great swelling, of an œdematous character, is often present, the result, evidently, of the compression of the veins and lymphatics impeding the return of their contents. As the tumor enlarges, the distal portion of the artery contracts, and conveys less of its wonted supply to the lower parts. Gradually, however, this is compensated for by the collateral vessels, which, naturally existing, augment in size, and, in time, amply atone for the diminished stream in the main trunk. If it were not for this arrangement, the parts would soon shrivel and wither, or, worse, fall a prey to gangrene. Fortunately, such an event can only happen when the aneurism is of extraordinary bulk, or of very rapid development, thereby compressing also the collateral vessels and the principal nerves.

Aneurism of the thoracic aorta, and of the innominate and carotid arteries, is nearly always attended with distressing dyspnœa, severe pain, and palpitation of the heart, which is itself often seriously implicated in the disease, being especially liable to suffer from hypertrophy, softening, and fatty degeneration, along with chronic endocarditis and disorder of the tricuspid and semilunar valves. As the tumor enlarges, the respiratory difficulty rapidly increases, rendering walking painful, and the maintenance of the recumbent posture ultimately impossible. Compression of the trachea may induce asphyxia; of the œsophagus, inanition. In the abdomen and pelvis, aneurism of the larger arteries, besides causing violent pain, may occasion serious functional disturbance, by interfering with the return of the blood in the vena cava, and thus leading to ascites and anasarca.

4. DIAGNOSIS OF ANEURISM.

Although the symptoms of aneurism are, in general, so well marked as to render it difficult to mistake their import, yet, as the disease may be simulated by other affections, and as doubts may thus arise in the mind of the inquirer concerning its true nature, it is necessary, in every case, however well characterized it may apparently be, before he comes to a final decision, to institute a faithful examination into its history, progress, and present condition. It has been for the want of proper care in the investigation of this disease that some of the most serious and disgraceful blunders that disfigure the records of surgery have been committed; and, although such errors are now less frequent than they were formerly, owing to the more general use of the exploring needle, and a better acquaintance with pathological anatomy, yet it cannot be denied that what has occurred once may happen again, and that with tenfold effect, as it respects the character of the surgeon, who, to his skill as an operator, is always supposed to unite that of an enlightened diagnostician. The affections with which aneurism is most liable to be confounded are, chronic abscesses, glandular tumors, and encephaloid growths. Attention to the following circumstances will, if carefully remembered, enable the practitioner to avoid error.

1. Aneurism is always, from the first, seated in the direction of one of the

larger arteries, whose course may often be distinctly traced by the finger; it is soft and elastic, pulsates more or less violently, is free from pain, and is unattended with discoloration of the integuments. Abscess, on the contrary, begins as a hard swelling, and becomes soft only after it has passed through its different stages; if chronic, matter will form very slowly, and, although it may surround the artery, and thus receive its impulse, yet the peculiar fluctuation of the swelling, and the changes that may be induced in it by pressure and posture, will always suffice to prevent error. In acute abscess, there is severe pain, pus is poured out rapidly, and there is marked discoloration of the surface, with more or less constitutional disturbance. Glandular lymphatic swellings are most common in the neck, axilla, and groin in children and young persons of a strumous diathesis; they generally advance pretty rapidly, and, after having attained a certain bulk, either remain stationary, or alternately advance and recede; they are usually multiple, and not unfrequently occur simultaneously on both sides of the body. External aneurism, on the contrary, is most common in the popliteal, femoral, innominate, and carotid arteries, in middle-aged and elderly subjects, and, progressing slowly but steadily, never recedes, and rarely exists in more than one situation at the same time. Encephaloid growths occur at all periods of life and in nearly all regions of the body; soon acquire a large bulk; are of varying degrees of consistence, some parts being solid, some soft, and some semi-solid; are attended with great enlargement of the subcutaneous veins; and soon give rise to that pale and sallow state of the features known as the cancerous cachexia. Aneurism, as just stated, advances tardily, is of uniform consistence, especially in its earlier stages, is not accompanied by any enlargement of the subcutaneous veins, and, although the general health may seriously suffer, there is an entire absence of cancerous impress.

2. Aneurism pulsates the moment it is developed; no matter how small it may be, it throbs and heaves isochronously with the action of the heart, and possesses all the characteristic traits that distinguish it in its later stages, although they are perhaps less strongly marked. Abscesses and solid tumors, on the contrary, are seldom affected by the beating of the underlying vessel until they have acquired some bulk, and even then the impulse is often very faint, occurring rather as an undulatory movement than as a distinct shock.

3. In aneurism the tumor is generally firmly fixed, any attempt to grasp and lift it up proving abortive; possibly, it may be pushed gently to one side or the other, but this is all. Moreover, whatever changes may be effected in its relations none can be effected in its pulsations; it throbs and heaves as before. With solid growths this is not so; unless very large, they can be readily isolated from the vessel, and be thus deprived of all impulse, however strong.

4. The pulsation in aneurism is generally uniform, being perceived equally at every point of the circumference of the tumor, which rises and falls synchronously with the systole and diastole of the heart; in abscess and solid growths, on the other hand, it is very irregular, and is usually limited to a particular spot. In aneurism the swelling bounds and recedes under the hand; it feels as if it were alive and panting; in solid tumors the morbid mass rises at each impulse, but there is no expansion and contraction.

5. When an aneurism is firmly and uniformly compressed, it sensibly diminishes in bulk, which, however, recovers itself the moment the hand is removed; in solid growths and abscesses, pressure produces no such result.

6. In aneurism, the size of the swelling is diminished by pressure upon the cardiac side of the tumor, and increased by pressure upon the distal side. In morbid structures not arterial, no change of bulk follows this procedure.

7. The sounds of aneurism are different from those of solid tumors. Both may yield a sawing, bellows, or rasping noise, but in the latter this is never conjoined with the peculiar thrill, or whirring noise, which constitutes so prominent a symptom in the former.

8. Aneurism of the larger arteries ordinarily affords two alternate shocks, one of which corresponds with the diastole of the heart, the other with its systole.

These phenomena are never present in solid tumors and abscesses, and are therefore pathognomonic.

Such are the distinguishing characters of aneurism and of the more important diseases with which it is liable to be confounded. It must be obvious, from what has been said respecting them, that mistake can only be avoided by the most rigid and thorough examination, made not once, but repeatedly, in every case of tumor situated along the course of an artery and influenced by its pulsation. When, after such a pains-taking process, no satisfactory decision can be arrived at, our only resource is the insertion of a delicate exploring-needle, which, while it can do no possible harm, if it is properly employed, will at once determine the diagnosis.

In the examination of aneurismal tumors about the neck, the surgeon cannot be too cautious in his manipulations, lest he detach some of the clots, and thus give rise to apoplexy by inducing obstruction in the cerebral vessels. Several instances strikingly illustrative of this danger have been reported within the last few years, and should serve as a warning to officious interference. In a case mentioned by Esmarch, the tumor had attained the size of a hen's egg, and was readily diagnosticated as an aneurism of the common carotid. A surgeon, wishing to reduce its volume, made very firm pressure upon it, when the patient fell suddenly back with symptoms of apoplexy, of which he died in three days. The dissection disclosed complete occlusion of the internal carotid, middle cerebral, and ophthalmic arteries by dark-brown clots, whose identity with those in the aneurismal tumor was proved by the microscope. A somewhat similar case has been recorded by Mr. Teale, of Leeds. The subject was a middle-aged female, with a tumor in the neck. While several surgeons were engaged in handling and compressing it with a view of ascertaining its character, she suddenly turned pale and slipped off the chair. On being raised, she was found to be hemiplegic, and in this state she died in a few weeks. The tumor was aneurismal, and some of its contents had no doubt produced obstruction of the cerebral arteries.

5. EFFECTS AND TERMINATION.

The effects which aneurism exerts upon the surrounding parts vary according to circumstances, of which the most important are, the situation of the affected vessel, and the size of the tumor. An aneurism of the arch of the aorta will, other things being equal, produce more serious disturbance, both organic and functional, than one of the abdominal portion of that vessel, and an aneurism of the carotid artery than one of the popliteal. It is obvious also that a small tumor will, as a general rule, cause less serious effects than a large one.

The effects which such a disease produces upon the parts with which it is in contact are purely of a mechanical character, eventuating in their displacement, compression, or ulceration, or in all these occurrences combined. An aneurism of the thoracic portion of the aorta must necessarily encroach more or less upon the contents of the chest, pushing the heart and lungs out of their natural position, and thereby interfering essentially with the performance of their proper functions. In aneurism of the carotid artery there will be displacement of the trachea, œsophagus, and the great vessels of the neck, along with compression of these parts, and also of the pneumogastric and sympathetic nerves. In popliteal aneurism the portion of the limb below the site of the tumor generally suffers from obstructed circulation, as is evinced by the occurrence of anasarca and decrease of temperature, with a feeling of numbness, the result of interruption of the nervous current. When the embarrassment to the flow of blood is very great, or long continued, mortification of the distal portion of the limb is liable to ensue.

When the tumor is situated externally it may produce serious changes in the muscles, which, in many cases, are not only widely separated from each other, but remarkably pale, flattened, and attenuated, exhibiting more the appearance of thin ribbons than of thick, solid, fleshy bodies. The nerves, too, are often very much spread out, the vessels are thrust aside, and the aponeuroses are stretched

out like tense sheets. When pressing upon an important joint, the tumor is sure to impede its motion, and may even cause permanent ankylosis, as occasionally happens in aneurism of the popliteal artery.

The effect produced by aneurism upon the osseous tissue is sometimes very remarkable. It is generally most conspicuous in the dorsal portion of the spine. When the disease involves the thoracic aorta, the tumor, crowded into a comparatively small space, is liable, especially when it is of large bulk, to encroach seriously upon the bony walls of the chest, pressing upon and eroding the bodies of the vertebræ behind, as seen in fig. 252, the sternum in front, the ribs at the side, and the clavicle above. There is no osteological cabinet, of any extent, that does not contain specimens of this kind. I have seen cases where as many as four of the bodies of the dorsal vertebræ were completely absorbed as far as the spinal canal, which, forming the posterior boundary of the tumor, was thus freely exposed to its pulsations. The sternum suffers mostly at its lateral and upper aspect, but occasionally, as in an instance now under my care, it is perforated at the centre, the movements of the aneurism being distinctly visible at that part. The ribs and their cartilages do not generally participate to any considerable extent in the erosion, and the clavicles are rarely affected, unless the tumor is of great bulk, and projects unusually high up into the neck.

Fig. 252.

Erosion of the vertebræ from aneurism.

adjacent textures, which, taking on inflammatory action, become matted together by interstitial deposits, which, for a time, thus materially strengthen the aneurismal sac. But this state of things is not destined to last long; gradually the morbid action increases, the superincumbent tissues are more and more expanded, and, at length, ulceration setting in, the integuments yield over the more prominent portion of the sac, followed by destructive hemorrhage.

6. SPONTANEOUS CURE.

Unfavorable as the prognosis of aneurism generally is, it is extremely gratifying to know that a cure may occasionally be effected spontaneously, without the intervention of art in any way. That such an event is rare, forming merely an exception to the great law, is unfortunately too true; yet it sometimes occurs under circumstances apparently the most desperate, bidding defiance alike to medical and surgical skill. There are, indeed, few practitioners of enlarged experience, who have not met with cases of this disease in which, contrary to all calculations of the doctrine of chances, the patient made an excellent recovery, after having literally hovered, for days and weeks, over the very verge of the grave; where, in short, everything portended speedy destruction, and yet every vestige of the aneurism ultimately disappeared, the person living for years afterwards in the enjoyment of good health, and in the exercise of his former occupation. How the cure is effected in these cases, our information does not enable us to explain, as an opportunity is seldom afforded of making a dissection of the body after the event has taken place, in consequence of the individual being usually lost sight of. A knowledge, however, of the possibility of such a cure

is highly encouraging, and holds out the hope that it may be of more frequent occurrence than has hitherto been imagined.

The most remarkable case of the spontaneous cure of this disease that I have ever seen, was that of a gentleman, aged 62, whom I attended, in January, 1862, along with Dr. E. L. Carter. The tumor, which had come on about twelve months previously without any assignable cause, presented all the characteristic features of an aneurism of the left subclavian artery. It occupied the whole of the triangular space above the clavicle, between the trapezius and sterno-cleido-mastoid muscles, where it formed a large prominence, heaving and pulsating synchronously with the contraction of the left ventricle of the heart, and imparting a peculiar blowing or sawing sound to the ear. The patient experienced excessive pain in the tumor, as well as in the shoulder and arm; there was great numbness of the whole extremity, and he was obliged to be constantly propped up in bed, as well as to make free use of anodynes to enable him to sleep. The prognosis, in fact, could not have been more unpromising. Early in May, however, he was able to take gentle exercise in the open air; his health now gradually improved, and the tumor began to diminish in size, the process of absorption steadily progressing until December, 1863, when every trace of it had disappeared. The left arm and hand remain cold and atrophied, but in all other respects the recovery is perfect. The treatment consisted principally of the internal use of iron and quinine, along with a properly regulated nutritious diet.

Although we are not always able to account for the manner in which the patient gets well in this disease, observation has demonstrated that it generally occurs in one of five ways, all leading, essentially, to the same result, namely, the formation of clots, by which not only the aneurismal sac is closed up, but also the artery immediately above and below it. When the cure is gradual, the clots are usually arranged concentrically, and exhibit every mark of organization; but the reverse is the case when it is effected suddenly, for then they are nothing but soft, red blood-masses, similar to what are so often observable after death in the heart and large vessels.

1. The most common way in which the cure takes place is by the gradual filling up of the sac by the formation of clots, thereby ultimately converting it

into a firm, solid tumor. The most beautiful and perfect specimen of this kind, represented in fig. 253, that I have ever seen, was presented to me, some years ago, by an old pupil, Dr. Shumard, who had removed it from the body of a young steer. What renders it still more interesting is the circumstance that it was connected with the hepatic artery, which had given way at one side from the rupture, apparently, of its inner and middle tunics. The tumor, which is of a rounded shape, and nearly three inches in diameter, is occupied by hundreds of la-

An aneurismal tumor obliterated by the deposition and organization of fibrin.

miellæ, many of them not thicker than a sheet of paper, of a pale grayish color, closely adherent to each other, concentrically arranged, of a dense, firm texture, and, beyond question, thoroughly organized, even those most recently deposited. At the centre of the tumor, a small irregular cavity exists, which still admitted some blood, as is proved by the fact that the hepatic artery is completely pervious. This mode of repair is greatly facilitated by the small size of the opening of communication between the artery and the aneurismal sac.

2. Another mode of spontaneous cure is the occurrence of inflammation, fol-

lowed by the coagulation of the contents of the sac, and the ultimate obliteration of its cavity as well as of the artery in its immediate vicinity. The disease may begin in the tumor itself, or be propagated to it from the circumjacent structures; if it is mild and slow, the cure may be easy and safe, but, if it is very active, it may terminate in suppuration, and thus endanger life by hemorrhage, the matter being evacuated along with the clots before the artery is hermetically sealed by an internal coagulum.

3. The repair occasionally occurs through the intervention of gangrene, either beginning in the tumor itself, or extending to it from the parts immediately around it. The blood coagulates in the sac as it does in an artery in ordinary gangrene, and when the sloughs separate the clots are discharged, the gap being afterwards closed by the granulating process. Such a mode of restoration must necessarily be infrequent, inasmuch as the morbid action by which it is effected generally terminates fatally.

4. The contents of an aneurism are sometimes solidified by the compression of the artery leading to it, caused either by the tumor itself or by some morbid growth in its immediate vicinity. Such a result may follow with nearly equal certainty, whether the pressure is applied to the cardiac or to the distal portion of the vessel.

5. Finally, a very rare mode of spontaneous obliteration may take place, consisting in the detachment of a small clot and of its introduction into the distal portion of the artery, thereby more or less completely blocking it up. The blood, thus checked in its onward flow, soon coagulates, just as it does in artificial compression. It was upon a knowledge of this species of spontaneous cure that Mr. Fergusson recently attempted to found a new mode of treatment of aneurism by breaking up the contents of the tumor by manipulation, and thus urging them on into the communicating vessel.

When, by any of the above modes, a radical cure is effected, the tumor is gradually brought under the influence of the absorbent vessels, and is ultimately completely obliterated, or, at all events, so far reduced as to leave only a small nodule, indicative of the former site of the disease. The period required for the perfection of these changes varies from three or four weeks to as many months, according to the size of the aneurism and the state of the part and system.

Although an aneurism may occasionally get well spontaneously, or under internal treatment, such an event is entirely exceptional. The great law of the disease is death. The period at, and the mode in, which this takes place are extremely variable, and can, therefore, be pointed out only in a general manner. In aneurism of the aorta, especially in the arch of this vessel, the disease often terminates in less than three months from its commencement; in the innominate its course is also generally rather rapid, and a similar remark applies to aneurism of the primitive iliac; in aneurism, on the contrary, of the carotid, subclavian, axillary, external iliac, femoral, and popliteal arteries, the fatal event is often postponed several months longer. To these statements there are, of course, many exceptions; thus, on the one hand, we occasionally meet with an aneurism that kills in a few weeks, the tumor expanding rapidly, and perhaps bursting quite suddenly during a violent muscular effort; and, on the other, the disease may continue, with very little variation, as to size, for a number of years.

There are three distinct modes in which aneurism may cause death: 1. By the injurious compression which the tumor exerts upon the neighboring organs. 2. By the sudden rupture of the sac, and the occurrence of hemorrhage. 3. By the development of inflammation, suppuration, or mortification.

1. Aneurismal tumors of the neck and chest often cause death by compression of the trachea and bronchial tubes, although perhaps not as frequently as has generally been supposed, owing to the wonderful power which these tubes possess of flattening themselves, so as to make room for the entrance of air into the lungs. Indeed, I am inclined to think that death from direct suffocation, from this cause, is an uncommon event. Great difficulty is often produced by the *pressure of the sac upon the pneumogastric and phrenic nerves*, and it is

extremely probable that life is sometimes destroyed in this way, the more especially when the pressure is conjoined with serious lesion of the air-passages. Finally, death occasionally proceeds from compression of the heart and lungs, interfering with the circulation and respiration; or from compression of the œsophagus, causing inanition. In the abdominal and pelvic cavities, and also in the extremities, the danger from compression is not nearly so great, as the structures here are less important to life, as well as more disposed to yield under the encroachment of the tumor.

2. After an aneurismal tumor has attained a certain bulk it is extremely apt to give way, as in fig. 254, either suddenly or gradually, under the impulse of the blood, or under severe muscular exertion. Such an occurrence will be the more likely to happen when the tumor has been of rapid growth, and especially if its interior has not been fortified by the formation of hard, organized clots, so as to increase the thickness and strength of its tunics. It is in this manner that most of the internal aneurisms, which do not cause destruction by mere compression, ultimately terminate, the immediate cause of death being hemorrhage into some internal and contiguous organ. Thus, in the chest the tumor usually

Fig. 254.

Aneurism of the descending aorta, burst, the patient dying suddenly in consequence.

opens into the trachea, bronchial tubes, pleura, pericardium, mediastinum, or œsophagus. Sometimes a communication is established between the sac and the heart, between it and the pulmonary artery, or, lastly, between it and the vena cava. An aortic aneurism has also been known to burst into the spinal canal, some of the bodies of the vertebrae having previously been destroyed by absorption. In the abdomen, the tumor may break into the peritoneal cavity, or into one of the hollow viscera, as the stomach, intestine, or urinary bladder. In the neck, axilla, groin, and extremities, the aneurism, if permitted to pursue its course, generally finds its way to the surface, very much after the manner of an abscess.

The hemorrhage succeeding to the rupture of an aneurism may be slight, as when the aperture is small or devious, or copious and destructive, as when the opening is large or straight. Most commonly, life is worn out by the frequent recurrence of the bleeding; thus, twenty ounces of blood may be lost to-day, in a week twenty or thirty ounces more, and so on until the patient dies completely exhausted, his condition being, in the meantime, perhaps sadly aggravated by serous effusions into some important cavity. Occasionally the aneurism gives way by a large rent, and the patient expires instantly in consequence of the hemorrhage.

3. More or less inflammation attends all aneurisms; whatever may be their volume or situation, their age, or character, they play the part of intruders, encroaching upon, compressing, and irritating the surrounding structures, and thus giving rise to various deposits, especially of serum and plasma. It is by means of the latter that, as was previously stated, the sac increases in thickness and density, so as to qualify it the better to bear with impunity the impulse of the inflowing current of blood; without such an occurrence few tumors of this kind would be able to maintain themselves for any length of time, but would soon yield to the resistless pressure from within; in a word, speedy rupture of the sac, and fatal hemorrhage would in most cases be inevitable. But, although inflammation is set up for wise and beneficial purposes, the process, unfortunately, is not always kept within the strict limits required to fortify the sac and protect it against early rupture; on the contrary, many circumstances occur to provoke its increase, and to cause it to pass into ulceration, suppuration, and even mortification. Among these circumstances some are

of a constitutional, others of a purely local, character; thus, mere plethora and the use of stimulating food and drink may powerfully augment the inflammation, and bring about these untoward results. In general, however, it will be found that the mechanical compression of the tumor, in consequence of the resistance offered to its extension, has more to do with its production than anything else. Sometimes a clot is accidentally detached, and thus becomes a cause of mischief. In external aneurism, the manipulation employed in examining the tumor is occasionally productive of severe inflammation, and similar effects often follow the injudicious use of the affected limb.

Suppuration of the tumor is an infrequent event. A case occurred in 1857, at the Pennsylvania Hospital, in the service of Dr. Pepper, in which an abscess had formed in connection with an aneurism of the innominate artery, and destroyed the patient, a man aged 38, by bursting into the trachea. A report, with a drawing of the case, has been published by Dr. Humphreys, in the Transactions of the Pathological Society of Philadelphia. Ulceration and mortification are more common, and are particularly liable to take place, when the tumor is of large size.

Finally, aneurism may prove fatal by exciting inflammation in an important internal organ, as the lung, heart, or pleura. In popliteal aneurism, the pressure of the tumor upon the nerves and arteries below sometimes causes death from mortification of the leg and foot.

TREATMENT.

Notwithstanding the vast amount of attention that has been bestowed upon aneurism, from the earliest periods of medical science down to the present, it may truly be affirmed that there is no subject connected with practical surgery that has been so little understood by the great mass of the profession as this. This circumstance has arisen, it seems to me, not so much from a want of ability on the part of the practitioner to comprehend the nature of this lesion, as from the obscure and imperfect manner in which it is usually discussed in our lecture-rooms and in our systematic treatises. Much difficulty also has grown out of the defective nomenclature of aneurism and of the ambiguity which, until recently, existed in regard to the pathology of this affection, both tending to give rise to erroneous ideas of practice. Light, however, is gradually breaking in upon us; and it is highly probable that the advances of modern science will enable us, ere long, to treat aneurism with as much confidence as any other class of maladies.

Leaving, for the present, out of view the treatment of internal aneurism, as belonging as much to the department of medicine as that of surgery, I shall proceed to consider the various remedies that have been proposed for the cure of the external form of the disease, or, more properly speaking, of those cases of aneurism which are more directly and immediately amenable to topical measures. In doing this, it will be necessary to bear in mind the divisions of aneurism pointed out in the commencement of the section, as each requires corresponding modifications of management.

In the time of Celsus, as well as for a long period subsequently, the treatment of aneurism was conducted in the most cruel and unscientific manner. The only operation which appears to have been known was to lay open the tumor by a bold incision, and, after turning out its contents, to apply the hot iron to the extremities of the affected artery, so as to seal up their mouths. The effect of such a procedure may easily be imagined; upon the separation of the eschar, hemorrhage was sure to take place, and in this way nearly every patient perished, either at the first onset of the bleeding, or by its frequent repetition. This miserable practice continued in vogue until the introduction of the ligature by Ambrose Paré. A different mode of procedure was now adopted, although it can hardly be said to have been much of an improvement upon the one just described. It certainly, however, possessed the advantage of being more scientific, and of being less frequently followed by hemorrhage, notwithstanding it could claim little on the score of simplicity as far as its execution was concerned. It consisted in

ligating the artery above and below the tumor, which was then freely opened, thoroughly cleared out, and stuffed with charpie, to promote suppuration and occlusion, the object being to heal the wound from the bottom. Occasionally the more adventurous surgeon took the more speedy route of extirpating the tumor, adopting a plan similar to that which is sometimes pursued at the present day in treating aneurism at the bend of the arm consequent upon venesection. The result, too, of this operation was often most disastrous; many of the patients died of the effects of inflammation, some of secondary hemorrhage, and not a few of the shock of the amputation performed as a *dernier resort*, to save them from impending destruction. To prevent these sad occurrences, and afford the sufferer a better chance of recovery, the removal of the limb was often the only expedient thought of for his relief.

a. DELIGATION OF THE ARTERY AT THE CARDIAC SIDE OF THE TUMOR.

It is very surprising that some of the procedures above described should have continued in vogue until near the close of the last century. The fact attests, more fully than any other circumstance with which we are acquainted, the low state of surgery up to that period. The merit of performing the first operation for the cure of aneurism upon strictly scientific principles is due to Mr. John Hunter. From having witnessed so many failures from the ordinary methods, he was led to the conclusion that the cause consisted in the fact that the artery is always diseased for some distance above the aneurism, and that it was, therefore, incapable of becoming sufficiently occluded prior to the detachment of the ligature to prevent hemorrhage. Acting under this conviction, amply confirmed by dissection and observation, he determined, upon the first favorable opportunity, to apply the ligature to a sound portion of the vessel. While thus revolving the matter in his mind, a man, laboring under popliteal aneurism, was admitted into St. George's Hospital, of which he was then one of the surgeons. The patient was a coachman, forty-five years of age; and the tumor, first perceived three years previously, was not only quite large, but attended with great swelling of the foot and leg. The operation was executed in December, 1785, the femoral artery being exposed a little below its middle, and surrounded by four ligatures drawn so gently as simply to bring the sides of the vessel together. "The reason for having four ligatures was," as is stated by Sir Everard Home, by whom the case was reported, "to compress such a length of artery as might make up for the want of tightness, it being wished to avoid great pressure on the vessel at any one part. The ends of the ligature were carried directly out of the wound, the sides of which were now brought together and supported by sticking-plaster and a linen roller, that they might unite by the first intention."

It is unnecessary to enter into any details respecting the after-treatment of the case. It will be sufficient for my purpose to state that on the second day after the operation the tumor had lost more than one-third of its original bulk; that the ligatures, some of which came away on the fifteenth day, excited severe inflammation in the artery, as well as in the surrounding parts; and that the man left the hospital on the 8th of July following, in good health, and with no appearance of any tumor in the ham. He subsequently resumed his former occupation as coachman, and died from an attack of remittent fever, fifteen months after the operation. The limb being dissected, the femoral artery was found to be impervious as high up as the profunda, while below the site of the ligatures, as far down as the tumor, it was open, and contained blood, except just where it entered the aneurism, where it had become obliterated. The sac was a little larger than a hen's egg, but more oblong and flattened, and contained a solid coagulum adherent to its internal surface.

I have been induced to give a brief outline of this case for two reasons. In the first place it deserves to be commemorated because it embodies the application of a new principle to the cure of a disease which, until then, was almost uniformly fatal; and, secondly, because it will enable us to establish, in a more satisfactory manner than we could otherwise do, the claims of Mr. Hunter to the credit of

having originated the operation, which has been so sturdily denied him by the French surgeons, who have, almost with general consent, ascribed it to their countryman, Dominic Anel.

The case of Anel fell accidentally into his hands during a visit which he made to Rome in 1710. His patient was a priest, who, from a prick of the brachial artery received in venesection, had an aneurism at the bend of the arm; the tumor was large, and seemed to have been on the point of bursting. Having controlled the circulation in the limb by means of the tourniquet, he cut cautiously down upon the artery, and, after separating it from the accompanying nerve, he raised it upon a hook, and tied it as near to the tumor as possible. All pulsation instantly ceased, the ligature came away on the eighteenth day, and at the end of a month the friar was able to use his arm as well as ever.

It will thus be perceived that the operations of the English and French surgeons differed from each other in every particular; and it is only surprising that there ever should have existed any contrariety of opinion respecting them. The procedure of Anel was executed for the cure of a traumatic aneurism; the artery was perfectly healthy, and it was tied as closely to the tumor as possible. He never supposed that he was about to establish a new principle in surgery; he nowhere alludes to any such intention; his only object seems to have been to afford his patient, who was suffering great agony, and who might bleed to death at any moment from the sudden bursting of his tumor, prompt relief. Hunter, on the contrary, had studied the subject with extraordinary care and attention; he had made numerous dissections, and even performed some experiments upon the inferior animals, as the dog and horse, with a view of ascertaining the condition of the artery in aneurism and its ability to bear the ligature; and he had clearly perceived that, as the cause of failure of the old operation was that the ligation was always made too near to the tumor, the only safety would be to tie a sound portion of the vessel, even although this should be at a very considerable distance from the aneurism. His object was not to cut off the supply of blood at once, but simply to weaken its passage through the tumor, thereby giving its contents an opportunity of undergoing gradual coagulation, and at the same time preventing the distal parts of the limb from perishing from the sudden stoppage of the circulation. The result of the case above detailed proved the correctness of his reasoning, and established, upon a firm and immutable basis, what is now universally recognized in Great Britain and in this country, as the Hunterian operation for aneurism.

The operation of Hunter has been performed upon almost every artery of the body liable to suffer from aneurism. Even the aorta itself has been repeatedly tied; and, although all the cases have proved fatal, yet the result has been such as to show, most conclusively, that the event has been due much more to the injury inflicted upon the surrounding structures than to the violence done to the circulation by cutting off so great a quantity of blood from its accustomed channels. Great simplicity now characterizes the operation; a healthy portion of artery is selected, great care is taken, in exposing the vessel, to disturb its sheath as little as possible, and only one ligature is used, but that is drawn so tightly as to lacerate the inner and middle tunics, when, a double knot being made, one extremity is cut off, and the other is brought out at the nearest point of the wound, which is then treated in the ordinary manner. Cessation of pulsation usually occurs at once upon tightening the ligature, although not necessarily so; sometimes, indeed, several days elapse before it is fully established, but even then it is commonly very much diminished in force, thus paving the way for the gradual formation of clots upon which the cure ultimately depends. The persistence of the circulation, after the main artery of a limb has been ligated, arises from the anastomosing branches continuing to pour their contents into that portion of the vessel which lies between the cord and the sac, as well as into the sac itself, and perhaps also into the distal portion of the artery. When these branches are inordinately large, or numerous, they may keep up such a supply of blood as to compromise effectually the success of the operation.

The operation is generally followed by a slight diminution of temper

the limb, but this rarely lasts beyond a few hours, when it is succeeded by a marked increase of heat, owing to the augmented activity of the cutaneous circulation, in consequence of the blood being forced principally through the superficial capillaries. Subsequently, however, as the anastomotic branches enlarge, and the circulation becomes equalized, the temperature sinks again, and now perhaps somewhat below the normal standard, the parts really feeling, for the first time, the loss of blood occasioned by the ligation of the artery. In not a few cases the limb retains its temperature after the operation with hardly any variation, as if nothing at all had happened.

Instead of the ordinary silk ligature, Dr. Stone, of New Orleans, in a case of aneurism, in 1859, tied the common iliac artery with a silver wire, simply approximating the sides of the vessel, and leaving the wire in the wound, convinced of its entire harmlessness. The patient died on the twenty-sixth day, but, as no autopsy was made, the disposition of the ligature was not ascertained. At the Clinic of the Jefferson Medical College, in 1861, I secured, in a similar manner, the femoral artery in a case of popliteal aneurism; the patient rapidly recovered without any untoward symptom, and the wire still remains in the thigh, nearly the entire wound having healed by the first intention. Since that period I have operated, equally successfully, with the metallic wire upon two other cases.

In ligating an artery in its continuity for the cure of aneurism the greatest possible care should be taken not to wound the accompanying veins, as such an accident inevitably endangers the issue of the case by provoking a bad form of phlebitis, from the effects of which few persons recover. The ligature, passed through the vessel, embraces a portion of it tightly along with the artery, and, consequently, acts precisely as a seton, causing diffusive inflammation, not only in the vein itself, but also in the surrounding structures. The risk will be particularly great when an artery is tied close to the aneurism, as, during the progress of this disease, the inflammation of the sac not unfrequently extends along the cellular substance which connects the two vessels, thus rendering them specially intolerant of interference. When such an accident happens, the ligature must at once be withdrawn, and repassed with more care, either at the same point or a short distance above or below. The bleeding is easily arrested by compression.

After-treatment.—The treatment after the operation must be conducted with great judgment and attention. The patient being carried to bed, the limb is placed in an easy and relaxed position, but not elevated, lest arterial influx be interfered with; and it is well, especially if there is a diminution of temperature, that it should be enveloped for some time in wadding. Cold applications must be carefully avoided, even if the skin manifest inordinate heat with some degree of swelling, as they could not fail to be prejudicial by lowering the vital powers, and so laying the foundation for mortification. A full anodyne should be administered immediately after the operation, to tranquillize the action of the heart; light diet is to be observed, with cooling drinks; and the temperature of the apartment is not permitted to exceed 65° of Fahrenheit. The bowels must not be opened for several days, and then only by the mildest laxatives, drastic purgatives being particularly objectionable on account of their tendency to cause excitement and throbbing of the arteries; occurrences which would inevitably be injurious after such an operation.

Causes of Failure.—The causes of failure after the Hunterian operation are, first, violent inflammation, followed by mortification; secondly, death of the limb from deficiency of blood; thirdly, secondary hemorrhage, either from premature detachment of the ligature, or rupture of the sac; and, fourthly, maintenance of the circulation by means of a redundant anastomosis.

Ligation of an artery is not often followed by severe *inflammation* at the seat of the operation; the parts, indeed, generally unite by the first intention, or, if there is any suppuration, it is chiefly at the seat of the ligature. It is only, or mainly, in persons of bad constitution that the resulting action is apt to become excessive, or to assume an erysipelatous character, threatening limb and life.

Mortification of the limb below the seat of the operation, from inflammation

and defective circulation, is met with almost exclusively in the inferior extremities after ligation of the femoral artery for aneurism of the popliteal. Of 156 cases of this operation, analyzed by Dr. Norris, 28, or about $5\frac{1}{2}$ per cent., were followed by this accident. Of these cases 11 died, and 7 recovered, 6 of the latter having escaped with the loss of the affected limb. The probability is that gangrene may arise from a mere want of blood in the parts, but most generally it is dependent upon inflammation of the artery leading to the formation of fibrinous clots, and the consequent closure of the caliber of the vessel and also of some of the collateral channels. The mortification usually begins within the first forty-eight hours in the distal portion of the limb, from which it gradually spreads until the patient dies, as he usually does in from five to ten days after the first appearance of the disease.

The best means of averting this untoward occurrence is to place the limb in a proper position and to guard against overaction in the parts. If gangrene manifest itself, notwithstanding our endeavors to prevent it, immediate recourse should be had to amputation, the limb being, if possible, removed above the seat of the aneurism.

The occurrence of *secondary hemorrhage* after this operation may usually be expected about the time of the separation of the ligature, but it may come on before this, or it may not take place until much later. In general it supervenes from the seventh to the eighteenth day. A diseased state of the artery, excessive inflammation, or the mal-application of the ligature may be considered as so many exciting causes of the accident.

The frequency of secondary hemorrhage after the Hunterian operation has been differently estimated by different writers. Lisfranc collected 180 cases, of which 32 were followed by this occurrence. In 530 cases analyzed by Porta, secondary hemorrhage took place in 73, of which more than one-half perished, either directly or indirectly, from loss of blood. If we descend to particular operations it will be found that of 38 cases of ligation of the carotid there were 7 cases of secondary hemorrhage with 2 cures and 5 deaths; the external iliac affords 8 cases out of 97, of which 5 died and 3 were cured. Of 187 operations upon the femoral artery, 19 were followed by hemorrhage, and of these 9 died and 9 were cured, the other recovering after amputation, rendered necessary on account of the persistence of the bleeding.

The principal remedies for secondary hemorrhage, after such an operation, are gentle but systematic pressure at the site of the bleeding, and also over the main trunk of the vessel, assisted by the internal use of acetate of lead and opium in union with veratrum viride. Occasionally it will be necessary to tie the artery higher up; or even to amputate, especially if, when the surgeon is called to the case, the loss of blood has already been great, and the parts are much obscured from swelling and infiltration.

Rupture of the aneurismal sac is uncommon after the operation. It is observed chiefly in cases of long standing, where interference has been delayed on account of the neglect of the surgeon, or the obstinacy of the patient. The rupture may be caused either by the gradual absorption and attenuation of the sac, aided, perhaps, by the pressure of some bony prominence, or it may be due solely to the effects of inflammation. In the latter case, which is by far the more frequent of the two, the accident generally occurs at a comparatively early period after the operation, and is always preceded by well marked local and constitutional symptoms, indicative of the impending mischief.

Rupture of an aneurismal sac hardly admits of satisfactory treatment. When the tumor is favorably situated, the best plan would be to lay it freely open, and to secure the main artery leading to it above and below. When this is impracticable, our chief reliance must be upon well adjusted pressure, assisted by cold applications and the use of means calculated to moderate the force of the circulation.

A return of *pulsation* in the aneurismal sac is occasionally observed, and is generally due to a redundant collateral circulation, or an anomalous arrangement of the main artery leading to the tumor, as, for example, the high division of the femoral. In some cases it continues after the application of the ligature; in

general, however, it comes on at a variable period, and now and then an instance occurs in which it reappears several times during the progress of the after-treatment. The pulsation usually ceases spontaneously, followed by the gradual shrinking of the sac. When it continues obstinate, and the tumor either retains its former bulk, or progressively enlarges, the remedy most likely to be successful is steady compression both of the aneurism and of the main artery of the limb. In popliteal aneurism forced flexion of the leg might be tried.

None of these accidents, save the last, and that is a very improbable one, will be likely to happen if the part and system have been thoroughly prepared for the operation, if the disease has not made too much progress, and, finally, if proper care and judgment be employed in managing the case after the application of the ligature. Deligation of the carotid arteries for the cure of aneurism is liable to be followed by inflammation of the brain and lungs, with softening of the former of these organs and hepatization of the latter. Much of the mortality from the operation is caused by these diseases.

Cases have occurred in which this operation has been followed by phlebitis, pyemia, tetanus, and apoplexy, but such results are extremely rare, and scarcely deserve to be taken into account in connection with the procedure.

No recent *statistics* of the Hunterian operation, on a large scale, have appeared. The most satisfactory, so far as I know, are those of Mr. Thomas Inman, of Liverpool, published in 1844. His table was made up of all the reliable cases that had been recorded up to that period in the various medical and surgical periodicals.

Arteries.	Cases.	Deaths.	Proportion.
Innominate	6	6	...
Subclavian	40	18	1 in 2
Carotid	40	11	1 in 4
Abdominal aorta	3	3	...
Common iliac	8	3	1 in 2½
Internal iliac	4	2	1 in 2
External iliac	27	9	1 in 3
Femoral	42	7	1 in 6
Total	170	59	1 in 3

Benjamin Phillips has collected 380 cases of this operation, of which 112 proved fatal. Of 418 cases analyzed by Porta, 117 perished. Lisfranc found 38 deaths in 125 cases. It thus appears that the mortality after this operation is truly frightful; a circumstance which should induce every practitioner to regard it with suspicion and distrust.

It is hardly worth while to remind the reader that such an operation should never be performed when the case is attended with great disorder of the general health, serious disease of an important internal organ, as the heart or lungs, or the coexistence of aneurism in any of the large vessels, more especially if the concomitant lesion has already made unusual progress. Particular inquiry should always be made into the condition of the kidneys; for there is hardly any affection which exercises so prejudicial an influence upon recovery as albuminuria. Pregnancy should be no bar to the procedure; and several instances have been reported in which the patients made an excellent recovery, and lived for a considerable period, after the deligation of a large artery for the cure of an aneurism complicated with aneurism of the arch of the aorta.

b. DELIGATION OF THE ARTERY AT THE DISTAL SIDE OF THE TUMOR.

It is well known that aneurism occasionally occurs so near the trunk as to render it impracticable to perform the Hunterian operation, or that the artery, although accessible at the cardiac side of the tumor, is too much diseased to enable it to support a ligature. Mons. Brasdor, a professor in the old school of surgery at Paris, upwards of seventy years ago, after much reflection upon the subject, arrived at the conclusion that gradual and efficient coagulation of the blood in the aneurism might be produced by placing the cord upon the artery at its distal aspect. He had no opportunity, however, of solving the problem

upon the human subject. The merit of this was reserved for Deschamps, although the case upon which he tried it could hardly have been worse for such an undertaking. The patient, besides being old, was worn out by suffering, and the tumor, which occupied the upper part of the thigh, extending to within a short distance of Poupart's ligament, was nearly seventeen inches in circumference. The operation was tedious and difficult, on account of the depth of the artery, and the absence of pulsation, but the vessel was at length discovered and effectually secured. Contrary, however, to expectation, the aneurism, which had made marked progress for some time previously, now rapidly increased in volume, and on the fourth day, when it appeared to be on the point of bursting, it was resolved to perform the ordinary operation, notwithstanding the reasons which had just before been urged against its adoption. Two ligatures were applied, but the operation was attended with copious hemorrhage, and the man died in eight hours after.

The operation of Brasdor was next performed by Sir Astley Cooper, in a case of aneurism of the external iliac artery, extending so high up into the abdomen as to render it impossible to place a ligature between it and the heart. The femoral artery was, therefore, tied a short distance below Poupart's ligament, between the epigastric and profunda. The patient did well for some days, when the tumor, which had been gradually diminishing in volume, burst, causing death by hemorrhage.

What the results of these two attempts might have been, if the cases had been of a more favorable character, is a matter which must, of course, be left to conjecture. It is certain, however, that no attempt was made to repeat the operation until 1825, when, almost forgotten by the profession, it was performed by Mr. James Wardrop, of London, in a case of aneurism of the carotid artery. The success was complete. The ligation was followed by an immediate diminution of the tumor, which gradually progressed until, at the end of the fifth week, the neck had nearly regained its natural form; the ligature had dropped off, and the general health was entirely re-established. The patient, a woman, aged seventy-five, continued to be perfectly well three years after the operation.

Having been equally successful in several other cases, Mr. Wardrop was induced to extend the principle of Brasdor's operation to aneurism of the innominate artery. It occurred to him that, by tying one of the branches of this artery, the force of the circulation might be so far diminished in the tumor below as to cause the solidification of its contents; and, a favorable opportunity soon after arising, he was not slow in putting his ideas in practice. The patient, a female, aged forty-five, had a pulsating swelling, of the size of a turkey's egg, in the inferior part of the neck, its base being concealed by the sternum, and evidently connected with the innominate artery. For the cure of this disease the right subclavian was tied in July, 1827, with the effect of a gradual amelioration of the distressing symptoms, and the ultimate disappearance of the tumor, its site being occupied merely by an unnatural hardness, the result, probably, of the remains of the aneurism. This was the condition of the patient fourteen months afterwards, at which time the carotid artery still pulsated, although not so vigorously as the left, and the woman was in better health than she had been for a long time.

The procedure now described constitutes what is called Wardrop's operation, although it is in reality, as was before intimated, merely an extension of that of Brasdor; and is only applicable to aneurism of the innominate artery. It has been performed within the last twenty years in a considerable number of cases, generally by tying the common carotid; but the results have, for the most part, been unfavorable, owing, as has been alleged, and as is probably the fact, to the occurrence of violent inflammation both in the aneurismal sac and in the vessels in immediate communication with it, terminating fatally in a few days, or, at most, in a few weeks.

Deligation of the artery at the distal side of the sac has hitherto been most disastrous. Thus, of 27 cases, collected by Mr. Erichsen, death speedily occur-

red in 20, while in the remaining 7, although the patients escaped with their lives, no benefit whatever resulted in regard to the cure of the aneurism.

The annexed cuts afford an illustration of the various methods of ligating arteries for the cure of aneurism, above described. A glance will serve to show how inefficient such an operation must be when performed according to the plan suggested by Mr. Wardrop.

C. INSTRUMENTAL COMPRESSION.

The treatment of aneurism by compression dates back to a very early period of the profession, and, although the principles upon which it was formerly conducted were far from being scientific, numerous cases have been published illustrative of

its efficacy. It is not my design to inquire into the history of the operation, or to seek out its inventor for the purpose of awarding him praise for his ingenuity and enterprise; it is sufficient to state that the compression was originally applied directly to the tumor, or to the tumor and the limb upon which it was situated, either by means of an apparatus specially constructed for the object, or by a compress and roller, extended from the distal portion of the extremity upwards, beyond the seat of the disease. The practice was most frequently employed for the relief of traumatic aneurism, particularly that form of it consequent upon injury of the brachial artery, at the bend of the arm; and, although it proved occasionally successful, not a few cases occurred in which it was followed by violent inflammation of the sac and limb, eventuating in ulceration, abscess, or gangrene.

In the latter part of the last century, Vernet, a French military surgeon, conceived the idea of curing aneurism by applying compression upon the artery immediately beyond the tumor, upon the same principle as that upon which Brasdor soon after suggested the use of the ligature. He thought that the operation was particularly adapted to aneurism situated so near to the trunk as to forbid a resort to the ligature, or compression upon the cardiac side of the swelling. It would appear, however, that he practised it only in one instance—upon a man affected with inguinal aneurism—and that so great was the disturbance which it created in the pulsations of the sac, that he was obliged, in a very short time, to abandon it. From the want of success attending the case, ill adapted as it was to test the principles of a new process, no one, it seems, felt afterwards disposed to make further trial of it, and it was accordingly forgotten, or remembered only as an ingenious suggestion.

Compression of the artery above the tumor, or between it and the heart, was first distinctly insisted upon as a remedy for the cure of this disease, by the late Mr. Freer, of England, in his observations on aneurism, published early in the present century. In the work here referred to, he gives special directions for applying the compression, enjoining that it should be made by enveloping the whole limb with a bandage, and placing upon the vessel, in the most superficial portion of its extent, a small pad, which was then to be screwed down by means of a tourniquet. To render its action more effective, a plate was secured to the opposite side of the limb, which, while it defended the integuments and muscles from injurious constriction, concentrated the force upon the particular point of the artery where it seemed to be most needed. Notwithstanding this precaution,

the application of the tourniquet was soon followed by pain and œdema of the extremity, generally so violent as speedily to necessitate its removal. Short, however, as the compression was, it occasionally laid the foundation of a cure, which was afterwards perfected by the steady but cautious use of the ordinary compress and bandage.

Acting upon the suggestions of Freer, Dupuytren and others applied themselves to this mode of curing aneurism, devising useful and ingenious instruments as substitutes for the more clumsy contrivance above described. The French surgeon, in particular, invented a most admirable compressor, at once simple and efficient, which still bears his name, and which he employed successfully in several cases of aneurism of the inferior extremity. The cures, however, that were effected in this way were few compared with the great number of failures, and the consequence was that the treatment never met with much favor. What added to the dissatisfaction of practitioners was that, in quite a considerable number of cases, it was followed by results highly prejudicial to the limb, if not to both limb and life.

Thus stood the treatment of aneurism by compression, when, in 1843, it was destined to experience a complete revolution in the hands of several eminent surgeons of Dublin, particularly Hutton and Bellingham, the latter of whom, in a short tract upon the subject, was the first to point out, upon correct and scientific principles, the manner in which it acts in curing the disease. Prior to this period, one replete with interest to the progress of surgery and humanity, compression was a very painful and hap-hazard proceeding, conducted without any discrimination and judgment, and, consequently, without any certainty as to its results. The idea was that, in order to succeed, it was necessary that it should be applied firmly and steadily, so as to arrest the circulation, and cause adhesion of the sides of the artery, very much as in the operation of ligation. Hence the poor patient was generally subjected to immense torture, often compelling the speedy discontinuance of the treatment, which, however, notwithstanding this, was occasionally followed by the worst consequences, as manifested in the violent swelling of the affected limb, and perhaps its ultimate loss by gangrene. The procedure was altogether a blind one, and, therefore, just as likely to prove prejudicial as useful. It was employed by one practitioner simply because it had occasionally been employed successfully by another, and not because any one had, as yet, been so fortunate as to lay down any broad and definite rules of action. It was for this reason that it was so long in acquiring the confidence of surgeons; that it was totally abandoned at one time, and resumed, with doubts and misgivings, at another. Its principles were not yet fully developed, or placed upon a just and comprehensive basis. This labor was performed by Dr. Bellingham and his able associates, who thus created a new era in the treatment of aneurism, hardly less brilliant than that of the ligature. What the ultimate fate of this treatment will be time alone can determine; that it is destined to supersede entirely, as some have predicted, the use of the ligature, is extremely questionable, and yet, considering the remarkable success which has attended it, such an occurrence seems not improbable.

Compression, as now conducted, is not only safe, but comparatively free from pain; and, although it is often tedious, yet few cases will ultimately resist its influence. It is more particularly applicable to the cure of popliteal aneurism, in which its greatest triumphs have hitherto been achieved, but it has also been successfully employed in aneurism of the lower part of the femoral artery, and in aneurism of the brachial, particularly at the bend of the arm. It is applied at the site of the Hunterian operation, that is, upon a sound portion of the vessel, at the cardiac side of the tumor, and generally at a considerable distance from it; gently and intermittently, not firmly and persistently as in the old method; just sufficiently to retard and weaken the circulation in the sac, not to arrest it, and so as to favor the gradual formation of clots; allowing time for the development of the collateral vessels, and the maintenance of the nourishment of the distal portion of the member. Occlusion of the artery at the site of compression is *not wished for*; on the contrary, it is desirable that the vessel

should remain pervious, and retain as many of its normal properties as possible. As the stratification of the sac proceeds; as layer after layer of fibrin is deposited, and becomes firmly cemented to that which preceded it, the hollow pouch is gradually filled up, and usually, along with it, also the upper orifice of the artery. To this rule, however, there are occasional exceptions, the blood continuing to flow from the artery in a direct stream across the sac in a sort of ditch, groove, or narrow channel.

For the purpose of making the compression, various instruments have been devised, one of the most simple and efficient of which is represented in fig. 258; it is a modification of that of Charrière, and was successfully employed by Dr. Gibbons, of this city, in a case of aneurism of the popliteal artery. It consists of a long, wide, concave, steel plate, supporting three semicircles of the same metal, arranged in two segments, which slide upon each other, and are connected each at their free extremity with a screw and pad. The whole construction of the instrument is such as to enable the surgeon to regulate the pressure with the greatest nicety; making it more or less firmly, and at one or more points, or alternately at different points, as circumstances may seem to require.

Gibbons's modification of Charrière's compressor.

The annexed drawings, figs. 259, 260, and 261, are added for the purpose of enabling the reader to avail himself of the use of other compressors, if the one here described should prove inadequate.

Carte's compressor for the cure of femoral and popliteal aneurism.

Hoey's clamp.

It will generally be well, if the patient is at all intelligent and trustworthy, to instruct him in the use of the instrument, so that he may regulate the compression according to its effects; lessening it if it is productive of pain, and conversely.

One important principle in the treatment is to compress the artery against the bone, as a point of support; if the pressure is widely diffused it will only serve to embarrass the venous circulation, and to retard the cure. The preliminary treatment should be the same as in the Hunterian operation; and during the progress of the cure the limb should be kept constantly bandaged from its distal extremity upwards, to support the capillary vessels, and prevent œdema. Strict quietude, both of mind and body, should be observed; the diet should be mild

but sufficiently nutritious; and free use should be made of aconite, opium, and acetate of lead, as suggested under the head of the treatment of internal aneurism. If the case is very protracted, and the health is likely to suffer from the consequent confinement, gentle exercise may be permitted in the open air, the instrument being worn several hours in the morning and evening. If any considerable swelling arise in the limb, all treatment must be temporarily suspended, and measures adopted for the relief of the morbid action. To continue the compression under such circumstances would be to jeopard the safety both of the part and patient.

The period at which a cure may reasonably be looked for in this treatment, is subject to much diversity; in some instances compression for a few hours has sufficed to produce this event; in others, and these embrace the great majority of cases, a number of days are required; occasionally, several weeks elapse; and examples have been reported where the stratification and obliteration of the sac were not completed under two months. As a general rule, it may be assumed that, other things being equal, the cure will be more rapid in proportion to the smallness of the tumor, the tolerance of the part to compression, and the absence of complications.

The results of the treatment of aneurism by instrumental compression are, on the whole, highly flattering, contrasting most favorably with those of the Hunterian deligation. Thus, of 127 cases of compression, rigidly analyzed by Broca, 116 were successful, or in the proportion of 91 to the 100. Altogether, not more than five or six cases have died from the effects of the operation. On the other hand, the statistics of Dr. Norris, of 188 cases of aneurism of the femoral artery, treated according to the Hunterian principle, show a mortality of 46, or in the ratio nearly of one death to three recoveries. The tables of Mr. Inman, given in a previous page, exhibit a similar result.

Besides its indisputable safety, compression has the advantage, if it fail, that it does not preclude the propriety afterwards of a resort to the ligature.

d. DIGITAL COMPRESSION.

Digital compression for the cure of external aneurism has not attracted as much attention, either in this country or abroad, as its importance demands. Originally proposed as a distinct measure, in 1846, by Professor Vanzetti, of the University of Padua, it was first successfully employed, a year later, by Professor Knight, of New Haven, in a case of popliteal aneurism, in which he cured his patient in forty hours, the compression having been maintained by a relay of assistants.

In a communication in the *North American Medico-Chirurgical Review* for January, 1859, Dr. S. W. Gross has narrated the details of a case of femoral aneurism cured by digital compression, and he has accompanied his paper by a statistical report of twenty-two other examples treated by the same method. As this paper gives a more full account of the subject than any other which has fallen under my notice, I shall freely avail myself of its contents.

It is to aneurisms of the extremities that this procedure is mainly, if not exclusively, applicable, as the compression must be made to bear upon some point of the principal artery of the limb. So far as we have been able to ascertain, the brachial has been compressed in three instances only; once for aneurism of the radial artery near the wrist, and twice for arterio-venous aneurism at the bend of the elbow. In all these cases, the pressure was easily maintained, and the cure was effected in a short time. The femoral artery, at different portions

Fig. 261.

Carte's circular compressor.

of its course, has been the seat of compression nineteen times for popliteal and femoral aneurism, of which thirteen cases have been cured. The external iliac has been subjected to the same procedure in two cases of inguinal aneurism; in one the pressure was insupportable, and in the other the assistants became so fatigued that it was discontinued. Moreover, it is very difficult in this situation to keep up the pressure, and such cases should, therefore, be excluded.

It has been shown that digital compression has been successful where mechanical compression was unbearable, or had failed, whether alone or conjoined with other means, interrupted or continued, complete or incomplete; it has even, in several cases, been applied by the patients themselves, and in these instances either a cure was effected, or the tumor was so modified that subsequent ligation, or mechanical compression of the artery always resulted in recovery. In no case has it ever been followed by any bad consequences, as is so apt to happen in ligation.

The pain produced by the pressure of the finger is not greater than that caused by the pad of an instrument; should the point of pressure become tender, flour may be sprinkled upon the surface, or a thin, wet cloth may be interposed between the finger and skin. However this may be, suffering, both local and general, may easily be allayed by the free exhibition of anodynes, which should never be neglected.

Of the 23 cases tabulated in the paper of Dr. Gross, 15 were popliteal, with 10 cures, and 5 failures; 4 were femoral, with 3 cures; 2 were inguinal, both being unsuccessful; and 2 were arterio-venous, with a favorable result. Thus, of the 23, 15 were perfectly successful. Of the latter, the compression in 5 was employed independently of other means; in 5 the digital alternated with mechanical compression; in 4 cases, apparatus had been abandoned, when digital compression effected a cure; and in 1 the compression was of a mixed character. Of the failures, in 6 cases digital compression was employed before other means, and in 2 after trial by apparatus had been abandoned.

An examination of the facts here detailed will serve to show that digital compression, alternating with the use of apparatus, succeeded in every instance in which it was resorted to, and that, when employed primarily and alone, there were five cures out of seven cases. It seems to me, therefore, that the double method, in which digital and instrumental compression alternate with each other, is the most eligible, not only on account of its having effected cures in every case in which it has been used, but because it is more easy of application, and gives rise to much less inconvenience to the assistants; in fact, the patient himself may sometimes regulate the pressure with perfect success.

The period required for the cure of aneurism by this method is incomparably shorter than by any other known plan of treatment. Thus, of fourteen cases, the shortest time required for a cure was three and a half hours, the longest being seven days, and the average two days and two-thirds. When compared with the cases cured by instrumental compression, the length of time is most striking. In the London hospitals, according to Mr. Hutchinson, the average time for the cure of twenty-six cases of femoral and popliteal aneurism was nineteen days; while Broca found that the mean duration of treatment in ninety-nine cases was about fifteen days. The greatest objection to digital compression is the difficulty of procuring a sufficient number of competent assistants. Since the publication of Dr. Gross's paper, not less than from fifteen to twenty additional cases of cure by digital compression have been reported.

e. FORCED FLEXION.

This mode of treatment, for the introduction of which the profession is indebted to Mr. Ernest Hart, of England, is applicable chiefly, if not exclusively, in aneurism of the ham and bend of the arm; possibly cases might arise in which it might be employed with advantage in aneurism of the groin and axilla. The principle of the treatment consists in moderating and retarding the flow of blood in the tumor by bending the leg forcibly upon the thigh, so as to approximate

the heel to the buttock, and confining it there by means of a strap, the limb being previously enveloped in a bandage. The patient need not be rigidly confined to bed, but may occasionally sit up, and even exercise on crutches. Pain and stiffness of the limb may be diminished with inunction of oil and chloroform. Care is taken to move the knee occasionally, lest ankylosis should occur. The cure is always tedious, from three to six weeks being generally required for the complete arrest of the pulsation, and in a number of the cases in which this treatment has been pursued it has signally failed; in several, the patient was unwilling to bear the restraint which it imposed, and in one at least it caused the rupture of the sac into the joint, necessitating the ligation of the femoral artery.

It is obvious that this mode of treatment, which commends itself by its great simplicity and freedom from pain, is more likely to succeed in small and recent aneurisms than in large and old, in which it must of necessity be occasionally attended with failure. Indeed, it can hardly be considered as applicable to the latter class of cases, as it might induce rupture of the sac, as in the instance related by Mr. Moore, or be productive even of gangrene of the leg.

f. GALVANO-PUNCTURE.

It would seem that this operation for the radical cure of aneurism was first suggested, in 1832, by Mr. Benjamin Phillips, of London; so far, however, as my information extends, it was not practised by him upon the human subject, and the idea had almost been lost, when, several years ago, it was revived, principally through the agency of Mons. Pétrequin, of Lyons. The operation is founded upon a knowledge of the fact that the galvanic current has the effect, if properly directed, of coagulating the blood as it circulates through the different parts of the body. It is executed by means of two long, slender steel needles, introduced into the aneurismal sac at right angles, and in such a manner as to touch each other, their heads being then connected to the chain of a galvanic battery of moderate tension. The action of the battery is maintained uninterruptedly for a period varying from ten to twenty-five minutes, according to the tolerance of the part, and is usually required to be several times repeated. When the tumor is large the number of needles is increased, and the direction of the current frequently changed, so as to afford a better chance for the formation of clots. As the operation is generally very painful, it is proper that the patient should be placed under the influence of chloroform during its performance. Moreover, as there is danger of seriously charring the integuments, and thus endangering the sac by mortification, the needles should be carefully coated, in a part of their extent with gum-lac. The success of the procedure is enhanced by compression of the artery above and below the tumor, thereby preventing the clots from being washed away, before an opportunity has been afforded them of becoming consolidated and united with each other and the walls of the aneurism. The after-treatment consists in the application of ice to the part, in perfect quietude, and in the administration of a full anodyne, to tranquillize the action of the heart and arteries.

Experience has not yet fully determined the value of this mode of treatment. That it is liable to occasional failure is sufficiently evident from the unsuccessful cases that have from time to time been published in England and on the continent of Europe. On the other hand, a considerable number of cases have been reported where its employment was followed by a perfect cure. Of twenty-two cases, collected by Mons. Boinet, in 1851, in which the operation had been practised, nine are stated as having been successful, and thirteen as having been failures. Cases of cure, by this method, of aneurism of the brachial, subclavian, popliteal, and external iliac arteries have been reported by different observers since that period, and, doubtless, others have occurred of which I have no knowledge.

Galvano-puncture is not only **naïf**
In some of the reported cases it ~

~ danger.

tion of the sac, followed by great swelling of the limb, together with excessive constitutional disturbance threatening the destruction both of the part and system. The operation is, therefore, a hazardous one, and on this account should never be attempted without due consideration of its consequences, especially when the aneurism is large and situated at, or near to, the trunk. Coupling this circumstance with the want of success of the operation, and the severe pain attending its execution, not to say anything of the danger of producing sloughing in the skin and sac by the action of the galvanic fluid as it is being transmitted from the battery to the tumor, it is questionable whether it is worthy of repetition, notwithstanding the high estimate placed upon it by Pétrequin, Burci, and some other surgeons. The force of this conclusion derives additional support from the facts collected by Mons. Boinet, that in seven of the successful cases, above referred to, compression and ice were employed simultaneously, thus creating a just doubt in the mind of the inquirer whether these agents had not as much to do with the cure as galvano-puncture, if, indeed, not more. I am not aware that this operation has ever been performed in this country, and I trust that it may never be undertaken by any one who is not perfectly familiar with the pathology of the disease.

g. INJECTION.

Attempts have been made in modern times to effect the radical cure of aneurism by the injection of certain fluids with a view of favoring the concretion of the blood, the consolidation of the sac, and the obliteration of the affected artery at the seat of the disease. The practice was originally suggested, early in the present century, by Professor Monteggia, of Milan, who proposed the use of solutions of acetate of lead, tannin, and other astringents, as, in his opinion, well adapted to the purpose, although he never, it would seem, performed the operation. His idea was that, by throwing these substances into the sac, so as to bring them fully into contact with the blood within, it might be possible to provoke the rapid formation of coagula, and thus effectually arrest the circulation. He supposed, moreover, that the remedy might occasionally be advantageously combined with Brasdor's operation and with compression of the artery upon the cardiac side of the tumor, applied by means of a tourniquet or some other suitable instrument, very much as it is performed at the present day. The suggestion of the Italian surgeon, however, received little, if any, attention, until within a comparatively recent period, when it became the subject of numerous experiments upon the inferior animals, as the sheep, dog, and horse, principally by the French practitioners, who, after having tried various articles, have at length been induced to give a decided preference to a concentrated solution of perchloride of iron in water. The fluid is introduced into the sac by means of a small glass syringe, invented by Dr. Pravaz, of Lyons, and represented in fig. 262, a puncture having

Fig. 262.

Pravaz's syringe.

previously been made with a delicate trocar and canula, the latter of which is retained in the sac until the injection is completed. The piston of the syringe is moved by means of a screw, so as to enable us to perform the operation more steadily, and without the risk of throwing in more than five or six drops of fluid, that quantity having been found to be quite sufficient for the purpose. As it takes at least half a minute before the blood can be made to coagulate, during which the heart performs not less than thirty-five pulsations, it is necessary to keep the contents of the tumor perfectly quiet, while the injection

is progressing, by compression of the artery immediately above and below the aneurism.

The operation is generally productive of severe pain, and as it is liable to be followed by considerable inflammation, it often becomes necessary to make use of antiphlogistic measures, both locally and constitutionally. Its repetition must be governed by circumstances; if everything passes off well, and the sac is promptly solidified, no further interference will, of course, be demanded; but if the reverse is the case, a similar quantity of the solution is thrown in at the end of the third or fourth day, and in the same cautious manner as before. The slightest inflammation of the tumor contraindicates the repetition of the injection.

Since 1853, when Pravaz first published the results of his experiments on animals, a number of cases have been reported in which injections of the perchloride of iron have been employed in aneurism of different parts of the body, as well as in aneurism of different kinds, as spontaneous, traumatic, and varicose. The arteries upon which the disease occurred were the supra-orbital, carotid, humeral, ulnar, femoral, popliteal, and tibial.

Although a few cures have been effected by this treatment, such is the great risk of inflammation, suppuration, and even gangrene, both of the sac and of the surrounding structures, that it is extremely questionable whether any prudent surgeon should repeat it. Of eleven cases, reported by Malgaigne in 1854, it is announced that four had proved fatal, that every one had had bad symptoms, and that only two had been successful. This statement alone, if true, as no doubt it is, is sufficient to condemn the operation as unsafe, and to render its adoption improper in the face of the more unexceptionable methods of ligation and compression. The great desideratum is to discover an article, which, while it shall promptly coagulate the blood, will not cause any severe irritation in the sac and parts around it. It has been supposed that the acetate of the peroxide of iron might have this effect, but, although at least one successful cure by its use has been reported, it has not been tried sufficiently often to enable us to pass any definite judgment upon its true merits. I should myself have more confidence in the efficacy and safety of the persulphate of iron than in any other preparation of this metal. It is perfectly destitute of caustic properties, and is the most prompt and efficient coagulator of the blood at present known.

h. MANIPULATION.

The treatment of aneurism by manipulation was first formally proposed by Mr. Fergusson, of King's College, London. It consists in the forcible squeezing of the tumor, with the intention of breaking up its fibrinous contents in order that some of the fragments thus detached may be carried by the circulation into the distal extremity of the artery, thereby closing its orifice, and so effecting a radical cure. The operation was performed for the first time in 1852, in a case of aneurism of the right subclavian artery, seated partly within and partly on the outside of the scalene muscles, the tumor being about the size of a hen's egg. The sac being emptied of fluid blood, its sides were forcibly rubbed against each other, with the immediate effect of an arrest of pulsation in all the vessels in the limb below. The pulsation, however, returned in about seven hours, and the manipulation was accordingly repeated the next day with a similar result, but it was not until the end of a week that any permanent impression appears to have been made upon the circulation. The tumor now gradually diminished in size, and everything gave evidence of an ultimate cure, when suddenly, seven months afterwards, the patient was seized with violent fever attended with excruciating pain in the part, and died after a few days' illness. Although the axillary artery was found, on dissection, to have been blocked up, the tumor, instead of being obliterated, not only remained hollow, but had extended downwards over the axillary plexus of nerves, the pressure upon which had probably caused the excessive pain which immediately preceded dissolution. In another instance, operated on by the same gentleman, the result was more fortunate, but the cure was not finally effected until towards the end of the second year.

Within the last few years several other cases, also successful, have been reported by other surgeons, among whom I may mention Professor Blackman, of the Medical College of Ohio.

In a case of popliteal aneurism in 1859, reported by Mr. Teale, of Leeds, this plan of treatment was successfully conjoined with digital compression. After the latter had been carried on for some time with, apparently, very little effect, a portion of clot was detached, leading at once to the consolidation of the tumor.

No opportunity has presented itself to me of trying Mr. Fergusson's plan of treatment, but it is extremely questionable, I think, whether it ought to be repeated. The great objections to it are, first, the uncertainty of the operation, even when the distal end of the artery has been blocked up; secondly, the tardiness of its progress; and, thirdly, the danger that some of the detached clots may find their way into the brain, as in aneurism of the neck, thus causing fatal apoplexy, as has already happened in several cases in which the method has been tried. If employed at all, therefore, it should, in my judgment, be restricted to aneurism of the subclavian, axillary, femoral, and popliteal arteries, in the early stage of the disease, before the tumor has acquired any considerable bulk.

2. VALSALVA'S TREATMENT OF INTERNAL ANEURISM.

Internal aneurisms, inaccessible to the ligature and compression, occasionally recover under a regular and systematic course of treatment designed to promote the coagulation of the blood in the interior of the tumor, by increasing the plastic properties of this fluid, and quieting the action of the heart and arteries. This treatment, which was originally suggested by Valsalva, and which still bears his name, consists in the strict observance of the recumbent posture, perfect mental quietude, the occasional abstraction of blood from the arm, and the use, simply, of a sufficiency of food and drink to prevent starvation. When, writes Morgagni, Valsalva had taken away as much blood as was deemed necessary, he diminished the diet "more and more every day, until only half a pound of pudding was taken in the morning, and in the evening half that quantity, and nothing else except water, the weight of which was also regulated, and which he medicated with what is called quince-jelley, or the lapis osteocolla, ground down into a very fine powder. After the patient had been sufficiently reduced by this method, so that he could scarcely raise his head from the bed, to which, by Valsalva's direction, he was confined, the quantity of aliment was day by day increased, until the strength that was necessary to enable him to get up had returned." Most modern writers, in speaking of this method, recommend, as important adjuvants, the internal exhibition of digitalis, acetate of lead, and opium, with a view of insuring more speedily and effectually the ends proposed by Valsalva and his followers; the digitalis being given to diminish the number and force of the pulsations of the heart and arteries, the lead to increase the coagulability of the blood, and the opium to allay pain and nervous irritability.

We have no account of the number of cases of aneurism successfully treated by Valsalva by this method, but that he cured several persons with it is a conjecture warranted by the statements of Morgagni, by whom it was first described. What is still more to be regretted is the fact that we are equally ignorant in regard to the results obtained by others. But, notwithstanding this, it seems to me that the treatment is worthy of more attention than it has hitherto received, especially of late years, when so little has been said and done concerning it. The question, however, arises whether it might not be beneficially modified, so as to render it better adapted to the attainment of the object which it is designed to accomplish. In reflecting upon the subject, some years ago, it occurred to me that, instead of bleeding and starving the patient, upon which so much stress was laid by the Italian practitioner, the end might be more easily and speedily obtained by the abandonment of the lancet altogether, and the substitution of nutritious food, in as dry, concentrated, and non-stimulant a state as possible. If the object be to procure a more plastic and coagulable condition of the blood, to promote the formation of clots, this can certainly be done much

more advantageously, as well as in a much shorter time, by such a course than by one of an opposite character. Repeated bleeding, and a light farinaceous diet, comprising a little pudding and jelly, taken twice a day, must, unquestionably, render the blood very thin and watery, and therefore less disposed to fibrinization, the very reverse of what is really needed for the cure of aneurism. It would be more in accordance, then, with sound physiology and practice, to refrain from venesection entirely, and to put the patient upon a moderate allowance of food, as a few ounces of equal parts of hashed meat and bread, potato, or rice, at dinner, with a suitable quantity of stale bread, toast, or cracker at breakfast and supper; tea, coffee, and all other drinks, excepting water and lemonade, as well as all kinds of condiments, being scrupulously avoided. The patient should be kept perfectly at rest, in the recumbent posture, with the mind in as tranquil a state as possible, while the system should be steadily maintained under the free use of the tincture of aconite, or of veratrum viride, conjoined with acetate of lead and opium, or, what would probably be better, the persulphate of iron. The pulse should be brought down, if practicable, to forty or forty-five beats in the minute, and the chances of success would be all the greater if a prolonged state of somnolency could be maintained, the patient sleeping the greater part of the twenty-four hours. Protracted constipation of the bowels should be aimed at; if purgatives become indispensable, they must be of the mildest character, as all irritating and griping articles are sure to do harm by exciting the action of the heart and arteries.

The length of time during which this treatment should be continued must vary according to the circumstances of each individual case, and no attempt should, therefore, be made to reduce it to any general principles. It certainly might, with judicious management, be kept up, without detriment, for several consecutive weeks. As the patient emerges from it, he should return, most gradually and cautiously, to his accustomed diet, except that, for a long time afterwards, it should be free from all stimulants; nor should he, for many months, take any, except the most gentle exercise. In short, everything should be done calculated to second nature in her efforts to effect the cure thus auspiciously begun, and which, other things being equal, will always be so much the more likely to take place if the aneurism is small and of recent standing.

Since the publication of the first edition of this work, I have had an opportunity of treating three cases of intra-thoracic aneurism according to the plan here sketched; but, although the patients seemed to be materially benefited, as far as their pain was concerned, and the pulse was brought down below fifty, I was not able to satisfy myself that the progress of the disease was at all retarded. It is proper, however, to add that all the cases were far advanced when they fell into my hands.

j. GENERAL MEDICAL TREATMENT.

Persons affected with aneurism often experience, as stated elsewhere, great pain and other suffering, both from the inflamed condition of the tumor and from the pressure which it exerts upon the surrounding parts. In aneurism of the thoracic portion of the aorta and of the arteries at the root of the neck, the pain and dyspnoea are sometimes excessive, demanding prompt and vigorous measures for their relief. If the patient is plethoric, and the pulsation in the tumor uncommonly active, the loss of twelve, fifteen, or twenty ounces of blood will be useful, but care must be taken not to carry the venesection too far, otherwise injurious reaction may take place, and thus aggravate the suffering. When the tumor is accessible, or situated externally, whether partly or entirely, the blood is often most advantageously abstracted directly from the part by means of leeches, which, even when employed only in small numbers, generally afford immense relief, both as it respects the pain and the difficulty of breathing. Topical depletion is always extremely serviceable in inflamed aneurism, and it is here also that fomentations and refrigerating lotions, simple or medicated, come into play, frequently exerting their happiest influence. Our choice of these remedies must be governed in these, as in other cases, by the tolerance of the part and

system. Attention to position and rest must be enjoined, and strictly carried out. The bowels are not neglected, but great care is taken to avoid active purgation, experience having shown that such a procedure always produces undue excitement of the vascular and nervous systems. Anodynes are always well borne in these cases, and should be administered in full doses, either alone or in union with diaphoretics and expectorants, according to the condition of the skin and of the respiratory organs. Any complications that may arise during the progress of the disease, whether self-existent or dependent upon the irritation produced by the pressure of the tumor, must be treated upon broad general principles.

FALSE ANEURISM.

A false aneurism consists, as already stated, of a pulsating tumor formed external to the affected artery, and, consequently, without any aid from its tunics, which are altogether excluded from its composition. A number of affections, of a very opposite character, have been described under this appellation, and the result has been, as might have been anticipated, much confusion. To remedy this evil, I shall limit myself, in the account which I am about to give of the disease, to two varieties of false aneurism, the arterial and arterio-venous, the tumor in each being strictly circumscribed, and connected, in the former, with an artery, and, in the latter, both with an artery and a vein. What is called a diffused aneurism is, in fact, as stated elsewhere, no aneurism at all, but merely an accumulation of blood in the subcutaneous and intermuscular cellular tissue, which, although it may be somewhat condensed around it, yet does not, in reality, in the true meaning of the word, constitute a proper aneurismal sac.

The most common cause of the spurious arterial aneurism is external injury, as a stab or puncture, such, for example, as is so often inflicted in venesection at the bend of the arm, permitting the blood to escape in small quantity into the surrounding cellular substance, which is soon condensed into a firm, circumscribed, pulsating cyst, often not exceeding the volume of a pullet's egg, and of a rounded or ovoidal figure. Similar effects occasionally follow the laceration of an artery, as that of the ham, from the sudden and forcible extension of the leg, from the intrusion of the sharp end of a broken bone, or from ulcerative action.

Sometimes the aneurismal formation is secondary; that is, consequent upon the partial cicatrization of the wound, the interposed or overlying plasma being unable to withstand the impulse of the blood, and so yielding before it. However induced, all the tunics of the artery are at once perforated, and the blood is sent abroad into the circumjacent cellular tissue, in the manner and with the effect just stated.

The sac in this variety of aneurism, formed originally, as has just been remarked, out of the neighboring cellular tissue, is speedily strengthened by the effusion of plastic matter, so that, in time, it often acquires considerable thickness with an extraordinary degree of density. I have seen a number of cases where the cyst, even at an early stage of the disease, was of a very firm, compact, fibroid consistence, and of a white, glistening appearance, its substance being convertible, by dissection, into several distinct strata. The tumor, particularly in cases of long standing, generally contains well organized concretions, arranged in the same concentric manner as in the true sacculated aneurism, and presenting a similar hue and consistence. The course, symptoms, and termination of this disease do not require any special notice, as they do not differ, in any respect, from the ordinary form of the affection.

The *treatment* may be conducted by compression, or, this failing, by ligature. The compression is applied, as in true aneurism, upon the cardiac aspect of the tumor, four, six, or eight inches from it, with the instrument already described, retardation of the circulation and gradual obliteration of the sac being steadily kept in view. If an operation becomes necessary, a free incision is carried across the tumor, and a ligature applied immediately above and below, as in an ordinary wounded artery. The tumor may then be dissected out, or, as some prefer, though I think improperly, it may be left to the influence of the absorbents. As

a preliminary step, a tourniquet is cast round the limb to control the circulation in the affected vessel. Although one ligature is occasionally sufficient to effect a cure in this disease, I would strongly advise the ligation of the vessel both above and below the swelling, lest trouble should arise on account of the recurrent circulation, and thus lead to the necessity of doing at a subsequent period what ought to have been done in the first instance. The memorable case of Anel affords an excellent illustration of the fact that an aneurism of this kind, especially when seated at the bend of the arm, may occasionally be cured by one ligature applied just above the tumor.

1. The *arterio-venous aneurism*, originally described under the name of *varicose aneurism*, consists of a tumor which is situated, as the term implies, between a contiguous artery and vein, so as to admit of a ready interchange of the two kinds of blood. The most common site of the lesion is the bend of the arm, as

Fig. 263.

Varicose aneurism; external appearance.

seen in figs. 263 and 264, where it is generally caused by a puncture in bleeding, in which the overlying vein, usually the median basilic, is completely transixed along with the superficial wall of the brachial artery. A similar accident may, of course, happen in any other part of the body, from a stab or wound of a contiguous artery and vein, as between the femoral, or the aorta and vena cava; and, what is remarkable, the disease occasionally does not show itself until long after the infliction of the injury. Thus, Roux relates a case in which an arterio-venous aneurism formed at the bend of the arm four years after venesection; and Rokitsansky observed a similar tumor in the axillary artery and vein thirty years after they had been struck by a shot. Sometimes, again, the aneurism forms in consequence of ulceration, beginning in one vessel and gradually extending to the other, and so eventually establishing a communication between them through the intervention of a sac. Dissection has proved that such a connection may take place with deeply-seated as well as with superficial veins. In a case described by Schottin the aneurism existed between the radial artery and the cephalic vein; and in one seen by Charnal it had formed between a deep vein and the bronchial artery.

Fig. 264.

Varicose aneurism, internal view. *a* The artery. *b* The vein. *c* The intermediate cyst.

In whatever manner the aneurism is formed, the cyst is usually of small size, seldom exceeding, and not often equalling, that of a pullet's egg. It is composed partly of condensed cellular substance and partly of plastic matter, the latter always greatly predominating, as is shown by its extraordinary thickness as well as density, which closely resembles that of the fibrous tissue. The tumor, although seldom the seat of much pain, interferes more or less with the functions of the affected limb. The opening of communication being always very small, the blood rushes into it with a peculiar noise, not unlike that produced by the buzzing of a fly in a paper box, or the purring of a cat. Sometimes it is of a whirring character, similar to the prolonged articulation of the letter R. It is

perceived both by the ear and finger, and is so extraordinary that it may be regarded as pathognomonic of the nature of the affection. The sac rarely contains any well-formed fibrinous concretions, and, on laying it open, it is often found to be perfectly smooth and white, like the interior of an artery. Manifesting little disposition to increase, it sometimes remains stationary for years, but seldom, if ever, undergoes spontaneous cure, or terminates in rupture, ulceration, or gangrene.

When the tumor is very small, not exceeding the volume of a filbert or a pigeon's egg, and does not occasion any suffering, interference is neither desirable nor proper; it is merely an inconvenience, and had better be let alone. The reverse, however, is usually the case, and then the same treatment will be required as in spurious aneurism connected with an artery only; that is, the vessel is tied just above and below the tumor, which is left to undergo absorption, lest its removal should give rise to phlebitis in consequence of the unavoidable injury inflicted upon the affected vein.

When the disease occurs in connection with the aorta and vena cava, operative interference will, of course, be out of the question; nor can anything be hoped for from medical treatment. The case, in fact, is irremediable, and will be sure, in time, to cause death, either by the gradual giving way of the sac, or by exciting violent irritation, pain, and constitutional disorder.

2. *Aneurismal varix*, fig. 265, consists in a direct communication between a contiguous vein and artery, without the intervention of a sac; it differs, therefore, essentially from a varicose aneurism, in which, as has just been seen, there is

Fig. 265.

Aneurismal varix.

always a distinct cyst, formed out of the surrounding tissues, along with more or less plasma. The affection is altogether so unlike aneurism, whether true or spurious, that it is surprising it should ever have been included under the same category.

The cause of aneurismal varix—a disease first described by Dr. William Hunter, in 1756—is usually some external injury, such as a puncture, transfixing a vein and piercing the contiguous wall of an underlying artery. Hence the lesion is most common at the bend of the arm, between the median basilic vein and brachial artery, in consequence of venesection. It may, however, occur between other veins and arteries lying in juxtaposition with one another, either through accident, or from the effects of ulceration commencing in the coats of one vessel and gradually perforating those of the other. The orifice of communication is usually small, and of a circular shape, with well-defined margins, although there is, in this respect, no particular uniformity. The adhesion between the two vessels is generally very firm, as well as of considerable extent, and it is well that it should be so, otherwise there would be constant danger of the connection giving way. Owing to the incessant interchange and commingling of the two kinds of blood, the vessels gradually undergo important changes, the most interesting of which are that the vein assumes the properties of an artery, and the artery those of a vein. The vein, from the impetuous manner in which the arterial blood is sent into it at each stroke of the heart, becomes greatly enlarged both above and below the abnormal opening, at the same time that it acquires an extraordinary degree of density, and pulsates with unusual force. In the arm, where I have met with several instance of this disease, I have found the dilatation of the vein to extend, on the one hand, nearly as high up as the axilla,

and on the other, as low down as the middle of the forearm. The artery, which now receives black blood, but not in any large quantity, is eventually transformed into a soft, thin, flexuous tube, which, possessing the properties of a vein rather than those of an artery, pulsates but feebly under the finger.

The formation of this disease is generally attended with some degree of pain and swelling, along with interstitial effusions, causing the integuments to pit slightly on pressure. The parts below the seat of the lesion are imperfectly nourished, and hence they usually feel somewhat cold and numb until the circulation is fully re-established through the agency of the collateral branches. As the blood passes from one vessel into the other it produces a peculiar jarring sensation and a singular whirring noise, not unlike the purring of a cat, which often extends to a great distance along the dilated vein, now performing the vicarious functions of an artery, and which may be regarded as the pathognomonic signs of the disease.

In the cases of this lesion which have fallen under my observation, the inconvenience has been so trifling that I have not considered it proper to resort to operative interference. In one instance the patient had an aneurismal varix on the right arm from venesection performed upwards of fifteen years previously, and, although he was a blacksmith and a hard working man, it did not in the slightest degree interrupt his occupation. When trouble arises so as to render treatment necessary, relief may be attempted by compression of the brachial artery, as in varicose aneurism; this failing, the artery should be exposed by a careful dissection, and a ligature applied both above and below the orifice of communication, all disturbance of the vein being avoided.

SECT. VII.—ANEURISM OF PARTICULAR ARTERIES.

ANEURISM OF THE THORACIC AORTA.

The merest glance at the situation of this vessel is sufficient to impress us with the great importance of its relations, and to show that any deviation from its normal condition, however slight, may be productive of the most frightful consequences.

The disease may exist, 1st, as a fusiform expansion; 2dly, as a dilatation of the coats of the vessel, affecting the greater portion, if not the whole, of its circumference; or, 3dly, as a true, false, or mixed aneurism, properly so called, of variable size and shape, generally connected with the anterior or lateral aspect of the artery, the posterior being seldom implicated. The ascending portion and arch of the aorta, especially the latter, are by far the most frequent seats of the disease, owing to their vicinity to the heart, which thus imparts to them its impulsive and expansive movements, and to their greater proneness to fatty and other degenerations, rendering their tunics weak and brittle, and consequently liable to laceration. In most cases, the aneurism is of the true species, commencing as a sac-like enlargement, which, as it increases, usually inclines to the right side of the chest, and is capable of acquiring a volume equal to that of a double fist. It soon becomes occupied with organized clots, which occasionally, though very rarely, accumulate to such an extent as to lay the foundation of a spontaneous cure. The opening of communication between the tumor and the artery varies in size from that of a dime to that of a twenty-five cent piece.

The disease, which is more common in men than in women, not unfrequently arises at a comparatively early age, as from twenty-five to thirty, in consequence, apparently, of severe straining and other bodily exertion. Sailors and mechanics are peculiarly liable to it. The astonishing frequency of aneurism of this vessel is shown by the tables of Mr. Crisp, embracing 915 cases, of which 382 affected the thoracic aorta.

The duration of thoracic aneurism varies from a few months to upwards of three years, the average being from nine to twelve months. The tumor usually bursts into the left pleura, pericardium, trachea, bronchial tubes, œsophagus, or posterior mediastinum; sometimes into the heart, lungs, &c.

sometimes, again, but also very rarely, externally. Dr. Darrach, of Illinois, has shown by an analysis of twenty-three cases that aneurism of the descending aorta terminates pretty uniformly by rupture, while that of the arch generally ends by exhaustion and irritation, or some concomitant disease of the heart,

Fig. 266.

Aneurism of the arch of the aorta opening into the trachea.

brain, lung, or kidney. Occasionally the tumor gives way when it is not larger than a pullet's egg. Fig. 266 represents an aneurism of the arch of the aorta which has burst into the trachea.

The *symptoms* of aneurism in this situation are chiefly of a mechanical character, arising from the pressure of the tumor upon the surrounding structures. They consist mainly of pain, cough, dyspnoea, dysphagia, enlargement at the sterno-clavicular region, and of various kinds of sounds, synchronous with the action of the heart.

Pain, from the constancy of its occurrence, is a symptom of great value. It comes on early in the disease, is more severe in sacculated than in fusiform aneurism, and is evidently dependent, at first, or so long as the tumor is comparatively small, upon the pressure which the aneurism exerts upon the spinal and sympathetic nerves, and afterwards upon this cause and upon the erosion and perforation of the tissues, especially the sternum, ribs, and vertebrae. It varies much in degree, character, and situation. In the earlier stages of the disease it is most conspicuous on the left side; it is sharp, lancinating, and intermittent, not unlike the pain of neuralgia, darting about in different directions; at one time into the neck and face, at another through the chest and spine, now along the shoulder and arm, and now through the diaphragm and even the loins. As the tumor enlarges, and, by its pressure, erodes the neighboring structures, the pain becomes more steady, fixed, and severe; it gradually shifts to the right side, and is generally of a burning, gnawing, or boring character.

Cough is also a common symptom; it generally begins early in the disease, and is liable to severe exacerbations, often productive of intense suffering. It is of a crowing, stridulous, or ringing character, and obviously depends upon the irritation caused by the pressure of the tumor upon the air-passages. Sometimes it is short, spasmodic, and laryngeal.

The dyspnoea is always more or less distressing, especially when the disease has made considerable progress, and is invariably aggravated by severe bodily exertion, as in walking up a hill, or ascending a flight of stairs. It is occasionally extremely violent, although the tumor may not exceed the size of a walnut, owing to the pressure which it exerts upon the trachea, or the trachea and bronchial tubes. During the latter stages of the complaint, the breathing is always so difficult as to prevent the patient from lying down, perhaps for days before he expires.

Dysphagia is seldom present until after the disease has made considerable progress, although it is sure, in the end, to become a prominent symptom; so that, ultimately, the sufferer finds it very difficult to swallow anything either in the form of food or drink.

It is not often that there is any external tumor, except when the aneurism points in front of the chest, as it frequently does in its latter stages, after it has partially destroyed the sternum and the ribs, or the ribs and intercostal cartilages. In the great majority of cases it shows itself on the right side of the chest from three to four inches below the collar bone, as a pulsating swelling, lifting up the integuments synchronously with the contraction of the heart, furnishing a distinct bellows, sawing, or purring sound, and being exquisitely tender on pressure. Occasionally the sac projects into the neck above the fourchette of the sternum, inclining towards the right sterno-clavicular articulation. When this is the case,

it must necessarily overlap the innominate, common carotid, and subclavian arteries on the right side, and may even so effectually compress them as to cause their obliteration, although such an event is very unusual.

A distinct aneurismal sound, or purring tremor, is usually perceptible at an early stage of the disease, although it is extremely difficult, if not impossible, always to refer it to its proper source. It is synchronous with the beat of the heart, and gradually becomes more and more faint as the disease advances, in consequence of the progressive filling up of the sac by coagula.

Among the less constant symptoms are, palpitation of the heart, wheezing, panting, or asthmatic respiration, tracheal and bronchial râles, sense of constriction of the chest, œdema and lividity of the face, permanent contraction, or, more rarely, dilatation of one of the pupils, feebleness and irregularity of the pulse at the wrist, from the pressure of the tumor upon the innominate or subclavian artery, and anasarca of the extremities, especially the inferior. Alteration of the voice is by no means uncommon, and occasionally amounts to complete aphonia. In the more advanced stages of the disease there is also frequently an enlarged and varicose state of the subcutaneous veins over the upper part of the chest, generally towards the right side.

The *diagnosis* of intra-thoracic aneurism is often extremely difficult; for, although the disease manifests itself by numerous symptoms, there is not one that can be considered as absolutely reliable. It is not surprising, therefore, that it should occasionally terminate fatally, without any suspicion as to its true nature. Such an error will be most likely to happen when the tumor is small, or when it bursts into some neighboring canal before it has sensibly encroached upon the walls of the chest. As it increases in volume, its character becomes daily more and more apparent, and all doubt must, of course, vanish when the tumor points externally, although even then a careless practitioner might regard it as an abscess, and, under this supposition, be perhaps even induced to open it, as I have known in two cases, notwithstanding the heaving and pulsating nature of the swelling, and the existence of all the other signs of aneurism. When the aneurism arises from the summit of the aorta, the tumor projects into the root of the neck, and may, in fact, ascend so high up as to simulate aneurism of the innominate or carotid artery. From this, however, it may in general be readily distinguished by the history of the case, by the impossibility of tracing with the finger the lower boundary of the tumor, by the dulness on percussion of the upper part of the chest, and by the presence of a larger amount of dyspnœa than usually attends cervical aneurism, particularly in its earlier stages.

The auscultatory signs rarely afford any conclusive evidence of intra-thoracic aneurism. Few surgeons are able to discriminate between the sounds of the heart and those of such a tumor, and the difficulty must necessarily be much increased when, as not unfrequently happens, aneurism and cardiac disease co-exist. When the heart is sound, and the aneurism has attained a considerable bulk, the diagnosis will be less ambiguous; but even then it will require a very practised ear to detect the varying shades of difference. The sound of a thoracic aneurism is more like the purring of a cat than the clear murmur attending the first sound of the heart, and its distinctive features are still further defined by the presence of a peculiar tremor or vibratory movement. In the sacculated variety of the affection, it is often impossible to distinguish any abnormal sound whatever; at first, because of the small size of the swelling, and subsequently, because the tumor is filled with coagula, impeding, if not preventing, the transmission of sound. In fusiform aneurism, and also in simple but extensive dilatation, the sound characteristic of the disease is generally easily recognized throughout its entire progress.

Dulness on percussion, in a marked degree, can exist only in the event of the tumor being of considerable bulk; a small aneurism may be present, and even prove fatal, without any change of resonance. When there is dulness, it is always most conspicuous at the upper and middle parts of the chest.

Sometimes valuable diagnostic information may be derived from the displace-

ment of the heart by the tumor, its pulsations being perceived in an abnormal position, where there is no evidence of pleuritic effusion or disease of the lung to account for the change.

The precise situation of an intra-thoracic aneurism is frequently, if not generally, indicated by the character of the functional disturbance. Thus, when the suffering is chiefly laryngeal, the inference is that the innominate artery, or the posterior and inferior portion of the arch of the aorta, is involved. Excessive pectoral constriction is caused when the tumor compresses the cardiac plexus, as when it springs from the ascending portion of the arch. Dysphagia denotes pressure either upon the œsophagus or upon the pneumogastric nerve, and a corresponding situation of the aneurism. When the disease produces bronchial asthma and orthopnoea, the probability is that the tumor involves the commencement of the descending portion of the arch. Permanent contraction of the pupil is caused by compression of the sympathetic nerve, as when the aneurism, arising from the superior and posterior part of the arch of the aorta or its primitive branches, projects backwards into the chest and neck.

Dr. W. T. Gairdner, of Edinburgh, who has carefully studied the nature of these functional disorders, states that "all aneurisms coming within the range of physical diagnosis, and not attended by any of the above symptoms, must necessarily arise either from the descending aorta, below the range of the pulmonary plexus, or from the upper part of the arch, projecting upwards and forwards; as it is in these situations alone that a thoracic aneurism can attain sufficient bulk to be discoverable, without involving important internal structures, and leading to very marked functional disturbance."

Among the affections with which aneurism of the thoracic aorta is most liable to be confounded are malignant tumors of the chest, especially encephaloid,

abscess of the neck and anterior mediastinum, disease of the heart, as hypertrophy and valvular derangement, and aneurism of the innominate, carotid, and subclavian arteries. The best security against error will be an attentive consideration of the history of the case, and a thorough study of its progress, time often throwing more light upon the character of the malady than the most elaborate auscultatory explorations.

The treatment of intra-thoracic aneurism resolves itself into the adoption of measures calculated to relieve the patient's sufferings rather than to cure his disease, of which there is, in any case, hardly even a remote possibility. If plethora exist, an occasional bleeding cannot fail to ameliorate, at least for a time, the pain and difficulty of breathing. The circulation should be controlled by the cautious exhibition of *veratrum viride*, the diet be light and concentrated, the bowels maintained

in a soluble state, and suffering allayed by anodynes. Perfect quietude of mind and body must of course be observed.

The annexed sketch, fig. 267, from Jones & Sieveking, represents an aneurism of the arch of the aorta, the cavity of which is nearly filled with laminated clots. Nature had evidently made an effort, almost a successful one, at spontaneous cure.

ANEURISM OF THE INNOMINATE ARTERY.

The relative frequency of aneurism of the innominate artery does not admit of any definite statement, owing to the great discrepancy in our statistics. Thus,

Fig. 267.

Aneurism of the arch of the aorta nearly filled with laminated clots.

in 179 cases of spontaneous aneurism, excluding those of the aorta, analyzed by Lisfranc, the innominate is mentioned only four times, while the carotid is mentioned seventeen times and the subclavian sixteen. In Mr. Crisp's table of 551 cases, embracing 234 of aneurism of the aorta, the innominate was affected in 20, the carotid in 25, and the subclavian in 23. The disease, as in the other arteries, is much more common in men than in women, and in the laboring than in the higher classes of persons. The greatest number of cases occur between the thirty-fifth and fifty-fifth year. It may exist by itself or be associated with aneurism of the arch of the aorta, the carotid, or subclavian. The extent of involvement varies from the slightest increase of the normal size to an enormous tumor, either tubular, fusiform, or sacculated in its character. Whether every portion of the vessel is equally liable to be affected is uncertain, but observation has shown that the disease is sometimes situated so low down as to become identified with the arch of the aorta, while at other times it is so high up as to extend into the carotid and subclavian. Occasionally, it is limited to the middle of the vessel, each extremity retaining its healthy appearance.

Symptoms.—Aneurism of the innominate artery usually begins as a small tumor at the right sterno-clavicular articulation, between the trachea and the inner edge of the mastoid muscle, immediately above the inner third of the clavicle. In some cases, the patient is conscious of the moment when the accident takes place, there being a feeling as if something had given way while he was shaken by a violent paroxysm of coughing or engaged in lifting a heavy weight. The tumor, at first, is generally very small, probably not exceeding the size of a little almond, of a rounded or ovoidal shape, distinctly circumscribed, and slightly movable on pressing the finger firmly down into the hollow at the top of the sternum. It is not long, however, before it increases in volume; commonly, in fact, it grows rapidly, soon attaining a large bulk, extending upwards into the neck, and laterally towards each side, but especially towards the right, where there is least resistance. As it progresses, it gradually pushes forwards the mastoid muscle, and even the sterno-clavicular articulation, forming thus a large prominence, beating and throbbing violently beneath the skin. Now and then, upon escaping from the chest, the tumor ascends high up into the neck, perhaps nearly on a level with the larynx, and it is then not uncommon for it to present a constricted, hourglass-like appearance, as if a cord had been drawn tightly across its middle.

Effects on Neighboring Structures.—The effects which the tumor exerts upon the neighboring parts, fig. 268, are chiefly of a mechanical character, and must be considered with reference, first, to the vessels of the superior extremity, neck, and head; secondly, the trachea and œsophagus; thirdly, the aorta, heart, and vena cava; fourthly, the nerves of the neck and chest; and, lastly, the sternum, clavicle, and ribs.

The pressure of the tumor upon the subclavian has the effect of weakening the force of the circulation at the wrist, and in some cases even of entirely suppressing it. Occasionally, the pulse is extremely irregular, beating not only more feebly than that in the opposite limb, but ceasing to act synchronously with it, the blood hitching and halting, as it were, on its way to the hand. Any tumor may of course produce such an effect, and there is, therefore, nothing characteristic in it. In aneurism of the aorta, the signs of enfeebled circulation are, as a general

Fig. 268.

Aneurism of the innominate artery, proving fatal by bursting into the trachea.

- rule, most strongly marked on the left side, as the tumor, from its proximity to the left subclavian, exerts a more direct and controlling influence upon that vessel than it does upon the right subclavian. The pulsation of the carotid and its branches is sometimes diminished both in innominate and aortic aneurism, but more frequently in the former than in the latter. It is, however, a rare occurrence in either case, and therefore of no diagnostic value.

Compression of the veins at the root of the neck, as the innominate, jugular, and subclavian, but especially the first, by impeding the return of blood to the heart, will occasionally cause *œdema* of the right side of the head, face, and eyelids, and of the corresponding limb, extending as low down as the hand and fingers. The occurrence, however, is uncommon, and it is probable that it may be due, in part, to injury sustained by the right lymphatic duct, as it lies just behind the tumor.

As the tumor enlarges it necessarily encroaches more and more upon the trachea, pushing it over towards the left side, and also somewhat backwards. When the displacement is considerable, the patient will breathe with difficulty, and will occasionally be unable to lie down, owing to the mechanical obstruction to the introduction of the air. Should the tumor be situated unusually low, or be of extraordinary size, it may compress and flatten the right bronchial tube. Dyspnoea from both of these causes, however, is less frequent in aneurism of the innominate artery than in aneurism of the arch of the aorta, as, in the latter disease, the tumor enlarges most in a backward direction, its progress forwards being interfered with by the sternum and clavicle. Displacement of the œsophagus is sometimes present in both affections, but not as often as has generally been supposed. When existing in a high degree, it may seriously embarrass the function of deglutition, especially the passage of solids.

When the aneurism occupies the inferior portion of the artery, and especially when it extends downwards into the chest, it follows, as a necessary consequence, that it must press upon the aorta, heart, and vena cava, pushing them out of their natural position, and perhaps seriously diminishing their capacity. The particular effect which such compression must exert cannot always be diagnosed, but it is reasonable to conclude that it will manifest itself in disordered circulation, especially in tumultuous and confused cardiac action, enfeebled pulse, and more or less dyspnoea. An aortic aneurism will of course be more likely to produce such phenomena than an innominate.

Pressure of the tumor upon the *nerves* of the neck and chest induces not only pain and cough, but gives rise, in many cases, to severe dyspnoea and dysphagia, the two latter symptoms being not always, by any means, exclusively dependent upon the displacement and flattening of the trachea and œsophagus. On the contrary, they sometimes exist in a very marked and even in an aggravated degree when there is apparently very little, if any, compression of these tubes. We must therefore look for some other explanation of these phenomena, and the most plausible one that suggests itself is that they are due to the compression of the pneumogastric, phrenic, laryngeal, and sympathetic nerves, which are thus disqualified for transmitting, in a regular and harmonious manner, their peculiar influence to the organs to which they are distributed, and in which they naturally play so important a part.

The *dyspnoea*, although not a constant symptom, is often enough present to render it one of great importance. It varies in degree from the slightest change in the natural respiration to the most frightful embarrassment, in which the patient is almost suffocated, and unable to maintain the recumbent posture. It is of course most severe and distressing when the tumor has acquired an unusual bulk, compressing the pneumogastric and other nerves, and so interrupting their healthy action. It may be constant, or paroxysmal, coming on at irregular intervals, lasting for some time, and then gradually receding, though perhaps at no time wholly absent.

The *dysphagia* is also variable in degree, being at one time very slight, and at another so severe as almost to prevent the patient from swallowing any kind of food, whether solid or fluid. In the more aggravated cases, the difficulty is con-

stant, and the patient finally dies from starvation. It is a remarkable fact that in almost every instance of dysphagia this symptom is preceded by dyspnoea.

The *pain* which accompanies the disease is most severe in the right side, in the situation of the tumor, from which it ramifies in various directions, particularly along the right side of the neck and head, and the corresponding side of the chest, shoulder, and arm. Occasionally, though rarely, it is also keenly felt on the opposite side. It is generally of a dull, aching, or gnawing character, and is often so excessive as to require the use of large doses of anodynes for its temporary relief.

Cough is occasionally present, probably in one case out of every three or four, but it is less common than in aortic aneurism, and is a symptom of no special value. It is evidently produced by the pressure of the tumor upon the laryngeal nerves, and varies much in frequency and severity in different cases and under different circumstances. From the same cause there is sometimes an altered state of the voice.

When the tumor is very large and extends outwards and downwards, so as to compress the cervical and brachial plexus of nerves, it may induce partial *paralysis*, as well as, in some cases, partial loss of sensation, in the upper extremity. Such an occurrence, however, is extremely rare, as the sac seldom attains so much magnitude.

Permanent contraction of the *pupil* on the affected side is occasionally noticed; it often comes on early in the disease, and is evidently due to the pressure which the tumor exerts upon the sympathetic nerve.

There is sometimes marked alteration in the *respiratory sounds*; more frequently, however, in aortic than in innominatal aneurism. The breathing, when affected, is disposed to be stridulous, or wheezing, and this is sometimes the case even when the patient is in the erect posture. The respiratory murmur is seldom affected in innominatal aneurism, obviously because the tumor encroaches but little, if any, upon the lungs; it is only when it extends deep down into the thorax that it is likely to produce such an effect, and then, but not otherwise, there will, also, of necessity, be dulness on percussion of the chest, over the site of the disease. Both these phenomena are more frequent in aortic aneurism, because the tumor in that disease always encroaches more upon the lungs than in the former case.

Finally, the pressure of the tumor occasionally induces serious disease in the neighboring *bones*, as the sternum, clavicle, and first rib, the contiguous portions of which are liable, in the first instance, to be displaced, then to become carious, and ultimately to be wholly absorbed. In some cases there is complete dislocation of the sterno-clavicular joint.

Diagnosis.—After what has just been said, it will easily be understood that the diagnosis of aneurism of the innominate artery must often be extremely difficult, its situation at the root of the neck rendering it liable to be confounded with aneurism of the arch of the aorta, the carotid, and subclavian. Then, again, certain tumors—fatty, fibrous, glandular, and encysted—sometimes form here, and receiving an impulse from the innominate, or even from the aorta itself, may thus simulate the affection in question. I have occasionally encountered great difficulty in determining the diagnosis of disease in the inferior cervical region in consequence of abnormal pulsation either of this vessel, or of the aorta, apparently dependent upon an anemic condition of the system, or neuralgia of the arteries, and so violent as to communicate a severe shock at every contraction of the left ventricle of the heart to the innominate and its two branches, the carotid and subclavian. The embarrassment, in these cases, is materially increased if, superadded to the pulsation, there is an unusual quantity of fat, or some solid growth, and the sharp thrill so common in the arteries of anemic subjects.

On the whole, the most reliable diagnostic signs of aneurism of the innominate are, first, the situation of the tumor at the right sterno-clavicular joint, immediately above the inner third of the clavicle, where it forms a distinct marked prominence; secondly, stoppage of aneurismal beat, thrill, and

sound, by pressure upon the carotid and subclavian; and, thirdly, unnatural weakness of the pulse at the right wrist, with pain and cedema on the corresponding side of the neck, shoulder, and arm. In aortic aneurism, the tumor seldom projects sensibly above the sternum; certainly not before it has attained considerable bulk, and then it is situated rather in the middle line than on the right side; the arterial pulse, if affected at all, is weakest on the left side, and there also the cedema and pain are most conspicuous; the dyspnoea, dysphagia, cough, stridulous respiration, and change of voice are more frequent than in the innominate disease; and compression of the carotid and subclavian produces no diminution in the sounds of the tumor.

Prognosis.—The prognosis of brachio-cephalic aneurism is extremely unfavorable. The disease, it is true, may last for a considerable time, but this is very rare; in general, it progresses very rapidly, and soon reaches a fatal crisis, the tumor either opening externally, into the trachea, or into the chest, or else, as is commonly the case, wearing out the patient by constitutional irritation, asphyxia, or inanition. No instance of spontaneous cure has ever been known to occur in this disease.

Treatment.—The treatment of aneurism of the innominate has hitherto been most unsatisfactory. Owing to the short and stunted character of this vessel, and the close proximity of the aneurism to the arch of the aorta, deligation on the Hunterian principle is, of course, altogether impracticable, and hence the only resource is either to treat the disease upon the plan of Valsalva, or to tie the carotid and subclavian at the distal side of the sac, according to the method originally suggested by Brasdor. The treatment of the Italian surgeon holds out but little encouragement, the disease generally going on from bad to worse until it reaches its fatal crisis, despite the most abstemious course of dieting, rest in the recumbent posture, the use of the lancet, and the exhibition of digitalis, opium, and acetate of lead, to promote the formation of clots. With the exception of Mr. Luke's case, there is hardly an instance upon record in which it was followed by any ultimate benefit. Squeezing the tumor, if practicable, would certainly not be justifiable, as the detached clots might, and probably would, fall into the aorta, and thus cause serious, if not fatal, results on the spot, from mechanical obstruction to the circulation. The operation of Brasdor has been performed in a number of cases, which I shall place before the reader in tabular form.

In only one case have the carotid and subclavian arteries been tied simultaneously. The patient died at the end of six days. At the autopsy, the left carotid and right vertebral arteries were found occluded, showing that the circulation of the brain had been carried on by the left vertebral alone. Rossi was the operator.

In three cases, the carotid and subclavian have been successively tied, as recommended by Mr. Fearn, of Derby, England.

No.	Operator.	Sex.	Age.	Carotid ligature.	Subclavian ligature.	REMARKS.
1	Fearn	f.	28	August 30, 1836	August 2, 1838	Died from pleurisy three weeks after second operation. The aneurismal sac was found filled with dense, organized coagula, except a channel the size of the artery for the passage of blood.
2	Wickham	m.	55	Sept. 25, 1839	Dec. 3, 1839	The aneurism increased, and burst with mortal hemorrhage 63 days after the second operation.
3	Malgaigne	m.	—	March, 1845	October 17, 1844	Four days after the operation the tumor increased rapidly in size, the tumefaction became diffused, and the patient died on the 7th Nov. At the autopsy, the sac could not be dissected; it was confounded with the muscles, in other words, the aneurism was diffused.

In four cases, the subclavian alone has been tied, with a result of three deaths and one recovery.

No.	Operator.	Sex.	Age.	Result.	REMARKS.
1	Dapuytren	m.	40	Death	The subclavian was tied immediately above the clavicle. The tumor diminished, but the pulsations continued. The patient died on the ninth day, from exhaustion following cough and secondary hemorrhage. At the autopsy, aneurism of the subclavian was found, with dilatation of the innominate and aorta.
2	Laugier	m.	57	Death	The vessel was tied immediately above the clavicle. The patient died from asphyxia one month after. The operator had supposed the case to be one of subclavian aneurism.
3	Wardrop	f.	45	Cured	The patient, cured of an aneurism occupying the upper part of the innominate, died two years after the operation, of a new aneurism formed above the first, apparently on the same trunk.
4	Blackman	—	—	Death	Tubular aneurism of the innominate and arch of the aorta; left carotid and subclavian obliterated; death on the eighth day from hemorrhage caused by jumping out of bed.

The carotid alone has been tied in twelve cases, of which two were cured, and the rest died.

No.	Operator.	Sex.	Age.	Result.	REMARKS.
1	Evans	m.	30	Re-covered	The tumor still existed, with constant pulsation, at the end of a year. Subsequently, the sac suppurated, and discharged much pus. At the expiration of nine years, there was no sign of any increase in the affection.
2	Mott	m.	55	Died	After the operation, the tumor was much diminished; but the patient died of asphyxia seven months after.
3	Dohlhoff	f.	—	INM	The aneurism was much improved, but the patient died from the effects of the ligature of the carotid upon the brain. At the autopsy, the aneurism was found occupying the external side of the innominate near its bifurcation; it was as large as a fist, and filled with fibrinous clots.
4	Key	f.	—	Died	The patient died a few hours after the operation from its effect upon the brain. The vertebral arteries were found smaller than natural.
5	Villardabo	m.	70	Died	The patient, a negro, died on the twenty-first day after the operation. At the autopsy, two aneurisms were found; one on the inferior extremity of the right primitive carotid, the other on the trunk of the innominate.
6	Ferguson	m.	56	Died	The patient died of pneumonia on the seventh day. The tumor had diminished, and, at the autopsy, was found nearly filled with firm laminated coagula.
7	Hutton	m.	47	Died	The size of the tumor and the pulsations diminished after the operation, but the sac inflamed, suppurated, and, opening into the trachea, caused death on the sixty-sixth day.
8	Portia	—	—	Died	The patient died forty hours after the application of the ligature. The autopsy showed an arterial dilatation of the innominate and its two branches, without true aneurism.
9	Campbell	m.	48	Died	The tumor began to disappear after the vessel was ligated, but the patient died of pneumonia on the nineteenth day.
10	Morrison	m.	42	Re-covered	The patient recovered from the operation, and expired suddenly twenty months afterwards. The cause of death is not given. At the autopsy, the right carotid was found dilated into a sac, and filled with a resisting fibrinous deposit. The brachiocephalic trunk and curve of the aorta were larger than usual, and their walls were diseased, but not aneurismatic.
11	Wright	m.	70	Died	The patient died on the eighty-eighth day from hemiplegia. The tumor was solidified by fibrin, a canal leading through it to the subclavian. Four abscesses were found in the right hemisphere of the brain.
12	Broadbent	m.	50	Died	Death occurred on the one hundred and fifteenth day from secondary hemorrhage, which recurred several times. No change was produced in the tumor by the operation.

A careful examination of the above cases affords the following conclusions concerning the deligation of the primitive carotid for the cure of innominate aneurism:—

1. It reduces the volume of the tumor. Thus, in the case of Mr. Evans, of

Derby, in 1828, although the aneurism was as large as a walnut, it entirely disappeared in a little upwards of a month. In Dr. Mott's case, in 1829, it was of the size of a pigeon's egg, and disappeared in twenty-six days.

2. The operation leads to fibrinization of the contents of the sac. These changes, which are due, not to arteritis, but to remora of the blood, were well displayed in the cases reported by Mr. Morrison, of Buenos Ayres, in 1834, and of Mr. Fergusson, of London, in 1841. In the former, the innominate artery was reduced to at least one-half its previous bulk; in the latter, the tumor was nearly filled with firm clots.

3. The operation does not involve any special risk. In five of the cases it was followed by death, not, apparently, from any agency of the aneurism, but because of the danger which naturally follows the ligation of the common carotid, for whatever purpose. Thus, in the case of Mr. Key, in 1830, the patient died of syncope, produced by coarctation of the left carotid and vertebral arteries. In two other instances, one by Fergusson, in 1841, and the other by Campbell, of Montreal, in 1845, death resulted from pneumonia. In Hutton's case, the cause of death was inflammation and ulceration of the sac, also a very common effect of the operation for carotid aneurism, whether the ligature is placed above or below the tumor. In the interesting case of Professor Wright, of Montreal, in 1855, the patient died of abscess of the brain, the first example of the kind on record after Brasdor's operation, although severe cerebral symptoms often succeed the ligation of the common carotid for accidents and tumors of the head, eye, and face.

4. The operation has not been productive of a long after-life: chiefly, perhaps, because the cases demanding it were nearly all inherently hopeless, from being associated with organic disease of the aorta, or of this vessel and of the heart. Distinct evidence of this fact existed in at least seven of the cases; in the rest no accurate examination was made. The influence of such complications is shown by the results which followed Brasdor's operation in aneurism of the root of the carotid unmixed with any other lesion. Of five cases of this kind, three completely recovered; one was successful so far as the aneurism was concerned; and in only one was there no improvement.

5. The operation lengthens life if perilled by rupture of the sac, or pressure on the windpipe. In fact, here is its great triumph. In the case of Professor Wright, although the man was in imminent danger before the operation, yet he survived it eighty-eight days. The mean duration of life after deligation of the carotid, under ordinary circumstances, is about four months and a half.

6. The operation has occasionally failed to effect any local improvement. This result followed in three of the cases, in consequence of a want of fibrinization of the contents of the sac.

The facts above stated, deduced mainly from the paper of Professor Wright, in the *Montreal Journal of Medicine*, clearly point, as that gentleman justly remarks, to a division of cases in regard to the applicability of the operation.

1. The most suitable cases are those of uncomplicated innominatal aneurism, being akin to the pure carotid form, the sac, which is confined to the part of the vessel near the bifurcation, springing from the left segment of the artery, and not coexisting with degeneration of its tunics or cardiac disease. 2. Those imperatively requiring it are such as entail imminent danger from external rupture of the tumor or from other causes. 3. The most favorable cases are aneurisms proceeding from the left segment of the artery, because then the introduction of blood into the sac is most effectively impeded, as it is derived from the current destined for the vessel which is tied, whereas, when the aneurism is dextro-lateral, the same benefit cannot be afforded, as the supply is furnished by the subclavian. Next to this situation, the most preferable, anatomically, would be the origin of the tumor from the anterior circumference of the vessel. 4. The less advantageous cases are those in which the external tumor extends towards the middle of the clavicle, for this occurrence denotes such an engagement of the subclavian as must effectually counteract any benefit derivable from ligation of the carotid. When the swelling is equal on each side of the innominate, or

symmetrical, then the only hope of a certain stasis of blood by tying both branches. 5. The cases contra-indicating the having complications with aortic aneurism, or serious disease excepted by extreme urgency.

ANEURISM OF THE COMMON CAROTID ARTERY.

Spontaneous aneurism of this vessel is less frequent than is generally supposed, owing, doubtless, to the fact that it is so seldom the seat of the fatty and osseous degeneration. Of 551 cases of aneurism of different parts of the body, embracing 234 of the aorta, the carotid is stated by Mr. Crisp to have been affected in 25, or in the ratio of 1 to 12.75. Of 179 cases analyzed by Lisfranc, 17 refer to the carotid, 16 to the subclavian, 14 to the axillary, 26 to the femoral, and 59 to the popliteal. The disease in 47 involved the aorta.

The affection is more frequent in men than in women, but not by any means in the same relative proportion as spontaneous aneurism of the other arteries. Thus, of 34 cases analyzed by Dr. Norris, 27 were males, and 7 females, being in the ratio nearly of four of the former to one of the latter; a ratio altogether unequalled by that of any other vessel.

The disease is most common between the thirtieth and the sixtieth year. It occurs with nearly equal frequency on both sides, and, in fact, sometimes exists simultaneously in both arteries. No occupation is exempt from it.

The site of carotid aneurism is variable. Sometimes the tumor is situated very low down in the neck, close to the origin of the vessel; on the other hand, it may be high up, near its bifurcation. In the great majority of cases, however, it will be found to be between these two points, at or near the middle of the artery; usually rather above than below.

Symptoms.—The tumor, when first observed, is generally quite small, perhaps not exceeding the size of a filbert, and of an irregularly globular, rounded, or ovoidal shape. The patient, upon being questioned as to the history of the case, usually expresses his ignorance as to the time of its occurrence, though occasionally he is rendered conscious of it by a peculiar stabbing sensation in the neck, or a feeling as if something had suddenly snapped asunder. Commonly the surgeon is not consulted until the tumor has made considerable progress, and acquired the volume of a hen's egg, or of a small orange, the patient, perhaps, having all along supposed that the swelling was merely an enlargement of some of the cervical ganglions. A careful inspection, however, promptly reveals its true character, its pulsation, thrill, and bellows sound affording unmistakable evidence of its close and intimate arterial connection. Pressure upon the cardiac side of the aneurism, by stopping its circulation, arrests these symptoms, and causes a sensible diminution of the size and consistence of the tumor, while pressure upon its distal side produces an opposite result. As long as it is small, the tumor may readily be moved about, and even raised out of its bed, especially if it be grasped with the thumb and forefinger during the relaxed condition of the sterno-mastoid muscle; as it augments in volume it becomes more fixed in its position, and is eventually rendered almost, if not entirely, stationary.

The symptoms of carotid aneurism are altogether of a mechanical character, being such as arise from the pressure of the tumor upon the neighboring parts; hence, their gravity is generally in proportion to the volume of the morbid growth. In the earlier stages of the disease, there is either no functional disturbance whatever, or it is so insignificant as not to attract any special attention; by and by, however, as it progresses, the tumor necessarily encroaches more and more upon the delicate and important structures of the neck, thus occasioning congestion of the brain by retarding the return of blood in the jugular vein, numbness, pain, and cough, by compressing the cervical, pneumogastric, and phrenic nerves, and difficulty of respiration, and, perhaps, ^{causing} against the trachea and œsophagus. The ^{an-} perfectly natural, becomes gradually indurated and are unusually conspicuous, and the neck is at

D.

The greatest enlargement of the tumor is generally in the direction of the median plane, as the resistance is much less there than externally, under the edge of the sterno-cleido-mastoid muscle.

Diagnosis.—Notwithstanding that the symptoms of carotid aneurism are usually well-marked, cases, nevertheless, occur in which they are so obscure as to render it extremely difficult to determine the diagnosis, even after the most careful and patient investigation. The affections of the neck which are most liable to be confounded with carotid aneurism, and to render the discrimination doubtful, are diseased lymphatic ganglions, abscesses, encysted tumors, goitre, dilatation of the internal jugular vein, and aneurism of the innominate artery and arch of the aorta.

Enlargement of the *lymphatic ganglions* of the neck is most common in young subjects, before the age of twenty, whereas aneurism of the carotid is rarely met with until after thirty; moreover, it is almost peculiar to scrofulous persons, while aneurism occurs in all classes of individuals, the strumous and the non-strumous. In aneurism the tumor is generally well-defined; its surface is smooth and uniform, and the swelling heaves and throbs, as if it were alive. In glandular enlargement, there is generally a chain of diseased ganglions, either scattered about in different parts of the neck, or stretched along the inner border of the sterno-cleido-mastoid muscle; the tumors feel hard, and may, with a little care, be easily separated, not only from each other, but from the carotid artery, so as to get entirely beyond the reach of its pulsation.

Aneurism of the carotid artery has sometimes been mistaken for *abscess*; the tumor has been punctured, and the patient has speedily perished of hemorrhage. Such an error, of course, implies great carelessness, and could hardly happen at the present day when our means of diagnosis are so much more perfect than they were formerly. The discrimination must be determined on general principles. If there is an abscess, the history of the case, conjoined with the unnatural heat and redness of the part, the rapid progress of the swelling, the febrile disturbance, and the absence of the characteristic pulsation, thrill, and bellows sound, will be sufficient to distinguish it from aneurism of the carotid artery.

Encysted tumors, usually containing a serous or sero-sanguinolent fluid, are liable to form at the front and sides of the neck, most generally in connection with the thyroid gland, but sometimes independently of it, in the cellular tissue beneath the muscles. They may usually be readily distinguished by their slow growth and fluctuating feel, the absence of pain and pulsation, and, when they are attached to the thyroid gland, by their obeying the movements of the larynx in the act of deglutition. If, after a careful examination of their history, any doubt exists as to their real nature, the only resource will be the cautious introduction of the exploring needle.

Goitre is liable to be mistaken for carotid aneurism only when it spreads laterally over the neck, so as to overlap the carotid, and receive its pulsation. It is certainly not possible to commit any error of diagnosis in the more ordinary and simple forms of the disease. Confusion is most apt to arise when aneurism and goitre coexist, or when, as occasionally happens, the latter disease is developed uncommonly rapidly, and is attended with considerable local distress. Ordinarily, goitre forms in early life, at a period when aneurism is extremely infrequent; it is generally tardy in its progress, several years elapsing before it attains any material bulk, and it is subject to occasional interruptions, and even total suspension, whereas aneurism generally advances rapidly and steadily, the symptoms proceeding from bad to worse, until it attains its crisis. Another important criterion is the fact that goitre is almost peculiar to females, whereas carotid aneurism occurs by far most frequently in men. But the most satisfactory diagnostic signs are, first, that, in goitre, the tumor obeys the movements of the larynx, whereas, in aneurism, it remains stationary, however strong the efforts at deglutition; secondly, that, in the former, the tumor may be drawn away from the vessel, raised up or pushed to one side, while in the latter the vessel follows it, forming, as it does, a part of it; and, lastly, that in goitre the general health rarely suffers, even when the tumor is of large bulk, whereas in aneurism it is always more or less impaired,

especially when it has reached such a stage as to be likely to occasion embarrassment in regard to the discrimination between the two affections.

A dilated condition of the internal *jugular vein* may simulate aneurism of the carotid artery. The deception will be the more likely to happen if the vein receives a pulsatory movement from the heart or from the carotid, as when the artery is overlapped by the vein. The venous tumor may generally be distinguished by its softness and compressibility, by its situation, which is commonly just above the sternum, and rather behind than in front of the mastoid muscle, and by the circumstance that its motion is more of an undulatory, wave-like, or tremulous character, than shock-like and vibratory, as in aneurism. Superadded to this is the fact that the venous swelling may readily be effaced by pressure applied to its distal extremity, whereas, in aneurism, the pressure, to produce any appreciable effect of this kind at all, must be applied to the cardiac extremity of the tumor, and then it will result only in a diminution, not in complete obliteration.

Finally, a carotid aneurism may be confounded with aneurism of the *innominate artery* or of the arch of the aorta, especially if it is situated low down in the neck. When this is the case, the difficulty may be very great, if not insurmountable. The most reliable diagnostic sign with which I am acquainted, and one that will rarely fail, in such an emergency, is afforded by our ability to insinuate the point of the forefinger between the top of the sternum and the lower extremity of the aneurism, while the head is being bent powerfully forwards, so as to relax as fully as possible the mastoid muscles. If this can be done, the probability is that the tumor is connected with the carotid; otherwise it may be inferred that it is formed by the innominate artery, or by the arch of the aorta.

Several examples have been recorded in which aneurism of the *vertebral artery* was mistaken for aneurism of the common carotid, the latter vessel having actually been tied for the relief of the disease. All the cases, about four in number, proved fatal.

Progress.—The progress of carotid aneurism, although usually rapid, is not so always. The annals of surgery contain several cases where the disease remained almost stationary for a considerable number of years; in one as many as fourteen. A spontaneous cure sometimes occurs, but such an event must necessarily be extremely rare. The tumor, if allowed to go on unchecked, eventually—generally at a period varying from three to twelve months—destroys life either by excessive constitutional irritation, hemorrhage, gangrene, pneumonia, or asphyxia. When seized by ulceration it may burst either externally, or it may open into the pleura, the anterior mediastinum, the trachea, or one of the bronchial tubes. A case has been related by Esmarch of fatal embolic apoplexy from the detachment of fibrinous clots in an aneurism of the left common carotid artery, in consequence of pressure exerted upon the tumor with a view of ascertaining its real character.

Treatment.—The treatment of carotid aneurism is generally conducted according to the Hunterian principle of ligating the supplying vessel at the cardiac side of the tumor; and, fortunately, as the disease is ordinarily situated rather high up, this may commonly be done without any very great difficulty, especially in the earlier stages of the affection, before the swelling has attained much bulk. When the tumor is of great size, or located at the inferior part of the neck, we may be compelled to adopt the method of Brasdor, and tie the carotid on the distal side of the aneurism, trusting that the blood in the tumor, no longer finding an outlet, will gradually coagulate, and so effect its obliteration. The fact is, this artery, owing to the total absence of collateral branches, is peculiarly adapted to this operation, and it is well that it should be so, seeing that, if it were otherwise, we should be obliged to resign many of the more severe cases of carotid aneurism to their fate, without any attempt whatever at surgical interference. It is obvious, from the relations of the vessels and nerves of the neck to the tumor, that compression, now so much employed in the treatment of aneurism of the lower extremity, cannot be brought in play here, the parts being intolerant of the requisite manipulation, to say nothing of the obstruction which it would occasion to the return of the blood in the internal jugular vein, which, being dammed up

in the brain and the sinuses of the dura mater, might speedily induce apoplexy, or other serious cerebral symptoms, endangering the patient's life. When the tumor is of extraordinary bulk, rendering ligation of the carotid impracticable at any point, our only hope, faint though it be, is the success of general measures, particularly Valsalva's method; for experience has conclusively proved that no benefit is to be expected from the ligation of the innominate artery, as originally proposed and practised by Dr. Mott. The deligation of the terminal branches of the carotid might be tried with a better prospect of success, but this also would be likely to fail, owing to the numerous offsets of the external carotid, which, unless included in separate ligatures, would continue to transmit the blood from the tumor with sufficient force and activity to maintain its circulation unimpaired, and so inevitably frustrate the intentions of the operation.

When the tumor is unusually voluminous, or even of moderate size, but situated very low down, overlapping and compressing the trachea, the symptoms may be so urgent as to demand the operation of laryngotomy, to save the patient from impending asphyxia. Such an event must, however, be very uncommon.

A very interesting case of carotid aneurism has been related by Dr. Robertson, of Edinburgh, in which he performed an operation after the tumor had burst into the œsophagus. The swelling was situated so low down that he was compelled to ligate the vessel only half an inch above its origin from the innominate artery. Notwithstanding these unfavorable circumstances, the patient made an excellent recovery, the ligature coming away on the seventeenth day.

The operation of tying the carotid is easy enough in ordinary cases, but when the aneurism is large, or the neck very short and fat, it is one of the most difficult and trying undertakings in surgery. The principal accidents likely to attend it are the inclusion of the jugular vein and pneumogastric nerve in the ligature, and the wounding of some of the smaller vessels of the neck, which it is sometimes more difficult to find and secure than the carotid itself.

Mortality and other Effects.—Of the mortality of the operation for carotid aneurism, a tolerably accurate estimate may be formed from the data now before the profession. Of 21 cases mentioned by Mr. Crisp, 10 were successful, and 11 fatal. In 5, the artery was ligated at the distal side of the tumor, and of these, 3 recovered, the other 2 being only somewhat benefited. Of the 11 fatal cases, 5 were lost by hemorrhage, 2 by inflammation of the sac and artery, and 1 by spasm of the glottis, the cause of death in the remaining 3 being doubtful. The table of Dr. Norris contains an analysis of 38 cases, in which the carotid was tied for aneurism, including 4, however, in which the disease was found, after the operation, not to have been connected with the artery. Of these cases, 22 recovered, and 16 died. The cause of death is mentioned in only 12 of the cases; in 5 it was hemorrhage, in 2 inflammation of the sac, in 2 apoplexy and congestion of the brain, in 1 cerebritis, in 1 spasm of the glottis, and in 1 exhaustion.

In 6 of the 38 cases, the aneurism suppurated, and either burst or was laid open; of these, 4 died and 2 recovered. In one instance the opening in the sac occurred four months, and in another nearly eight months, after the operation. In one fatal case the tumor burst into the pharynx fifteen days after the deligation of the artery, and in another case, which, however, recovered, it had discharged some of its contents into the mouth prior to the operation.

Return of *pulsation* in the tumor, after the operation, was noted in 9 of the 38 cases; in one the pulsation never ceased entirely for two months, and in another it continued for upwards of four months.

The detachment of the ligature occurred, in 13 cases, before the twentieth day; in 7, between the twentieth and thirtieth, and in 1 on the thirty-third day. The time, in the remaining cases, was not observed.

In seven of the cases, analyzed by Dr. Norris, there was a mistake in the diagnosis, as was proved on the dissection, for all the patients died. In four, the disease consisted of different kinds of tumors; in two, of aneurisms supposed to be abscesses; and in one, of an aneurism of the vertebral artery. The examples of mistaken diagnosis include the celebrated case of Mr. Liston, of a lad, nine years of age, who had a tumor on the right side of the neck of two

months' standing, which, although seated over the carotid, was entirely free from pulsation, except along the track of that vessel. Under the conviction that it was merely an abscess, a bistoury was introduced, the removal of which was followed by a gush of arterial blood to the amount of four ounces. The bleeding being arrested by closing the wound with the twisted suture, the common carotid was tied on the following day, October 21st, close to its origin from the innominate artery. On the 3d of November, the arterial hemorrhage suddenly recurred, but was suppressed by plugging the wound with lint; it, however, again broke forth, and proved fatal on the 5th, that is, fifteen days after the operation. Although the ligature had retained its hold upon the artery, the proximal end of the vessel was found to be quite patulous, no attempt having been made at the formation of a coagulum. The probability is that, as Mr. Liston has suggested, the tumor, in this remarkable case, was originally a scrofulous abscess, a part of the wall of which was formed by the carotid; the latter, becoming ulcerated, finally gave way, and thus sent its contents into the cyst inclosing the matter.

Injury to the internal jugular vein has been a cause of death in several cases of ligation of the carotid. In an instance in which Barovero included this vessel with the artery, the patient died on the sixty-ninth day of gastric fever. Mr. Crisp met with a case where a surgeon tied the internal jugular vein instead of the carotid; the patient was a child, and the error was not discovered until after death. Fatal results have occurred in several instances from injury done to the pneumogastric nerve in ligating this artery.

Various serious cerebral and pulmonic symptoms occasionally follow the ligation of the carotid artery, and are among the principal sources of the mortality from this operation.

The effects which the operation produces upon the *brain* have been elucidated both by experiments upon the inferior animals and by observations upon the human subject, and manifest themselves in various ways and at different intervals. Their full importance, however, was not determined until after the publication of the researches of Mr. Chevers, of London, in 1845, to whom the profession is greatly indebted for the valuable light which he has thrown upon a subject which, up to that period, had been entirely overlooked. In the 125 cases analyzed by Dr. Norris, in which the common carotid was tied either for aneurism, wounds, or erectile tumors, more or less severe cerebral disturbance occurred in 30. Some of these cases recovered completely, some got well of the operation, but remained afterwards in a crippled condition, and some, perhaps the majority, died, at a period varying from a few hours to several months.

Ehrmann has collected the statistics of 187 cases, in which one carotid was tied, in 42 of which more or less cerebral disturbance occurred.

There is no uniformity either in the character or in the manifestation of the cerebral symptoms. Sometimes they come on immediately, or, at all events, within a few hours after the deligation of the vessel; while at other times, and perhaps most generally, they do not appear until the end of several days, weeks, or months. Their access is usually sudden, but occasionally so gradual and imperceptible as to keep the patient in ignorance of it until it is discovered accidentally. The most frequent symptoms are convulsions and paralysis. The former may be general, but much oftener they are partial, affecting, for example, one arm, a leg, or one side of the face; in some cases, there are merely spasmodic twitches, or irregular, involuntary movements. The paralysis occasionally exists on the side of the affected artery, but in most cases it occurs on the opposite side, and then it may pervade one-half of the body, as in hemiplegia, though generally it is more limited, being confined, perhaps, to the face, tongue, throat, fauces, eyelid, hand, arm, leg, or thigh. Sometimes there is dimness of vision, with or without dilatation of the pupil; a feeling of drowsiness, somnolency, stupor, or coma; dizziness, vertigo, or headache; noise in the ears or partial deafness; delirium, either alone or conjoined with paralysis or convulsions; difficulty of deglutition; dyspnoea; a sense of coldness, or coldness and numbness. Various other symptoms, mostly of an anomalous, nervous character, are often present. Occasionally these effects rapidly disappear, but in general they are

more or less persistent, and in some cases they remain up to the moment of the patient's death. In some instances, inflammation of the brain, or of the brain and its envelops, supervenes, either soon after the deligation of the vessel, or at a more or less remote period.

How are these phenomena produced? Are they caused merely by an inadequate supply of blood to the brain, or are they the consequence solely of a loss of equilibrium in the cerebral circulation? To these questions it is of course impossible to return anything like a definite answer. It would seem probable, from the free anastomosis which exists between the branches of the internal carotid arteries, on the one hand, and between these arteries and the vertebral, on the other, that they could not be occasioned by a mere want of blood, inasmuch as these vessels are capable of furnishing the organ with an abundant supply of that material for the purpose of carrying on its healthy functions. Nevertheless, it is not unlikely that unpleasant effects may and do follow the sudden withdrawal of a certain quantity of blood from the brain, resembling those produced by copious bleeding at the arm, or by a smart concussion of the brain. In some instances, it is reasonable to conclude that they are the result of the inclusion of an important nerve; while in another class of cases, as when several weeks or months elapse before their supervention, they would seem to be the direct consequence of inflammation. Under the latter circumstances, dissection reveals softening of the cerebral substance and effusion of serum, or of serum and lymph, in the ventricles and upon the surface of the brain.

The most constant *pulmonary* effects occasioned by the ligation of the carotid artery are cough, bronchitis, and inflammation of the pulmonary tissue. Cough is not only a very frequent occurrence, but often one of great severity, rendering it sometimes extremely difficult to check it. It generally comes on soon after the operation, in fits of a violent spasmodic character, in which the patient is in the deepest distress, looking and acting as if he were about to be suffocated. Its duration is variable; sometimes lasting only a few hours, while at other times it continues, as a prominent symptom, for days together. When very severe, it may occasion hemorrhage in the wound, by reopening some of the vessels.

It is not easy to determine how this cough is induced. From the fact that it often follows immediately upon the operation, it is not unlikely that it may arise from the inclusion in the ligature of some nervous filament, which thus sets up irritation in the mucous membrane of the air-passages, especially of the larynx and trachea, causing an effect not dissimilar from that awakened by the sudden intromission of a drop of water into the windpipe. That the effect must be somewhat of this character would seem probable, when we reflect upon the spasmodic and uncontrollable nature of the cough which generally characterizes the attack. At other times, the cough may be purely sympathetic, or, what is more likely, may be caused by the compression of the filaments of the tri-splanchnic nerve, which are so abundantly distributed through the coats of the arteries, especially those about the neck and chest.

The effects which the ligation of the carotid exerts upon the bronchia and lungs set in at various periods after the operation, and are denoted by the usual rational and physical signs. On dissection, the mucous membrane of the former is found to be of a reddish color, either uniformly, or in patches, greatly engorged with blood, and covered with pus, or pus and lymph. The lungs are abnormally vascular, loaded with black blood, more or less hepatized, or solidified at one point and softened at another. Blood and pus are sometimes contained in the anterior mediastinum; the pleura has been known to be the seat of extensive effusions; now and then there are traces of inflammation of the larynx and trachea; and occasionally, though rarely, the examination reveals the existence of pericarditis and endocarditis. When the inflammation of the respiratory organs is at all considerable, the blood drawn during life generally evinces a buffed, if not also a cupped, appearance.

Such being the effects which are liable to follow, probably in one case out of every four or five, in the brain and lungs, in consequence of the deligation of the

carotid, it is obvious that they should be carefully looked for, in order that proper measures may be adopted for their prompt and efficient removal the moment they arise. Much may be done, in most instances, by way of prevention, by a judicious preparatory course, consisting of venesection, purgatives, light diet, and repose of mind and body, which cannot fail to contribute materially to the protection both of the brain and lungs. The operation having been performed, these organs are most sedulously watched, the least indication that presents itself being met by appropriate means; and, in this way, the case is safely conducted to a favorable issue. If the patient be pale and faint, alcoholic stimulants, cautiously and judiciously administered, will be of service; cough and convulsive symptoms are treated with anodynes and antispasmodics, particularly morphia; and inflammation is controlled by the lancet, leeches, blisters, purgatives, aconite, and antimonials.

Aneurismal Varix.—This affection is uncommon. It is generally caused by external injury, as a puncture made by a knife, dirk, shot, or piece of glass, establishing a communication between the carotid artery and jugular vein, so as to admit of a ready interchange of their respective contents. An instance has been published in which the affection was occasioned by ulceration. The symptoms present nothing peculiar. In the few cases of this variety of aneurism that have been recorded by different observers, as Larrey, Marx, Willaume and Laurie, life did not seem to have been at all abridged by the disease. Operative interference would, in fact, in any event, be unjustifiable, as it would be fraught with great danger. Of varicose aneurism of these vessels no instance has, I believe, ever been reported.

ANEURISM OF THE EXTERNAL CAROTID.

Spontaneous aneurism of the external carotid is perhaps still more uncommon than of the internal carotid; its history, consequently, is involved in obscurity. The situation of the tumor just below the angle of the jaw, its throbbing, pulsatile character, and its gradually increasing volume, would serve to distinguish it from ordinary growths in this portion of the cervical region. In an aneurism of this artery, digital compression would be worthy of trial; should this fail, the proper remedy would, of course, be ligation of the common carotid.

ANEURISM OF THE TEMPORAL ARTERY.

The temporal artery has never, so far as I know, been the subject of spontaneous aneurism, but an aneurism of this vessel is occasionally met with as a result of external injury. The tumor, rarely exceeding the volume of a pigeon's egg, is usually of a spherical shape, and situated just in front of the ear, where it can nearly always be readily distinguished by its history, by its firm consistence, by its pulsation, and by its peculiar whiffing sound. The only two diseases with which it might be confounded are cystic tumors of the parotid region and aneurism of the middle meningeal artery, attended with absorption of the walls of the cranium, the swelling thus presenting itself directly beneath the common integuments.

For the cure of this disease two procedures may be employed; the one consists in exposing and tying the temporal artery at the cardiac side of the tumor, as in the ordinary Hunterian operation, and the other in laying open the sac, and, after having turned out its contents, securing the vessel above and below. The former method, when practicable, should always be preferred, as it is not only more simple, but less liable to be followed by a disfiguring cicatrice.

ANEURISM OF THE SUPRA-ORBITAL ARTERY.

Of this rare affection only a few cases have been recorded. It is always produced by a wound or rupture of the vessel, and is readily recognized by its history, by the rounded or ovoidal shape of the tumor, and by the concomitant thrill

and pulsation. The proper remedy is incision of the sac with ligation of the artery. In an instance observed by Raoult Deslonge-champs, a cure was promptly effected by an injection of perchloride of iron.

ANEURISM OF THE MIDDLE MENINGEAL ARTERY.

The middle meningeal artery has, in a few instances, been known to be the seat of aneurism, the result, apparently, of external injury. The nature of the disease can be recognized only when the tumor, causing absorption of the walls of the cranium, appears externally under the temporal muscle. A case has been related in which an aneurism of this vessel, making its way into this situation, was mistaken for a common cystic tumor of the scalp. As there was no pulsation, the surgeon cut boldly into the swelling, and found, to his dismay, that it was filled with blood. After repeated but fruitless efforts to arrest the hemorrhage, the patient expired. The dissection showed that the disease had been an aneurism of the middle artery of the dura mater. Had the real nature of the case been suspected in time, the proper remedy would have been ligation of the external carotid.

ANEURISM OF THE OPHTHALMIC ARTERY.

Aneurism of this artery is rare, both as a traumatic and as a spontaneous affection. The former is usually caused by external injury, and is liable to be followed by excessive enlargement of the structures of the orbit with protrusion of the eye. A number of cases of spontaneous aneurism of this artery are upon record, in only a few of which, however, the nature of the disease has been verified by dissection. Aneurism by anastomosis is also sometimes met with. The progress of aneurism of the ophthalmic artery is usually slow, and the symptoms are always characteristic. The proper remedy is ligation of the common carotid artery as early in the disease as possible, before there is any serious structural change in the parts. In anastomotic aneurism, a cure has occasionally been effected by injections with perchloride of iron; and lately several cases have been successfully treated by digital compression of the carotid.

ANEURISM OF THE INTERNAL CAROTID.

Aneurism of the internal carotid has been observed only in a few instances, its deep situation at the side of the neck and its exemption from ossific and fatty degeneration serving to protect it from this disease. The diagnosis must be obscure. The tendency of the tumor is to extend inwards towards the pharynx, as there is much less resistance here than in any other direction, the only opposing obstacles being the constrictor muscle, some lax cellular tissue, and the mucous membrane. The consequence is that more or less prominence exists in the throat, attended with pain and pulsation, and closely simulating an abscess of the tonsil. The treatment is the same as in ordinary carotid aneurism.

A remarkable case of aneurism of this vessel has been recorded by Mr. Syme. The patient, a woman aged sixty, had had a tumor for about five months in the throat, in the usual situation of abscess of the tonsil. It had attained about the size of a large walnut, exhibited a diffused appearance when viewed through the mouth, and pulsated in a strong and characteristic manner in every portion of its extent. The ligation of the common carotid artery diminished, but did not completely arrest, the throbbing. The woman died in thirty hours after the operation without any assignable cause. Had a less careful surgeon had the management of this case, he might probably have punctured the tumor under the supposition of its being an abscess, and thus instantly hurled his patient out of existence, much to his own discredit and that of the profession.

INTRACRANIAL ANEURISM.

Intracranial aneurism possesses little interest in a surgical point of view. Of 62 cases, analyzed by Dr. Gull, of London, 20 affected the basilar artery, 15 the middle cerebral, 8 the internal carotid at the side of the sphenoid bone, and 6 the anterior cerebral. The disease is most common in males, from the fortieth to the sixtieth year, sometimes as a result of external injury, as a blow or fall on the head, but more generally without any assignable cause. The dilatation is almost always uniform, not partial or sacculated, and is usually confined to one artery. The size of the tumor ranges from that of a pea up to that of a pullet's egg. The vessels of the brain seldom exhibit any evidence of disease; but as the aneurism advances the cerebral substance becomes displaced and disorganized, one of the most frequent lesions being softening. The cranial bones seldom suffer.

The most reliable symptoms are apoplexy and hemiplegia, buzzing noises in the ears, deafness, dizziness, vertigo, and pain in the head, either circumscribed or diffused, intermittent or continued, increased by motion, and accompanied by peculiar morbid sensations. These symptoms may come on suddenly, without any premonition, or, as is more frequently the case, arise gradually and almost imperceptibly. The diagnosis is always very obscure. In a few instances, the nature of the disease has been detected by a loud, rough, or whizzing noise on one side of the head, heard by the patient, and distinguished by auscultation.

Death may be produced, first, by the sudden rupture of the sac, and the escape of its contents into the surrounding parts; secondly, by long-continued irritation; and, lastly, by disorganization of the cerebral substance. Of these different modes of termination the first is by far the most frequent.

Very little can be effected by treatment. When the diagnosis can be satisfactorily determined, the carotid artery should be tied on the affected side, as was done successfully in a case of this disease by Mr. Coe, of England.

Arterio-venous aneurism of the extracranial portion of the internal carotid artery is extremely rare. Instructive cases of it have been reported by Bérard, Desparanches, Joret, and Giralès, all caused by external injury. One instance has been observed in which it was occasioned by a wound inflicted in opening an abscess. In two of the cases here referred to, the carotid artery, as was shown by the autopsy, communicated with the internal jugular vein, and a well-marked aneurismal pouch existed between the two vessels. The symptoms and treatment are the same as in arterio-venous aneurism of the common carotid.

• ANEURISM OF THE VERTEBRAL ARTERY.

Aneurism of this artery, both spontaneous and traumatic, is extremely uncommon, a circumstance no doubt due to the deep situation of this vessel and to its freedom from ossification. In two very interesting cases of this disease, described by Ramaglia, of Naples, and South, of London, the diagnosis was so obscure that the true nature of the disease was not detected until after death. In both the common carotid was tied, without, of course, any benefit. In the former, which was an example of traumatic aneurism, situated behind the left ear, the operator, finding that the deligation did not arrest the pulsation, removed the ligature and treated the case upon general principles, death occurring soon after. In the other instance, in which the carotid artery could be distinctly traced over the tumor, this vessel was also tied under the supposition that it was the seat of the swelling. The tumor, however, rapidly increased, and in a fortnight after caused death by bursting into the trachea. Dissection showed that it was an aneurism of the vertebral artery, situated between the transverse processes of the fourth and fifth cervical vertebræ.

Möbus, a German surgeon, has reported a case of aneurism of the vertebral artery, the result of a wound of the neck, in which a cure was effected by compression and the use of ice.

ANEURISM OF THE SUBCLAVIAN.

Statistics prove that aneurism of the subclavian is nearly as frequent as that of the carotid. In Lisfranc's table the popliteal comes first, then the femoral, next the carotid, and then the subclavian, the latter having suffered in 16 cases out of 179. In the table of Mr. Crisp, comprising 295 cases of external aneurism, the subclavian was engaged in 23, and the carotid in 25. The disease is more frequent in the right artery than in the left, in men than in women, and in the laboring than in the higher classes. The period of life during which most of the cases occur is between the thirtieth and fiftieth years.

Although the disease may affect any portion of the artery, it is most frequent beyond the scalene muscles, a short distance before it becomes merged in the axillary. The form of the aneurism is generally globular or ovoidal, but cases are observed in which it has a singularly compressed appearance; and, on the other hand, it may be remarkably lobulated, especially when it is very capacious, and extends deeply among the surrounding structures, which thus indent its surface. Its volume is seldom very large, unless it becomes diffuse, when it may attain an enormous magnitude, reaching nearly up to the angle of the jaw, pushing out the clavicle, overlapping the trachea, displacing the scapula, pressing backwards against the ribs and spine, and dipping into the cavity of the chest so as to force down the lung and impede respiration.

As the tumor enlarges, it necessarily encroaches upon and compresses the neighboring parts, causing more or less pain, œdema, difficulty of respiration, dilatation of the veins of the neck, chest, and upper extremity, and a feeling of numbness and sometimes even partial paralysis. Originally small, deep-seated, circumscribed, indolent, and movable, it generally steadily augments in volume, approaching, as it does so, nearer and nearer to the surface, loses its defined shape, becomes the seat of incessant pain, and at length contracts firm adhesions to the surrounding structures, identifying itself, as it were, with them. Examined with the ear and hand, it readily imparts to them the peculiar beat, thrill, and bellows' sound so characteristic of aneurism in other regions.

Diagnosis.—The diagnosis of subclavian aneurism is sometimes extremely difficult, and several cases have been reported in which the vessel was ligated where no disease of the kind existed. The affections with which it is most liable to be confounded are aneurism of the innominate artery or arch of the aorta, abscesses, and various kinds of tumors, solid and encysted, benign and malignant. As these lesions are of frequent occurrence in this region, it is impossible for the surgeon to be too cautious in his examination of cases involving questions of diagnosis.

The history of the tumor and its situation at the side of the neck, just above the clavicle, generally afford important data in regard to the diagnosis. If the patient is under thirty years of age, it may almost certainly be assumed that the disease is not spontaneous aneurism, as there are probably not three well-authenticated instances on record in which the subclavian was thus affected at this early period. Aneurism of the innominate is situated lower down, and approaches nearer to the middle line, than aneurism of its subclavian division; and in aneurism of the aorta, the tumor, although it may extend into the neck, rarely projects as far above the clavicle as in the lesion in question; certainly not in its earlier stages, when alone a correct diagnosis can be of any avail in an operative point of view. If the case can be seen soon after its commencement, before the tumor has attained any considerable bulk, a very good idea may often be formed as to the precise portion of the artery that is affected by it. Thus, for example, if the aneurism occupies the space immediately exterior to the sterno-cleido-mastoid muscle, and manifests a tendency to extend upwards into the neck, and downwards in the direction of the axilla, it may be assumed that it is seated upon the outer portion of the vessel beyond the scalene muscles. On the other hand, it may be concluded that it is connected with the inner portion of the artery, if the tumor is placed under cover of the mastoid muscle, and is gradually making its way over towards the median line, thus leaving the inferior triangle of the neck

clear. It may be added that in subclavian aneurism the tumor is less liable to encroach upon the windpipe and œsophagus than in innominal and aortic aneurism, and hence there is generally much less cough, dyspnœa, and dysphagia in this than in the other affections. It is only, in fact, when the tumor is of great bulk, or when it happens, from the peculiarity of its position, to exert much pressure upon the pneumogastric, phrenic and laryngeal nerves, that any serious symptoms of this kind will be likely to arise.

Progress.—Subclavian aneurism is always a serious disease, a spontaneous cure, although possible, as several cases upon record testify, being an extremely rare occurrence. In general, the disease progresses until it attains a certain point of development, when it terminates fatally, either by ulceration and hemorrhage, or by the induction of constitutional irritation. The sac may open externally, a not uncommon event, especially when it is invaded by gangrene; or it may burst into the pleura, lungs, trachea, or œsophagus; in either case, death takes place either instantly or within a short time after the tumor has begun to give way. There are several cases on record in which the aneurism pointed in the axilla and on the shoulder, having completely eroded some of the upper ribs and the body of the scapula, the latter being scooped out so as to form a kind of bed for the accommodation of the sac.

Treatment.—The treatment of subclavian aneurism has hitherto been exceedingly unsatisfactory, and there is no probability, judging from the deep situation and intricate relations of the tumor, that much benefit will ever accrue from any mode of management that may be devised for its relief. The plan of Valsalva, varied in every possible manner, has signally failed in every instance, except a few, and no one seems now disposed to place any confidence whatever in its efficacy. Acupuncture and electricity, from which so much benefit had at one time been anticipated, have likewise disappointed expectation. Some time ago a case was reported in which a cure was alleged to have been effected by galvanopuncture, but the example is a solitary one, and the procedure is of too problematical a character to merit serious attention. Of what resource, then, can the surgeon avail himself in this unfortunate class of cases? Ligation of the affected artery is not only difficult, under any circumstances, in consequence of the position of the tumor and the intricacy of its anatomical relations, but is frequently absolutely impracticable on account of the diseased state of the artery, rendering it unable to support the ligature. Shall he adopt the operation of Dr. Mott, and secure the innominate, of which the subclavian, on the right side, is one of the main divisions? Here, again, obstacles meet him in every direction, for even if he should be so fortunate as to get his ligature round the vessel, which, however, is by no means always the case, he will find, by consulting the history of the operation, that every instance in which it has been performed has had a fatal termination. Nothing, therefore, is to be gained from this procedure. In short, the Hunterian principle of operation is hardly applicable to any case of subclavian aneurism. On the right side, we are not only obliged to encounter, as just stated, great difficulties in reaching the innominate artery, but in throwing a ligature round the vessel we effectually cut off a large and important supply of blood from the brain, thus greatly enhancing the dangers of the case.

The innominate artery has been tied for the cure of subclavian aneurism in 8 cases, and in 1 for hemorrhage from the latter vessel. The results are subjoined in tabular form.

Ligation of the Innominate Artery.

	Opera- tor.	Date.	Age.	Sex.	Disease.	Result.	REMARKS.
1	Mott	1818	57	m.	Subclavian aneurism	Died on 26th day	Artery tied half an inch below its bifurcation; ligature separated on the 14th day; hemorrhage on the 9th, and again on the 23d day; death on 26th day. Ulceration of the artery, and want of occlusion.
2	Graefe	1822		m.	Subclavian aneurism	Died on 67th day	Ligature came off on 14th day; death from hemorrhage.
3	Norman	1824				Died	
4	Arendt	1824			Subclavian aneurism	Died on 8th day	Cause of death, inflammation of the aneurismal sac and of the pleura and lungs.
5	Hall	1830	45	m.	Subclavian aneurism	Died on 5th day	Artery morbidly adherent, dilated, soft, and friable; torn in the attempt to separate it, at two points, between which the ligature was applied; copious hemorrhage during operation; plugging of the wound; participation of the aorta and carotid in the disease.
6	Bland	1832	31	m.	Subclavian aneurism	Died on 18th day	Ligature placed round the artery near its bifurcation; hemorrhage on the 17th day, proving fatal on the 18th; the innominate and carotid closed by solid clots; the subclavian still open.
7	Lizars	1837	30	m.	Subclavian aneurism	Died on 21st day	Ligature separated on 17th day; pleuritis; death caused by repeated hemorrhages; twenty ounces of coagulated blood at the root of the neck; arteries imperfectly closed.
8	Hutin	1842	26	m.	Hemorrhage after ligation of sub- clavian	Died in 12 hours	Tied for secondary hemorrhage, after subclavian had been secured for wound of the axillary
9	Cooper	1860	31	m.	Subclavian aneurism	Died on 41st day	Ligature, applied an inch from the aorta, detached on 18th day; patient did well for three weeks, when hemorrhage occurred, and finally caused death.

All the cases in the above table except one, proved fatal from hemorrhage of the wound, caused by the want of occlusion either of the ligated artery, or of the carotid and subclavian. It will be observed that Graefe's patient survived upwards of two months. I purposely exclude from the table the cases which are usually referred to as having occurred in the practice of Dupuytren and Bujalski, not considering them as sufficiently well authenticated to entitle them to a place in it. I also reject from it several reported cases in which the operation of ligating the innominate artery was commenced but not completed.

Dr. Peixotto, of Portugal, tied the innominate artery in 1851, on account of secondary hemorrhage from the common carotid, which had been ligated three weeks previously. The ligature, however, which was a precautionary one, was not tightened, but applied merely so as to flatten the vessel. The patient made a good recovery. Such an operation can hardly be regarded as a true case of deligation of the innominate artery. The cure was doubtless effected by the ligation of the other vessel.

Mr. Key, of London, in a case of aneurism of the subclavian, found it impracticable to apply a ligature to the innominate, in consequence of the volume of the tumor, and the diseased condition of the latter vessel. The patient was seized soon after the operation with symptoms of pulmonary distress and exhaustion, and died on the twenty-third day.

The operation of ligating the innominate artery is one of no inconsiderable difficulty, even in the dead subject, but in the living the perplexity is greatly increased by the proximity of the aneurism, by the presence of glandular swellings, and, above all, by the manner in which the parts at the root of the neck are matted together by plastic deposits, rendering it thus exceedingly troublesome to separate them. These embarrassments were experienced in a striking degree by Dr. Hall, of Baltimore; he had great difficulty in isolating the vessel, and, in attempting to do so, tore it at two points, ligating it afterwards between them.

Hemorrhage occurred at the time, but was checked by plugging the wound. Another obstacle to successful deligation is disease of the vessel, consisting either in a morbid dilatation, or in a softened and lacerable condition of its coats. Unforeseen difficulties were present in more than one-fourth of the cases in which ligation of the artery has been attempted, compelling the operators to desist, notwithstanding their great dexterity and profound knowledge of the anatomy of the neck.

Mr. Porter, of Dublin, in 1831, attempted to tie this artery on account of aneurism, but was obliged to desist in consequence of its diseased condition. The tumor, nevertheless, gradually disappeared, and the patient, a man forty-seven years of age, finally recovered.

Dr. Hoffman, of New York, in a case of subclavian aneurism in a man aged sixty-three, cut down upon the innominate artery with the design of applying a ligature to it, should he be unable to ligate the subclavian; but as the vessel was found to be much enlarged, it was deemed inexpedient to proceed any further, and the patient was accordingly abandoned to his fate. The operation was performed on the 26th of October, 1839, and death occurred on the 19th of January, 1840.

The proposal to ligate the innominate artery originated with Allan Burns, from a conviction that the circulation in the head and upper extremity could be maintained without the agency of this vessel, and that it could be easily enough exposed by tracing it downwards towards the aorta, by a careful and patient dissection, the head being at the time bent well back. It remained, however, for Dr. Mott, in 1818, to put the suggestion to the test of experiment upon the living subject; and, although the operation had an unfavorable issue, the man dying, as has already been stated, on the twenty-sixth day, we cannot but admire the genius which could plan, and the intrepid skill which could execute, so daring and brilliant a feat. The case was one of subclavian aneurism above the clavicle, and the design had been to apply the thread to the latter vessel, but after exposing it on the tracheal side of the scalene muscle, it was found that its tunics were too much diseased to bear the pressure of the ligature, and he accordingly tied the innominate in its stead.

In a case of subclavian aneurism, Dupuytren tied the axillary artery under the pectoral muscles. Hemorrhage, or, rather, oozing of blood commenced on the fifth day, and the patient died on the ninth.

A similar operation was performed by Pétrequin. The tumor continuing to pulsate, the sac was punctured, and eight or nine drops of a solution of the perchloride of iron were thrown in, the brachio-cephalic trunk being compressed during the injection, and for ten minutes afterwards. The next day all pulsation had ceased in the tumor, but the patient died of hemorrhage at the place of the ligature twelve days after its application.

Finally, benefit may occasionally arise in subclavian aneurism from *manipulation* of the tumor, as practised by Mr. Fergusson; some of the clots detached in the operation may accidentally find their way into the distal extremity of the vessel, and thus occlude its caliber along with the interior of the aneurismal sac. In a disease so desperate as this, in which every expedient hitherto devised has been tried in vain, any suggestion that holds out the least possible chance of relief is worthy of trial.

ANEURISM OF THE AXILLARY ARTERY.

Aneurism of the axillary artery is less frequent than that of the subclavian. In 364 preparations of aneurism in the London museums, examined by Mr. Crisp, including 249 of the aorta, the axillary artery was affected only in 8. In 551 cases analyzed by him from different sources, including 234 cases of aneurism of the aorta, 18 only were of the axillary artery.

The disease is most frequent in men, between the ages of thirty-five and fifty. It is very often of traumatic origin. The volume of the tumor ranges from that

of an egg to that of a child's head, the average being that of a fist. Arterio-venous aneurism of the axillary vessels is very uncommon.

Symptoms.—The symptoms of axillary aneurism are generally so well marked as to render it impossible to mistake their character. When the disease arises spontaneously, or without any assignable cause, it may exist for several months without attracting any particular notice, and the same thing occasionally occurs when it results from external violence, as a blow or strain. Generally, however, the tumor rapidly augments in bulk, and produces such a train of phenomena as to lead at once to its detection. Of these, one of the earliest, and at the same time most unpleasant, is the sense of fatigue or uneasiness in the affected part arising from the pressure on the axillary plexus of nerves. This symptom is usually succeeded in a few weeks, sometimes, indeed, in a few days, by a feeling of pain, which is always in direct ratio to the size of the aneurism, being comparatively slight when it is small, and more or less intense when large. Nor is the pain confined to the site of the disease; in most cases it radiates from it, as from a common centre, in different directions, outwards into the shoulder, downwards along the arm, and upwards into the neck. Pressure, severe coughing, the recumbent posture, and the weight of the limb greatly increase it. Numbness of the shoulder, chest, and arm, is another symptom which generally manifests itself at an early period of the disease, and is never absent when the tumor has acquired considerable magnitude. It is always very distressing to the patient, is greatly aggravated by pressure on the swelling, and commonly extends to the ends of the fingers. Indeed, it is at this point that the sensation in question is often most keenly felt.

The pulsation of the tumor, at first faint and scarcely perceptible, becomes very distinct during the progress of the disease, so that it cannot only be felt by the fingers, but seen at a considerable distance; sometimes, indeed, ten or twelve feet from the patient. On applying the ear or stethoscope to the tumor, the blood is found to rush into it with more or less violence, producing a peculiar thrill, or whizzing noise, synchronous with the contraction of the left ventricle of the heart. In the early stage of the disease, the swelling is soft and elastic, and may be readily emptied by pressure; by degrees, however, it becomes firm, tense, and, in great measure, if not entirely, incompressible. In some cases, especially in those attended with great enlargement, there is considerable diminution of the temperature of the affected limb, with indistinctness, if not entire absence, of the pulse at the wrist, more or less cough, dyspnoea, and shortness of breathing. Occasionally the pulse is fully as strong as in the other arm, but irregular or intermittent, losing several strokes in a minute.

In addition to these symptoms, there is always, when the swelling is large, so much displacement of the clavicle as to render it difficult, if not impossible, to distinguish the pulsation of the subclavian artery, the vessel being deeply buried behind and below the bone. In some instances the collar-bone has been found to be considerably imbedded in the tumor, or partially removed by absorption. Another symptom, which, from its frequency, especially in the latter stages of the disease, requires mention here, is the swelling of the affected limb. This varies in degree in different cases, often extends from the shoulder to the ends of the fingers, and is usually of an œdematous character, pitting under pressure, and becoming aggravated by the dependent position of the part. When thus affected, the muscles lose their contractile power, and the motions of the extremity are proportionately impaired, or entirely annihilated. Sometimes, again, owing to the great magnitude of the tumor, the patient is unable to approximate the limb to the side of the chest. Finally, there is another phenomenon, which, as it is almost invariably present in the latter stages of axillary aneurism, I am disposed to regard as pathognomonic. I allude to the peculiar attitude of the patient, arising from the constant inclination of the head towards the affected side, and the manner in which he supports the corresponding arm; the object of both being evidently to prevent the tension which would otherwise be caused in the tumor. Under these circumstances, too, the countenance wears an anxious

and distressed appearance, and, as the system always deeply sympathizes with the local affection, there is more or less derangement of the general health.

When the tumor is unusually bulky, it will necessarily greatly encroach upon the clavicle, forcing it upwards into the neck, and at the same time exerting severe pressure upon the subclavian artery, perhaps so much as to render it difficult, if not impossible, to distinguish the pulse at the wrist.

Diagnosis.—Notwithstanding that the symptoms of this disease are usually well-marked, it has sometimes happened that tumors of this description have been opened by ignorant practitioners under the belief that they were abscesses. For such an error no apology can be offered. Still, cases occasionally present themselves, though very rarely, in which it is extremely difficult, at first sight, to distinguish between this and other swellings in the armpit or subclavicular region. Enlarged lymphatic ganglions, adipose tumors, or encephaloid growths, for example, if they chance to lie along the course of the axillary artery, might have its pulsation imparted to them, and thus create some doubt in regard to their real character. Under such circumstances, the facility with which the mass can be elevated or removed from the vessel, the absence of the peculiar whizzing sound, previously alluded to, as being generally present in aneurismal disease, the slight pain and numbness in the part and in the corresponding limb, the continuance of the swelling on the application of pressure to the subclavian artery, and, above all, the history of the case, will generally be sufficient to enable the practitioner to arrive at a correct diagnosis.

In this disease the tumor may be situated either immediately below the clavicle, or in the axilla, properly so called. In the former case, it may not only elevate the clavicle, but extend up into the neck, beneath the bone, as far as the acromial margin of the scalene muscles. In the latter, it has been known to reach some distance down the arm, so as to compress the brachial artery and nerves, and prevent the approximation of the limb to the side.

Prognosis.—Axillary aneurism occasionally undergoes spontaneous cure, as in the instances reported by S. Cooper and Breschet. Such an occurrence, however, is extremely uncommon. Most generally, the disease, if left to itself, terminates fatally, either by rupture of the sac and exhausting hemorrhage, or by gangrene of the limb. Sometimes, though rarely, the tumor destroys life by inducing caries of the ribs and perforation of the pleura, followed by an escape of its contents into the cavity of the chest. In a case narrated by Mr. Guthrie, it was ascertained, on dissection, that the aneurism had forced its way into the right side of the chest by the destruction of a portion of the first five ribs, and had contracted adhesions to the upper lobe of the lung, into which it had gradually opened and discharged its contents, the man having spat blood more or less profusely for several weeks prior to his death. In a similar case mentioned by Dr. Neret, of Nancy, an aneurism, about the size of a large chestnut, communicated with a cavity of the volume of the head of a new-born infant in the upper part of the left lung. The man had been admitted into the hospital on account of hemoptysis.

Treatment.—The only remedy for this disease is ligation of the subclavian artery, and the sooner this is done the more likely will it be to succeed. The operation, however, should not be declined, even although gangrene of the sac has already commenced, provided there is nothing else to forbid it. I am not aware that aneurism of the axillary artery has ever been cured by compression, nor is this surprising when we reflect upon the difficulty of approaching the subclavian under such circumstances, and also the proximity of the axillary plexus of nerves, which could hardly be induced to brook such an attempt for a sufficient length of time to produce any good effect. If the procedure is ever admissible, it will be in those cases where the tumor is uncommonly small, and the subclavian more than ordinarily superficial. The vessel might then be reached and successfully compressed either by the finger, the handle of a key, or the instrument delineated at p. 509, fig. 169. If the parts were very tender, the patient might be kept gently under the influence of chloroform while the necessary pressure is main-

tained, just as the obstetrician occasionally blunts the sensibility of the female for many hours together in protracted and painful labor.

Mr. Syme, not long ago, laid open, with complete success, a spontaneous aneurism in this region, turning out its contents, and tying the axillary artery above and below the points of communication with the sac. As a means of safety the subclavian was compressed by the finger of an assistant against the first rib, through an incision in the neck which divided the skin and facia. By this procedure the circulation was so effectually controlled that there was hardly any hemorrhage. Few operators, unless possessed of the most consummate skill, would be willing to imitate the example of the Edinburgh surgeon, or not prefer the ligation of the subclavian artery on the outside of the scalene muscle.

Mortality.—Of 27 cases of axillary aneurism, which I analyzed in 1841 in the *Western Journal of Medicine and Surgery*, including one of my own, for which the subclavian artery had been tied, 17 recovered and 10 died, death occurring from the third to the thirtieth day, either from hemorrhage, gangrene of the arm, ulceration of the artery, pericarditis, pleurisy, or pneumonia. In one case it was caused by effusion into the brain, and in another, my own, by rupture of the aneurismal sac into the thoracic cavity. In the tables of Dr. Norris, showing the mortality in 69 cases in which the subclavian artery was tied for aneurism, including 9 of wounds of the axillary artery and 2 of tumors not aneurismal, though supposed to be so at the time, 36 recovered, and 33 died.

In three of the cases mentioned in my paper, the subclavian was secured on the tracheal side of the tumor, and all proved fatal. In one of the cases, that of Mr. Colles, the ligature was not tightened till the fourth day after the operation, owing to the supervention of excessive dyspnoea and cardiac oppression.

In my own case, a traumatic one, the tumor burst at the end of the twenty-sixth day after the operation, discharging its contents into the right thoracic cavity, and thus causing fatal pleuritis. The patient, a man aged thirty-six years, was suddenly seized with intense pain in the chest, which was particularly severe at the base of the right lung, from which it extended over towards the sternum, on the one hand, and up towards the axilla, on the other. The respiration was hurried, laborious, and fifty-six in the minute; and the pulse, which was quick and tense, rose rapidly to one hundred and forty. Two days after the accident, the patient experienced a sensation near the upper part of the chest, as if a fluid were passing from the pleuritic cavity into that of the aneurismal sac, and, on carefully auscultating the spot, a plashing sound could be distinctly heard at every inspiration, the noise resembling that produced by shaking water in a closed vessel. The respiration in the right lung was now bronchial, and there was extensive dulness on percussion of that side of the chest. It is proper to add that the tumor prior to the operation was about the volume of a large fist, and that the ligature, which had been placed on the artery on the external side of the scalene muscle, came away on the fourteenth day. The dissection revealed the following facts, the arteries having previously been injected.

The wound made in the operation was completely cicatrized, and the pectoral muscles, although somewhat attenuated, retained their natural appearance. The subclavian artery terminated abruptly at the outer margin of the scalene muscle, where the ligature had been applied, its caliber being closed by a mass of solid fibrin, about one-third of an inch in length, which adhered firmly to the lining membrane, and thus afforded an effectual barrier to the passage of the blood. Between this and the thyroid axis the vessel was occupied by a dark coagulum of blood, which as it was unadherent, was probably formed only a short time before death. Beyond the seat of the ligature the artery had a rough, ragged appearance, and was sufficiently pervious to admit of the ready passage of a small probe into the aneurismal sac. Superiorly the tumor was overlapped by the brachial plexus of nerves, while in front, at its lower part, was the subclavian vein, which, besides being thrown out of its natural course, was considerably diminished in size. No pus was anywhere discoverable, the parts immediately involved in the operation being intimately consolidated by plastic matter. The aneurismal tumor, placed immediately below the clavicle, was of a conical form,

and about the volume of a moderate-sized orange, being two inches and a quarter in diameter at its base. Its walls varied in thickness at different points from half a line to the eighth of an inch, and its interior communicated, by means of an oval aperture, one inch and three-quarters in length by an inch and a half in width, with the pleuritic cavity: it was situated between the first and second ribs, nearly equidistant between the sternum and spine, and was obviously the result of ulceration, induced by the pressure of the tumor. Both ribs were denuded of their periosteum immediately around the opening, and the serous membrane had a shreddy, ragged aspect. The aneurismal sac contained a few reddish clots arranged in a laminated manner, and closely adherent to its inner surface, especially at the part corresponding with the apex of the tumor.

The right thoracic cavity contained nearly three quarts of bloody-looking serum, intermixed with flakes of lymph and laminated clots, the latter of which were of a reddish-brown color, and had evidently been originally lodged in the aneurismal sac. The pleura exhibited everywhere marks of high inflammation, while the right lung was greatly reduced in volume, from the compression of the effused fluid. The left lung was considerably engorged, and at one or two points almost hepatized. The heart and pericardium were sound. The abdominal viscera presented nothing unusual. None of the arteries were diseased.

There can be no doubt, from the manner in which this case terminated, that the ulceration which gave rise to the opening above referred to, and which finally led to the escape of a portion of the contents of the aneurismal sac, commenced prior to the deligation of the artery, having been produced by the violent pulsative action of the tumor. Could such an accident have been foreseen, I should not have hesitated to empty the sac to relieve the parts of pressure, objectionable as such a procedure certainly would be in ordinary cases.

An instance of a character similar to the above occurred in 1823, in the practice of Mr. Bullen, of England, and is related in the twentieth volume of the *London Medical Repository*. The patient was a man, aged thirty-six years, and the aneurism, which was of nearly five months' standing, also occupied the right side. Eighteen days after the operation, the tumor began to increase in size and to become painful. Very soon evidence of suppuration appeared, and at the end of a week, from six to eight ounces of bloody pus were ejected during a violent paroxysm of coughing, the sac immediately diminishing one-half in volume. A puncture being made into the swelling, five ounces of a similar fluid were discharged, to the great relief of the patient. It was now apparent that there was a cavity between the first and second ribs, near their sternal extremities, through which the matter had found its way into the lung, and which now readily admitted air from the latter organ, whenever the man coughed, at which time a little also escaped at the artificial opening. By degrees, the discharge of matter ceased, the cough grew less and less, and at the end of three months the recovery was perfect.

Mr. Erichsen, struck with the extraordinary mortality after ligation of the subclavian artery, in the third part of its course, for spontaneous aneurism in the axilla, determined, if possible, to ascertain the cause of death. For this purpose he analyzed 47 cases of the operation, of which 23 recovered, and 24 were fatal. Of the latter 10 perished from inflammation within the chest, 6 of suppuration of the sac, 3 of hemorrhage, 1 of gangrene of the hand and arm, and 1 of general gangrene, the cause of death in 3 not being mentioned.

The ten cases in the first category died of pneumonia, or of this disease and of inflammation of the pleura and pericardium; produced, as Mr. Erichsen suggests, either by an extension of the inflammation of the deep cellular tissue of the neck to the contents of the chest, by the inward pressure of the aneurismal sac, or, lastly, by the injury inflicted during the operation upon the phrenic nerve.

Suppuration of the sac was the immediate cause of death in six cases, and it occurred also in two of the cases that died of inflammation of the chest. Besides these fatal cases there were six of recovery, making thus an aggregate of

14 cases, or a ratio of nearly one in three. The period at which the suppuration set in varied, on an average, from eight days to four weeks.

Hemorrhage proved fatal in three of the cases, and appears to be a frequent cause of death after suppuration of the sac. It may proceed from the distal orifice of the artery opening into the sac, or from one of the large branches in its immediate vicinity, as the subscapular or posterior circumflex.

Gangrene of the hand and arm was the cause of death in one instance only, although the disease occurred also in two others. In Blizzard's case, in which there was sloughing of the sac and pericarditis, the gangrene was confined to two fingers; while in Brodie's case it occurred both in the upper and lower extremities, thus showing that it depended, not upon a want of power in the collateral circulation, as in the other examples, but upon some peculiar state of the constitution.

LIGATION OF THE SUBCLAVIAN ARTERY ON ITS TRACHEAL ASPECT.

This vessel is sometimes ligated on the tracheal side of the scalene muscles. The subjoined table, comprising ten cases, will serve to place the subject in its true light.

No.	Operator.	Sex.	Age.	Result.	REMARKS.
1	Colles	m.	33	Death	In this case there was only a space of three lines between the sac and the bifurcation of the innominate. The patient died of hemorrhage on the fourth day.
2	Mott	f.	21	Death	The patient died on the eighteenth day of hemorrhage.
3	Hayden	f.	57	Death	Death on the twelfth day from hemorrhage.
4	O'Reilly	m.	39	Death	The patient died on the thirteenth day of hemorrhage.
5	Partridge	m.	38	Death	Fatal on the fourth day from pericarditis and pleurisy.
6	Liston	m.	—	Death	Death from hemorrhage on the thirteenth day.
7	Liston	m.	32	Death	The patient died on the thirty-sixth day of hemorrhage.
8	Auvert	—	—	Death	Fatal hemorrhage on the twenty-second day.
9	Auvert	—	—	Death	Fatal hemorrhage on the eleventh day.
10	J. K. Rodgers	m.	42	Death	Fatal hemorrhage on the fifteenth day.

The result in all the above cases, except one, was death by hemorrhage, notwithstanding the undoubted ability and skill of the operators, comprising some of the most illustrious names in surgery. Should this fact not be sufficient to deter practitioners from repeating the operation, or should they continue in their efforts to save life until some one, more fortunate than the rest, shall succeed in finding an exceptional case? The case of Dr. J. Kearney Rodgers, of New York, in which the artery was secured on the left side on account of an aneurism, is of the deepest interest in this respect, as showing that, although the patient finally perished from hemorrhage, yet the ligated vessel was completely closed by an adherent coagulum.

Until the operation of Dr. Rodgers, it was universally regarded as impracticable to ligate the left subclavian artery on the inside of the scalene muscles, such being the intimate relation of the vessel in this situation to the sac of the pleura, the carotid artery, internal jugular vein, pneumogastric nerve, and thoracic duct. It had been thought that, from the severe injury which would necessarily be inflicted upon the surrounding structures during the operation, violent and fatal inflammation must be the speedy and inevitable consequence. At all events, no one had yet been found ingenious enough to devise, and bold enough to execute, such an enterprise. Although it is not likely that the operation will soon be repeated, the case in question deserves notice here as a matter of surgical history, if nothing more.

The patient was a man, aged forty-two, who, in consequence of lifting a heavy weight, upwards of a month previously, suddenly became the subject of aneurism of the left subclavian artery. At the time of his admission into the New York Hospital, the tumor could be seen above the clavicle, about the size of a small

hen's egg, extending outwards towards the shoulder, and inwards towards the sterno-cleido-mastoid muscle, by the outer border of which it was considerably overlapped. The signs of aneurism were well-marked in every particular. The operation was performed on the 14th of October, 1845. Two incisions were made; one, three inches and a half in length, along the inner border of the sterno-cleido-mastoid muscle, terminating at the sternum, and dividing the integuments and platysma-myoid muscle; the other, two inches and a half in length, extending horizontally over the inner extremity of the clavicle, the two meeting at a right angle near the trachea. Several small veins having been ligated, and the flap thus formed dissected up, the sternal portion with half of the clavicular of the mastoid muscle was divided upon a grooved director, a procedure which fully brought into view the sterno-hyoid and omo-hyoid muscles and the deep-seated jugular vein, all covered by the cervical fascia. A part of the aneurismal sac was also in sight, overlapping a considerable portion of the anterior surface of the scalene muscle, upon which the operator could distinctly feel the phrenic nerve. By digging with the handle of the knife and fingers, the deep cervical fascia was now divided close to the inner edge of the scalene muscle, when, after a little search, the subclavian artery was easily discovered as it passed over the first rib, pressure upon this portion readily arresting the pulsation of the tumor. The next step of the operation consisted in passing the ligature round the vessel without injury to the pleura and thoracic duct, but this proved to be one of extreme difficulty, owing to the great narrowness and depth of the wound, the latter nearly equalling the length of the forefinger. This, however, was at length successfully accomplished by means of an aneurismal needle with a movable point, carried from below upwards. The moment the ligature was tied all pulsation in the tumor ceased, and the patient, if not entirely comfortable, made no complaint of any kind.

The wound became somewhat erysipelatous after the operation, but, on the whole, the patient got on well until the 26th of October, when, on changing his position in bed, hemorrhage supervened, and, continuing to recur at various intervals, destroyed him on the fifteenth day. On dissection, the wound was found to be filled with clotted blood, beneath which the artery had been completely divided by the ligature, which lay loose close by. The stump of the subclavian, between the aorta and the point of ligation, was about an inch and a quarter in length, and thoroughly impervious to air and liquids, its caliber being occupied by a solid and firmly adherent coagulum. The distal extremity of the subclavian contained a soft, imperfect clot, while the vertebral artery, which was given off immediately at the site of the ligature, was almost patulous, and had evidently been the seat of the hemorrhage which caused the patient's death. The aneurismal sac, the size of a small orange, was completely blocked up with coagula. The thoracic duct was uninjured, but the pleura at the bottom of the wound was found to be extensively lacerated, and through the opening thus formed a large quantity of blood had passed into the left cavity of the chest.

In reflecting upon this interesting case, Dr. Rogers regretted that he had not secured the vertebral artery and also the thyroid axis, believing that this would have effectually prevented the fatal hemorrhage. Professor Willard Parker, acting upon this suggestion, in September, 1863, tied the left subclavian artery on the inside of the scalene muscle, along with the common carotid and vertebral, on account of subclavian aneurism. The case progressed well until the tenth day, when there was a slight hemorrhage. The ligature separated from the vertebral on the twelfth day, from the carotid on the fourteenth, and from the subclavian on the twenty-fourth. Death occurred at the end of the sixth week from hemorrhage of the distal side of the subclavian.

ANEURISM OF THE BRACHIAL ARTERY AND ITS BRANCHES.

Spontaneous aneurism of the brachial artery and of its terminal branches, the radial and ulnar, is extremely uncommon, for the reason, adverted to in a previous section, that ossification and fatty degeneration of the coats of these vessels are

of such great rarity compared with the same lesions of the femoral and its principal divisions. In fact, I do not believe that it has ever been noticed in this country. Cases of this disease, however, are mentioned by foreign authors, among others by Desault, Palletta, Flajani, Pelletan, and Scarpa. Spontaneous aneurism of the ulnar and radial arteries is spoken of by several writers, but in so vague a manner as to render it difficult to determine whether the disease depended upon degeneration of the coats of the vessels, or merely upon laceration by external injury.

All these arteries are subject to traumatic aneurism; the brachial, however, is much more frequently involved than the radial and ulnar, and one of the most common causes of the occurrence is venesection at the bend of the arm, the puncture of the lancet establishing a communication between the vein and the artery, thus giving rise to what is called an arterio-venous aneurism. Or, instead of this, the instrument may almost completely sever the artery, and so induce a diffuse aneurism, not opening into the vein, but sending its

contents, up and down, over a large portion of the inner and fore part of the limb. Some of these latter cases are occasionally very formidable, requiring great judgment and skill for their successful management. A good illustration of the traumatic form of aneurism of the brachial artery is afforded in fig. 269.

An arterio-venous aneurism at the bend of the arm may sometimes be cured by systematic compression of the brachial artery, at a distance of five or six inches from the seat of the disease; but in general the most expeditious plan is to lay open the sac, turn out its contents, and tie the artery above and below, the inferior ligature being necessary to prevent hemorrhage from the recurrent branches.

Wound of the brachial artery, without communication with a vein, should be treated, if the case can be reached soon after its occurrence, by compression; but if there be extensive extravasation of blood, constituting what is usually, but improperly, called a diffuse aneurism, the vessel must be exposed at the site of injury, and ligated at its cardiac and distal extremities.

Aneurisms and wounds of the ulnar and radial arteries must be managed upon the same general principles as those of the brachial artery. Compression can rarely be rendered available, except at the wrist, and even here it will usually

be found to be unsatisfactory, on account of the difficulty of maintaining it in a firm and steady manner. Hence, the proper way is always to ligate the affected vessel at once, not waiting until the parts have become obscured by the extravasated blood. As both arteries are very deep-seated in the upper and middle portions of their extent, rendering it very difficult to expose them, it has been proposed, when they are wounded in these situations, to ligate the brachial; but the objection to this procedure is that, while the cardiac extremity of the affected vessel will thus be closed, the distal one will remain patent, and thus admit of a continuance of the hemorrhage by the recurrent circulation.

An interesting case of aneurism of the lower part of the radial artery, caused by a rupture of this vessel in an effort which the patient made to raise himself in bed upon his hands, has been recorded by Sir Astley Cooper. It was promptly cured by the application of two ligatures.

Wounds of the arteries of the hand, especially of the palmar arch, are best managed by free incisions and the application of two ligatures. It is great folly, under such circumstances, nay, it is positively worse than folly, to tamper with the comfort and welfare of the patient by the use of compression, either direct or indirect, if the vessel is of any considerable size. Only precious time is wasted; the bleeding will return whenever the mechanical support is taken off, and in this way the patient may lose quarts of blood before the hemorrhage is

Fig. 269.

Traumatic aneurism of the brachial artery.

inally arrested. The ligation of the radial and ulnar arteries will be equally unavailing, for blood will still be sent to the wound by the interosseous branch, and, even if this also were secured, still the probability is that the bleeding would go on, especially if some time had elapsed since the occurrence of the accident, owing to the communication of the anastomosing vessels. We now and then read of cases in which the brachial artery has been tied for the arrest of hemorrhage of the palmar arch. Can there be anything more absurd than such a procedure, or one that shows a greater degree of ignorance of the anatomy of the hand? The advice of John Bell, in his *Principles of Surgery*, in regard to the treatment of wounded arteries in general, cannot be too strongly enforced here: "Meet the danger boldly, and don't be afraid to look your enemy in the face."

A curious case of aneurism under the ball of the right thumb has been related by Mr. Pilcher, as having occurred in a goldsmith from the repeated though slight blows inflicted with his hammer in the exercise of his trade. The disease speedily disappeared after ligation of the radial and ulnar arteries at the wrist.

ANEURISM OF THE ABDOMINAL AORTA.

Aneurism of the ventral aorta is much more frequent in men than in women, and is met with chiefly between the ages of thirty and fifty. The disease, which is much less common than aneurism of the thoracic aorta, generally begins near the celiac axis, in the form of a sac-like expansion, connected with the antero-lateral aspect of the vessel, and communicating with it by a rounded opening, from the size of a quill to that of a finger. The volume of the tumor is variable; in some cases it may not exceed an orange, while in others it may equal an adult's head. Its contents, at first fluid, soon become solidified, and arrange themselves in the form of concentric lamellæ, the number and firmness of which are often very remarkable. The sac usually inclines a little to one side, generally the left, as there is less resistance in that direction than in the other; and, as it increases, it seriously encroaches upon the abdominal viscera, and even upon the diaphragm, especially when it is of large bulk or situated high up. The immediate cause of the disease is commonly the fatty, fibrous, or calcified degeneration of the artery.

The *symptoms* of aneurism of the ventral aorta resemble, in general terms, those of aneurism of the thoracic. The pulsation, however, is usually more distinct, while the functional distress is less, owing to the more yielding character of the abdominal viscera, and to the fact that they are not so important to life. The tumor, which is immovably fixed, is dull on percussion, especially in the flaccid condition of the bowels, and gradually increases in size and solidity with its age. The pain, at first slight, often becomes very severe, and usually darts about in different directions. It is generally most violent in the course of the solar, celiac, and hypogastric plexuses, and occasionally assumes a decidedly neuralgic character. When the vertebræ are eroded, the pain is of a boring nature, more fixed, and attended with a greater amount of sympathetic disturbance. Dyspeptic symptoms are frequently present; and respiratory embarrassment invariably exists whenever the aneurism seriously encroaches upon the diaphragm.

The aorta is sometimes the seat of *varicose aneurism*, caused by a communication with the vena cava from ulceration. The occurrence is uncommon. The tumor is of variable size and shape, compressible, especially in its earlier stages, and readily detectable by the finger. The pulsation is generally less distinct than in ordinary aneurism, and there is occasionally a loud whizzing noise heard both by the patient and the bystanders.

The *diagnosis* of ventral aneurism is sometimes very difficult. The most reliable considerations are derived from the history of the case, the sudden invasion of the attack, the existence of a pulsating and gradually enlarging tumor, with a distinct bellows' sound heard over the inferior dorsal, or the upper lumbar vertebræ, and the great pain which is experienced in the situation of the disease.

The affections with which the malady is most liable to be confounded are: aneurism of the ventral aorta, whether arising from an inflammation of its coats; hydatids of the liver; enlargement of the spleen; carcinomatous and other tumors of the omentum, stomach, colon, and intestines; indurated feces; and abscesses of the meninges. In order to render the examination perfectly satisfactory

Fig. 270.

Aneurism of the aorta, inducing caries of the vertebrae, and fatal compression of the spinal cord.

be well emptied as a rule, the patient should be placed in a horizontal position, and the tumor raised somewhat high. In this way the tumor will be more conspicuous, but the examination will be into it with greater facility, and will produce more active pulsation.

The prognosis is extremely unfavorable. The disease almost invariably ends in death occurring either from rupture of the aneurism, or from rupture of the peritoneum, behind the intestine, bladder, chest, or vena cava. The period of the event takes place varies from a few months to several years. In the annexed cut, fig. 1, the aneurism was taken, and the patient died of fatal compression.

The treatment is mainly symptomatic, the chief dependence being on mild laxatives, and anodynes, in union with veratrum viride. If the patient is plethoric, blood may occasionally be taken from the arm, to relieve the circulation and to subdue pain.

ANEURISM OF THE HEPATIC, GASTRO-EPIPLOIC, AND MESENTERIC ARTERIES.

Aneurism of these vessels has been observed in a few rare cases. The subject is of interest chiefly in a diagnostic point of view. Aneurism of the left gastro-epiploic artery, recorded by Dr. Allen, died from the rupture of the sac, from inordinate exertion in dancing. A young woman, in the fifth month of her pregnancy, and the aneurism was filled with blood, partly fluid, partly coagulated.

In aneurism of the gastro-epiploic artery, as well as of the hepatic, the tumor is always movable, changing with the patient's position, and is described, more or less globular, and accompanied by pulsation from side to side. In aneurism of the hepatic artery, on the contrary, it is fixed. In an interesting case of this kind, recorded by Dr. Keegan, the aneurism was bound down by the capsule of Glisson, and lay in close contact with the biliary ducts, which were remarkably dilated throughout the liver.

Besides the pulsation which is always present in aneurism of these vessels, the pressure of the tumor upon the liver and gall-bladder not infrequently produces jaundice, while its pressure upon the pancreas occasions indigestion, as indicated by the pain, flatulence, acid eructations, and some time after taking food. In a number of the recorded cases, hematemesis existed.

ANEURISM OF THE COMMON ILIAC ARTERY.

The history of aneurism of this vessel remains to be developed. It requires, in fact, of a careful analysis of the various recorded cases of

true light. That the disease is extremely uncommon in its occurrence is a circumstance which has long been familiar to surgeons. The table of Mr. Crisp supplies only two cases of aneurism of this artery in 551 cases of the lesion as it shows itself in different portions of the arterial system. Both occurred in males. In one, the tumor was seated on the right side; the patient was a sailor, exposed to hard labor in whale-fishing; the aorta was tied by Dr. Murray, of the Cape of Good Hope, but the man died twenty-three hours after the operation. In the other case, the aneurism, also seated on the right side, was of a fusiform shape, and communicated with the common iliac vein. No operation was performed.

The following table exhibits the results of five cases in which the abdominal aorta has been tied for aneurism of the common iliac.

No.	Operator.	Date.	Sex.	Age.	Result.	REMARKS.
1	Cooper	1817	m.	38	Died in 40 hours	The operation was performed for aneurism of the left iliac artery. The tumor was of enormous size, and extended four inches above and four inches below Poupart's ligament; the thread was applied three-quarters of an inch above the bifurcation of the aorta. The sac contained an immense quantity of clotted blood.
2	James	1829	m.	44	Died in 3½ hours	There was an external iliac aneurism, for which the femoral was ligated. Increasing in size, 33 days afterwards the aorta was tied. The ligature was applied eleven lines above the bifurcation of the vessel, and five below the mesenteric artery.
3	Murray	1834	m.	33	Died in 23 hours	There was an extensive aneurism of the right external iliac, the tumor reaching as high as the umbilicus, and more than half way across the lower part of the abdomen. Mortification of the limb was rapidly approaching when the operation was performed. The aorta was tied about four lines above its bifurcation.
4	Monteiro	1842	m.	31	Died in 10 days	A large tumor occupied the lower part of the abdomen and upper part of the thigh. It was a spurious aneurism of the femoral artery, caused by the bursting of that vessel. The patient died, at the expiration of ten days, of secondary hemorrhage, from a small opening in the vessel corresponding with the knot of the ligature, which had been applied four lines above the point of bifurcation.
5	South	1856	m.	28	Died in 43 hours	The aneurism occupied the external and common iliac, and was of immense size. The ligature was applied a little above the bifurcation of the aorta.

It will be perceived from the above table that the five cases in which the abdominal aorta has been tied, all terminated fatally; a result which might assuredly have been foreseen by the distinguished surgeons who performed the operation. Questionable as the propriety of such an operation is, I should, I confess, be strongly tempted to perform it if my patient were placed in circumstances precluding all hope of relief from any other source. That this was the feeling which prompted Sir Astley Cooper, in 1817, to undertake it, and which has since induced others to imitate his example, is more than probable, and our only regret is that their efforts were not crowned with success. What the effect might have been if the cases had been of a more favorable nature prior to surgical interference is, of course, merely a matter of conjecture, but it is perfectly evident, from their history, that they were all in as desperate a condition as they could well have been at the time. The tumor, in every instance, was of enormous volume, almost, in fact, ready to burst; in Mr. Murray's patient there was, besides, incipient gangrene of the lower extremity. In the case of Mr. James, an error of diagnosis had been committed, which led, improperly, as was afterwards proved, to ligation of the femoral artery, thereby causing the patient not only much suffering but the loss of much valuable time, upwards of four weeks having elapsed between the two operations.

In performing the operation, the peritoneum was divided in two of the cases, and left intact in three; in one instance, it was opened to the extent of nearly

four inches. Such a procedure would probably of itself have been a cause of death, had the patient survived the immediate effects of the deligation of the vessel.

The case of Dr. Monteiro, the most successful of all, is replete with interest, as it establishes the fact that the circulation may go on in the lower extremities, after the flow of blood in the abdominal aorta has been completely arrested by the ligature. The patient survived the deligation ten days, when he died of secondary hemorrhage, caused by a small aperture in the side of the vessel corresponding with the knot in the thread. The dissection showed that the peritoneum, which had not been cut in the operation, was perfectly free from inflammation. The aorta had been ligated four lines above its bifurcation, and an inch below the inferior mesenteric artery. The aneurism, which was a false one, had originated in a rupture of the superior extremity of the femoral artery, from which the blood had made its way upwards, underneath Poupart's ligament, through the intermuscular cellular tissue, into the iliac fossa, and thence on behind the peritoneum along the posterior part of the abdomen, as high up as the diaphragm and liver. The common and external iliac arteries were involved in the tumor, and were in an inflamed and friable condition. The external wound had nearly healed.

It is worthy of remark that the pulsation in the tumor ceased immediately on tying the ligature, but returned slightly on the third day, and became more marked on the fourth. Hemorrhage supervened the day before death. The operation was followed by coldness of the lower extremities, but in four hours afterwards this had passed off, and the temperature was now a little above the natural point. No paralysis of the limbs was at any time present.

ANEURISM OF THE INTERNAL ILIAC.

Aneurism of the internal iliac, gluteal, and sciatic arteries is very uncommon, and its history has not been studied with sufficient care to enable us to present anything like a satisfactory account of it. Owing to the deep situation of the former of these vessels, the diagnosis of aneurism occupying its course would necessarily be attended with considerable difficulty, and should not be declared without a good deal of reserve and circumspection. Aneurism of the sciatic and gluteal arteries is more frequently traumatic than spontaneous. In fat, muscular subjects the disease is generally difficult of recognition, and hence it is not surprising that solid growths have sometimes been mistaken for it. Mr. Guthrie once tied the internal iliac artery for a tumor which he had taken to be aneurismal, but which, after death, was found to be of an encephaloid character, the deception having been caused by the circumstance of the tumor having received a distinct impulse from the artery. I have not met with aneurism of the pudic artery, and am not aware that the disease has ever been observed in this country. Mr. Erichsen states that the only instance of the kind with which he is acquainted is exhibited in a preparation in the Museum of the College of Surgeons at London.

Aneurism of the gluteal and sciatic arteries may be treated by ligating the internal iliac, or exposing the sac by a free incision, turning out its contents, and tying the vessel above and below. Such a proceeding would, unquestionably, be very bloody, but far less hazardous in the end than deligation of the internal iliac.

The *gluteal* artery has been tied at least twice in this country for the cure of aneurism; once by Dr. Davidge, of Baltimore, and once by Dr. George McClellan. The tumors being of great bulk, the incisions were obliged to be unusually large, and the loss of blood was very profuse. Notwithstanding this, however, both patients made an excellent recovery.

ANEURISM OF THE EXTERNAL ILIAC.

Aneurism of the external iliac is a rare affection. In the table of Mr. Crisp, the most elaborate hitherto furnished, it occurs only 9 times in 551 cases, while

the femoral is mentioned 66 times, and the popliteal 137 times. In 364 specimens of aneurism contained in the London museums, the same writer found the external iliac affected in 7 cases, the femoral in 12, and the popliteal in 50. The nine cases analyzed by Mr. Crisp all occurred in males: two, between twenty and thirty; four, between thirty and forty; one, at forty, and one at fifty-six, the age of the other not being given. The disease is most common in hard working persons. One of the worst cases of it that I have ever seen occurred in a priest.

The tumor in this disease may be seated in any part of the artery, but in general it will be found rather low down, and, as it progresses, it manifests a tendency to pass underneath Poupart's ligament into the upper part of the thigh. It usually rapidly augments in size, and is capable of attaining a large bulk, encroaching upon the iliac fossa and the pelvic cavity, lifting up the peritoneum, and pressing forward the structures in the inguino-femoral region, so as to give rise to great deformity in this situation. The pulsation, thrill, and bellows' sound are usually very distinct. If the patient is very thin, compression of the abdominal aorta will arrest the movements of the tumor, and diminish its volume, thus serving to distinguish it from other affections. The diagnosis is, nevertheless, not always so easy as might at first appear. Several cases have been reported where the common iliac artery was ligated on account of morbid growths, supposed to be aneurismal, which afterwards proved to be of a malignant character. On the other hand, a tumor really aneurismal has occasionally been confounded with one altogether of a different character. Such a mistake is most likely to happen when the aneurism is partially solidified by the coagulation of its contents, thereby preventing the perception of pulsation. It is only necessary to allude to the possibility of such an occurrence in order to put the practitioner upon his guard in the investigation of his cases.

When an aneurism of the external iliac artery has attained a considerable bulk, the patient walks with extreme difficulty, and is unable to flex the thigh upon the pelvis. The whole limb is enlarged and œdematous from the obstruction to the return of the venous blood, while the pressure of the tumor upon the femoral nerves keeps up constant pain, with a sense of numbness and stiffness in the parts below, generally extending as far down as the foot and toes.

Aneurism of the external iliac artery, left to itself, proves fatal in one of three ways, by rupture and hemorrhage, gangrene of the sac or limb, or constitutional irritation. Occasionally a spontaneous cure occurs.

The only remedy hitherto employed in the *treatment* of this disease was deligation of the artery leading to the tumor; the external iliac, when the aneurism was situated low down, so as to leave a sufficiency of the superior portion of the vessel intact, and therefore in a suitable condition for the reception of the ligature; or, when the reverse was the case, the common iliac, one of the most formidable operations in surgery. I believe, however, that it will be found that the tumor may generally be promptly obliterated, especially in its earlier stages, by compression of the iliac as it passes over the brim of the pelvis; and, although I am not aware that this practice has ever been adopted, I am the more inclined to regard it as feasible, from the fact that the external iliac does not give off any branches, in any portion of its course, so as to offer any barrier to the process of solidification of the contents of the sac. The epigastric and circumflex iliac arise just above Poupart's ligament, and could not, therefore, in anywise interfere with the cure. If a case of aneurism of the external iliac should be presented to me, I should certainly give this mode of treatment a fair trial, with a sanguine feeling of success. Digital compression would of course be preferable to any other, on account of the greater facility of its application.

The result of the ligation of the artery leading to and feeding the tumor, has, on the whole, been rather encouraging. In the nine cases mentioned in Mr. Crisp's table, the common iliac was tied in two, one recovering and the other perishing of hemorrhage on the eighth day. In four cases the external iliac was ligated, and all got well. In one instance both the femoral artery and the ab-

dominal aorta were tied, but the man died a few hours after. One case was cured spontaneously, and another recovered.

Within the last few years the treatment of inguinal aneurism by compression has been tried. Of four cases thus managed, only one, by Nichols, of New Orleans—was cured. The thumb was pressed against the sac for thirty hours, by which time the pulsation had ceased. As a matter of precaution, it was continued for ten hours longer.

ANEURISM OF THE FEMORAL ARTERY.

Aneurism of the femoral artery is very common, although not so common as the popliteal. In Mr. Crisp's cases, 551 in number, 66 were of the femoral artery, of which 61 occurred in males, thus showing that the disease is more common in men than in women. The period of life at which it is most frequently met is from thirty to fifty. As in the other arteries, aneurism of the femoral artery is common in the laboring classes, particularly in those persons who are subjected to severe muscular exertion of the lower extremities, causing a rupture of the vessel. Instances have been observed in which each extremity was simultaneously affected with aneurism, and it occasionally happens that a single vessel has two such tumors connected with it.

The femoral artery is not equally subject to aneurism in all its parts. The superior third suffers more frequently than the rest of the artery. The inferior third is much less often the seat of aneurism than the superior third. Sailors are said to be particularly liable to aneurism of the femoral artery in this situation, owing, as Mr. Crisp supposes, to the violent flexion of the thigh which they are obliged to make in mounting the rigging and other labors on ship-board. I have never seen an instance of aneurism of the femoral artery in the lower third of the thigh, and general experience confirms the fact that such an occurrence is extremely uncommon. In some of the cases of aneurism of the femoral artery, the disease is described as having been femoro-popliteal, a term used to convey the idea that the lesion involved both the terminal portion of the femoral artery and the incipient portion of the popliteal.

Diagnosis.—The diagnosis of femoral aneurism, although sometimes involved in so much obscurity as to cause not a little difficulty, is more especially the case when the tumor is seated along the middle third of the thigh, where the artery is tightly bound down by the surrounding aponeuroses. Abscesses and various morbid growths, solid, cystic, and malignant and non-malignant, are the affections with which aneurism is to be confounded; and it behooves the surgeon, in every case, to exercise the most careful and thorough examination before he decides upon the treatment, in regard to its character, or permits himself to engage in any treatment without due consideration for its relief. The best diagnostic, unquestionably, is the compression of the femoral artery by the thumb upon the tumor, when the tumor is situated below Poupart's ligament, or of the ilio-femoral, when the tumor is situated above the superior part of the thigh. If the tumor is aneurismal, the thumb will arrest its pulsation, thrill, and bellows' sound, but, while the thumb is pressed against the tumor, it will enable the surgeon to squeeze out its contents, and thus to determine its volume, circumstances which cannot possibly occur when the tumor is of non-aneurismal character, whatever may be its structure or position. The exploring needle is only to be used in cases not admitting of the method here suggested, and then it should be so fine as to pierce the skin without exciting rhage or excite inflammation.

The femoral artery, in the upper portion of its extent, is covered forward by a *synovial bursa*, situated behind the psoas muscle and Poupart's ligament, especially when the pouch is inflamed and the tumor is large, in which case it will probably receive an impulse from the vessel, and the swelling to simulate aneurism. The proper way to detect aneurism is to flex the thigh upon the pelvis, a procedure which, by tal-

of the muscles, puts a stop to the pulsation of the tumor, and thus reveals the true nature of the disease.

A number of *lymphatic ganglions* lie in the upper part of the thigh, immediately upon and around the femoral artery. Enlargement of these glands has been mistaken for aneurism, and, conversely, aneurism for enlargement of the glands; but the history of the case and a careful examination of the parts will generally promptly clear up the diagnosis.

Psoas abscess occasionally points below Poupart's ligament, and might be mistaken, by a careless observer, for aneurism of this vessel, or of the external iliac. The best diagnostic signs are the want of pulsation, the soft and fluctuating character of the swelling, the absence of discoloration of the skin, and our ability to efface the swelling almost entirely, when the patient lies on his back with the thigh and pelvis a good deal elevated. Moreover, if there is pus, a drop will be sure to follow the withdrawal of the exploring needle.

Progress.—The course of the aneurism is variable. When it is situated high up, it is liable, in its progress, to extend upwards, and to project at length beneath Poupart's ligament into the pelvic cavity. When, on the other hand, it involves the inferior portion of the artery, it may pass down into the ham, and so simulate popliteal aneurism. The swelling usually increases rather rapidly, and, in time, often spreads over a large space, diffusing itself, in fact, widely, in consequence of the giving way of the two inner tunics of the artery. When this is the case, the limb below the seat of the tumor becomes greatly enlarged and œdematous, from obstruction to the return of the venous blood, and the patient constantly complains of stiffness, pain, and numbness in it, extending generally as low down as the feet and toes. In the more advanced stages of the disease, progression becomes difficult and finally impracticable, the whole limb feeling like a dead, heavy mass. A spontaneous cure occasionally occurs, as in a case from which the adjoining cut, fig. 271, was taken; but most commonly the disease goes on from bad to worse, until life is destroyed by gangrene, excessive suppuration, hemorrhage, or constitutional irritation.

Treatment.—The treatment of aneurism of the femoral artery may, I think, generally be successfully conducted by compression, especially now that our means of applying and regulating it are so much better understood than formerly. The compression may be made either with the finger or by means of one of the numerous mechanical contrivances now before the profession. In the case of a negress, aged thirty-two, who was under the joint care of my son and myself, in 1859, on account of a large aneurism of the upper third of the femoral artery, the assistants succeeded in effecting complete solidification of the contents of the sac in forty-six hours, by digital compression alone. The tumor progressed most favorably, and in less than three weeks after the operation, the woman was able to walk about the house. In this case, referred to in a previous section, there was not more than an inch of space between the aneurismal sac and Poupart's ligament, in consequence of which the compression was obliged to be applied to the iliac artery as it passed over the brim of the pelvis. Several instances of an equally gratifying termination have followed this treatment in the hands of other surgeons.

When compression is inapplicable, the only resource of course is deligation of the artery which supplies the tumor with blood. The operation is easily

Fig. 271.

Spontaneous cure of an aneurism of the femoral artery by the sac being filled with coagulum, the vessel remaining pervious.

done at Scarpa's triangle when the aneurism occupies the middle or lower third of the femoral artery, or even when it extends up to the inferior portion of this space, provided the coats of the vessel are sufficiently sound to bear the pressure of the ligature. When this is not the case, or when the tumor is situated high up, near Poupart's ligament, or projects beneath it partly into the pelvic cavity, the proper remedy will be ligation of the external iliac, an operation which, although not devoid of risk, has now been performed so often and so successfully as to be justly ranked among the established resources of surgery.

Mortality.—In Mr. Crisp's 66 cases, above referred to, the external iliac alone was tied in 43, and in two others both this artery and the femoral; 36 of the patients recovering, and 10 dying. Of the latter, three perished from hemorrhage, four from gangrene of the sac or limb, one from tetanus, one from exhaustion, and one without any apparent cause. In 12 of the cases the femoral artery alone was tied, with a result of 9 cures to 3 deaths. Amputation was successfully employed in five cases; in two, the tumor was obliterated by compression, and in one the disease spontaneously disappeared.

In the table of Dr. Norris, comprising 118 cases of ligation of the external iliac artery, of which, however, 97 only relate to aneurism, 85 recovered, and 33 died, three of the former having undergone amputation of the limb in consequence of gangrene. In 4 of the 97 cases of aneurism, the disease existed simultaneously both in the thigh and in the ham, and in 3 of these the operation succeeded in curing both tumors. A return of pulsation in the sac took place in 9 cases, and hemorrhage in 14, of which 7 proved fatal, and 7 recovered. In 10 cases the tumor suppurated after the operation, although they all ultimately did well. Gangrene of the limb occurred in 16 cases out of the 118, of which 12 died. In two instances the peritoneum was wounded, but both patients recovered.

Finally, a number of cases of femoral aneurism have been recorded in which a cure was effected simply by refrigerant applications to the tumor, aided by steady compression with the bandage, strict recumbency, and an abstemious regimen. This treatment has occasionally succeeded both in the spontaneous and traumatic form of the disease.

Varicose aneurism of the femoral artery and vein is occasionally observed. The accident is commonly produced by external injury, as a gunshot, knife, or sabre wound, but it may also be caused by ulceration, and Baroni has related a case in which it followed upon a contusion of the thigh. The treatment should, as a general rule, be entirely of a hygienic character, experience having proved that operative interference is usually followed by fatal results. In some of the recorded cases of this affection, the patients lived for many years—in one as many as twenty—in comparative comfort.

A very interesting case of *aneurismal varix* of these vessels was kindly brought to my clinic at the Jefferson Medical College last winter by Dr. W. B. Atkinson. The man had been wounded a year previously by a musket ball. He experienced no inconvenience whatever from the disease.

ANEURISM OF THE POPLITEAL ARTERY.

The extraordinary frequency of aneurism of the popliteal artery has long been familiar to pathologists and surgeons. With the exception of the thoracic portion of the aorta, there is no artery in the body which is so often the subject of this disease. The table of Mr. Crisp, already so frequently referred to, comprises an analysis of 551 cases of spontaneous aneurism, of which 137 occurred in the vessel under consideration, the thoracic aorta suffering 175 times. Three circumstances seem to serve to establish this extraordinary liability to aneurism on the part of this artery; one is its extreme proneness to ossific and fatty degeneration, another, the curve which it forms behind the knee, and the third, the frequent, sudden, and forcible extension to which it is so constantly exposed in the various movements of the lower extremity.

Age and Sex.—Popliteal aneurism occasionally occurs at a comparatively

early age, a number of cases having been observed in which it took place before the twenty-fifth year. Mr. Syme has related one in a child of seven years. The great majority of instances, however, are met with between thirty and fifty. Both sides seem to suffer nearly in an equal degree, and both are occasionally affected simultaneously, or successively, as I have myself witnessed in several individuals. The disease is almost peculiar to men. In Mr. Crisp's cases, 137 in number, 133 occurred in males, and only 4 in females. No occupation is exempt from aneurism of the popliteal artery, but the statistics which have been published upon the subject conclusively show that the laboring classes, especially soldiers, sailors, bargemen, and porters, who are in the constant habit of making long-continued and violent exertions of the muscles of the lower extremities, are more obnoxious to it than any other. The idea, first broached by Morgagni, that postilions and coachmen are particularly prone to popliteal aneurism, has been proved to be erroneous.

Diagnosis.—Aneurism of the popliteal artery is probably produced in most cases by a sudden and violent sprain or twist of this vessel while its coats are in a state of osseous degeneration, and consequently deprived of their elasticity, by which they are prevented from following the various movements of the leg with their accustomed freedom, a sudden rupture being thus induced, of which the patient is himself often made conscious, either by his feeling, or by a kind of snapping noise. The tumor, being at first quite small, generally escapes attention until it has acquired a considerable bulk, as, from the great depth at which the artery is situated, and the unyielding nature of the parts in the ham, it takes some time for it to reach the level of the surrounding surface, or to exhibit to the eye the characters of a distinct swelling. A careful examination, however, will always enable us, even at an early period, to arrive at a satisfactory conclusion respecting the nature of the case, except, perhaps, in very fat subjects. The tumor will be found to throb synchronously with the artery in the groin, and, by grasping it firmly between the thumb and finger, it may readily be pushed about in the hollow between the tendons of the flexor muscles, feeling like an elastic, circumscribed knob, which is easily diminished by pressure, but immediately regains its former size when the pressure is removed. As the disease progresses, the sac increases in volume, and encroaches more and more upon the popliteal space, pushing aside the soft parts, compressing the popliteal vein and nerve, and interfering seriously with the movements of the limb. The leg is habitually bent at an obtuse angle with the thigh, and all efforts to straighten it prove abortive; it is the seat of constant aching pains, with a sense of numbness or tingling; its temperature is notably diminished, and its subcutaneous cellular tissue, owing to the obstruction to the return of the venous blood, is loaded with serum, or serum and lymph, giving the surface a glossy, shining appearance, and causing it to pit under pressure. The ear and the hand readily detect the characteristic thrill and bellows' sound.

Aneurism of the popliteal region is liable to be confounded with other tumors, and we read of cases in which the sac was laid open under the impression that the disease was not arterial. The lesions for which it is most apt to be mistaken are abscesses, solid and fatty growths, and synovial bursae.

Abscess of the ham is of very uncommon occurrence, and is in general easily distinguished by the history of the case, its inflammatory character, by the absence of pulsation, by the presence of fluctuation, especially when the matter is considerable in quantity, and by our inability to produce any change in the volume of the swelling by compression of the femoral artery high up in the thigh. When any doubt exists, a small exploring-needle, carefully inserted into the tumor, will readily determine the diagnosis.

Solid growths, of various kinds, benign and malignant, are liable to form in the popliteal region, and might be mistaken for aneurism, especially by a careless and inexperienced surgeon. The fact that such tumors are usually stealthy in their origin, tardy in their development, firm in their consistence, and free from pulsation, will always readily distinguish them from aneurism of the popliteal artery.

A *synovial burse* is occasionally developed in this space, but the occurrence is rare, and it would be difficult to imagine how such a growth as this should ever be confounded with an aneurism in this region. In the *Louisville Medical Review*, a case of this affection is reported by Dr. S. W. Gross, in which the largest tumor of this description that I have ever seen, occurring in a man, aged twenty-nine years, was readily diagnosticated by the exploring-needle, although its history—especially the absence of pain and pulsation, its non-interference with the patient's occupation, and the preservation of the natural appearance of the leg below the knee—had been sufficiently denotive of its true nature without any expedient of this kind.

Progress.—Aneurism of the popliteal artery may remain circumscribed for a considerable length of time; in general, however, it soon becomes diffused, and by its pressure upon the surrounding structures causes not only great pain and swelling in the leg below the knee, but a tendency to mortification by cutting off the nervous and vascular supplies. Such a termination, in fact, is almost inevitable if the case is permitted to proceed unchecked. Sometimes a spontaneous cure occurs, probably in consequence of the pressure of the tumor upon the artery, thereby arresting the circulation in the sac. Professor Pancoast, some years ago, had a case of popliteal aneurism upon which he had intended to operate the next day; but when he got to his patient's room, he found that all pulsation in the tumor had ceased, and the man gradually recovered without any farther trouble. Occasionally the tumor opens into the knee-joint.

Treatment.—The treatment of popliteal aneurism was, until recently, usually conducted by deligation of the femoral artery in the superior third of the thigh, according to the method of Hunter, first practised in 1785. Since 1840 numerous instances have been cured by compression, and so gratifying has been the result of this procedure that the old operation is likely, before long, to become almost obsolete. In a case communicated to me by Professor Blackman, of Cincinnati, he succeeded in arresting completely the pulsation in a popliteal aneurism by digital compression for two hours, after the failure of various other methods. On the other hand, in a case of my own, digital compression was maintained incessantly for four days and a half without any benefit whatever. A cure was afterwards readily effected by ligation of the femoral artery.

Forced flexion, described at p. 696, is particularly applicable to aneurism of the ham, and always deserves a fair trial provided the tumor is not so large as to encroach seriously upon the structures of the joint or to threaten to burst into its interior. In a case which I treated in this way, in 1861, at the Clinic of the Jefferson Medical College, in a man, aged thirty-five, all pulsation in the aneurism ceased in less than twenty-four hours. The disease had come on three months previously, in consequence of a severe strain. The tumor was of an elongated, ovoidal shape, large, circumscribed, and characterized by the ordinary phenomena. A complete cure followed.

Mortality.—The mortality from the operation for popliteal aneurism by the Hunterian method would seem to be variable. In the table of Dr. Norris, comprising a list of 188 cases of aneurism, for which the femoral artery was tied, 142 were cured, and 46 died. It is proper, however, to add that the ligation in 33 of the cases was performed for other purposes than aneurism of the popliteal artery. The table of Mr. Crisp furnishes 110 cases, operated upon according to the Hunterian method, of which 91 recovered completely, 7 required amputation after the use of the ligature, and 12 died. Of the 11 cases of double popliteal aneurism comprised in it, all were cured; 10 by ligature, and one by compression. The greatest cause of the mortality after the ligation of the femoral artery is gangrene of the leg.

Varicose aneurism of the ham is uncommon. Cases of it have been recorded by Larrey, Hodgson, Porter, and other observers, generally as a result of injury, as a puncture or gunshot wound, but now and then as a spontaneous occurrence. The tumor may acquire a large bulk, and be accompanied by excessive dilatation of the popliteal vein. The treatment should be altogether hygienic, except when

the disease is productive of great pain and inconvenience, when the sac should be laid open, and the artery tied above and below.

Traumatic aneurism, properly so called, may occur in this region from a sabre wound, a musket ball, or the sharp end of a piece of bone, as in fracture of the femur or tibia. The blood is generally widely diffused, and the diagnosis is often greatly obscured by the attendant swelling. If the symptoms are urgent, the artery should be exposed and ligated at each extremity; otherwise the case should be treated upon general principles in the hope of gradual ulterior accommodation of the tumor, if not a spontaneous cure.

ANEURISM OF THE ARTERIES OF THE LEG AND FOOT.

Spontaneous aneurism of the arteries of the leg is almost unknown. The traumatic form of the disease, however, is occasionally met with, and there are few cases in surgery more difficult to manage, especially when the lesion involves the posterior tibial artery, owing to the great depth at which this vessel is situated, and the confused condition of the parts in consequence of the extravasated blood. The proper remedy, of course, is free exposure of the affected vessel, removal of the coagula, and ligation of both ends. To accomplish this to the best advantage, often involves great coolness on the part of the operator, and an unusual amount of anatomical knowledge and dexterity. During the operation, the iliac artery should be compressed at the brim of the pelvis, or a tourniquet be applied round the upper part of the thigh. Without such precaution, the hemorrhage might be frightfully profuse.

The annexed cut, fig. 272, affords a good illustration of an aneurism of the posterior tibial artery, undergoing spontaneous cure, the sac being filled with concentric coagula. The tibial nerve is spread over the back part of the pouch.

Wounds of the arteries of the foot are often followed by troublesome hemorrhage, which may eventually lead to great, if not fatal, exhaustion. The cause of this is twofold, the deep situation of the plantar arteries, and their extensive and intricate anastomoses with each other. The general arrangement bears a very strong resemblance to that of the palmar arteries. It might be supposed, at first sight, that, when these vessels are wounded, the bleeding could readily be arrested by regular, steady, and systematic compression. This, however, is not the case. Why, then, not ligate them at once, without waiting until the patient is blanched and worn out by the loss of blood, in the vain hope that the operation may at length put a stop to it? That this is the proper course is unquestionable; hence the sooner it is carried into effect the better. The only objection to it is the large wound that is obliged to be made in order to expose the bleeding vessel; but this must be done at all hazard, and a ligature applied to each extremity, lest the hemorrhage should continue through the recurrent circulation.

It has been proposed in these cases to cut down upon and tie the principal arteries of the leg, and we read of instances in which even the great trunk of the thigh was ligated for such a purpose. Such a procedure cannot be too strongly condemned, as being contrary both to common sense, anatomical knowledge, and sound experience. The experiment of tying both the tibial arteries has been tried again and again under such circumstances, and the almost invariable effect has been complete failure; as might, indeed, have been anticipated from a careful study of the disposition of the arteries of the foot.

Notwithstanding the somewhat pointed manner in which I have here spoken against compression in hemorrhage of the plantar arteries, it is but proper to add

Fig. 272.

Aneurism of the posterior tibial artery, with the nerve spread over the back part of the pouch, which is entirely obliterated by concentric coagula.

that I have seen this very method occasionally put a most prompt and effectual stop to the flow of blood. I recollect distinctly the case of a little girl, which came under my observation many years ago, where I succeeded, by a single dressing, in arresting an exhausting and daily recurring hemorrhage of upwards of a month's duration. A graduated compress placed over the orifice of the bleeding vessel, and confined by a roller extending from the toes upwards, aided by elevation of the leg and cold applications, constituted, as it always should when such a procedure is adopted, the means employed on the occasion.

Sometimes we may advantageously resort to the expedient of compressing the anterior and posterior tibial arteries by means of two corks, placed directly over the vessels, opposite the malleoli, and bound down firmly by a suitable bandage, passed round the foot and leg in the form of a figure 8. The corks should each be wrapped up in a bit of patent lint, and should be at least three-quarters of an inch in length, and of proportionate thickness and breadth, otherwise it will be difficult to make them retain their proper position. When the compression is obliged to be made with great firmness, it may be well, in order to defend the soft parts, to extend a piece of sheet-lead across the limb under the bandage.

SECT. VIII.—OPERATIONS ON THE ARTERIES.

LIGATION OF THE INNOMINATE OR BRACHIO-CEPHALIC.

Although the innominate may easily be exposed on the dead subject, as was shown by Dr. George McClellan as early as 1820, by a linear incision carried vertically down in front of the trachea, without dividing any of the cervical muscles, yet I believe that such a plan would be ill suited to the purpose when there is a large tumor pressing upon and displacing the parts which environ this vessel. The operator must have ample room, and it will not, I presume, materially affect the issue of the case whether a little more or a little less tissue is cut. The plan suggested by Dr. Mott, in his celebrated case, is, on the whole, it seems to me, the one best adapted for obtaining ready access to this artery, and is that which I should myself follow if I were called upon to secure the innominate for the cure of aneurism. The incision resembles, in outline, the shape of the letter L, the horizontal limb corresponding with the upper border of the clavicle and sternum, and the vertical with the inner margin of the sterno-cleido-mastoid muscle, each being about three inches in length. The lower incision extends as far inwards as the centre of the trachea. The triangular flap thus mapped off, embracing the skin and platysma-myoid, being dissected up, the sterno-cleido-mastoid, sterno-hyoid, and sterno-thyroid muscles are respectively separated upon a director from their inferior connections and turned out of the way. A layer of the deep cervical fascia is now cautiously pinched up and divided, when, by a little scratching with the finger-nail, the handle of the scalpel, or the end of a probe, the carotid will be brought into view a few lines above the top of the sternum, accompanied by the jugular vein and pneumogastric nerve. Taking this vessel as his guide, the surgeon can easily trace the course of the innominate downwards towards the heart, and isolate it from its associate vein. The ligature, when the case admits of it, should be applied about the middle of the vessel, the needle being carried round it from left to right and from behind forwards.

In performing this operation, it should be remembered that this artery is only about sixteen lines in length; that it rests upon the trachea, which it crosses somewhat obliquely at the base of the neck; that the middle thyroid veins, and sometimes the middle thyroid artery, run along its inner side; and that on the right side, and on a plane anterior to it, is the innominate vein, the two vessels being intimately united together by cellular substance, and in close relation behind with the pneumogastric and phrenic nerves, the latter lying external to the former. The top of the pleura is a little inferior and external to the artery, and might, unless great caution is used, be easily wounded. The middle thyroid artery is sometimes given off by the innominate on its tracheal aspect, and should

be looked for in isolating the vessel, as its division might be followed by annoying hemorrhage.

LIGATION OF THE COMMON CAROTID.

To Mr. Abernethy is usually, but erroneously, ascribed the merit of having first tied the common carotid. From some remarks of Hebenstreit, it appears pretty certain that the operation had been performed some time previously by a surgeon during the extirpation of a scirrhus tumor of the neck, in which he accidentally divided this vessel, and immediately surrounded it with a ligature, the patient soon recovering. The English surgeon did not ligate the artery until 1798; the case was one of wound of the internal carotid, and the man died in thirty hours. The first operation that was performed upon it for carotid aneurism was by Sir Astley Cooper, in 1805, and was unsuccessful, the case terminating fatally on the nineteenth day. Three years subsequently, he ligated the vessel again, and now with a happy result.

There are two points at which the common carotid may be tied, the place of election being regulated by the circumstances of the particular case. These are the upper and inferior cervical regions, and it will be well, in every instance before the operation is begun, to recall to mind the more important anatomical relations of the parts, otherwise serious blunders may arise, such, for example, as tying the omo-hyoid muscle or jugular vein instead of the artery, or including along with the artery the vessel just named, or some important nerve, as the pneumogastric, sympathetic, or laryngeal. As the artery proceeds upwards, it is overlapped by the sterno-mastoid, sterno-hyoid, and sterno-thyroid muscles, and crossed by the omo-hyoid towards its superior extremity. Running down in front of its sheath is the descending branch of the ninth pair of nerves, a little, thread-like filament, easily recognized by its whitish appearance, while within the sheath are, on the external side of the artery, the internal jugular vein, and behind and between them the pneumogastric nerve, the sympathetic and recurrent being posterior to the sheath. These relations are very intimate, and therefore the utmost caution is necessary in isolating the parts previously to the application of the ligature. The embarrassment is often immensely increased by the manner in which the artery is overlapped by the jugular vein, which occasionally, though less frequently than is generally supposed, swells out enormously during every effort at expiration, so as to obscure the vessel and render its ligation extremely difficult. The best way of remedying this is to request an assistant to compress the vein both at the upper and lower angle of the wound, the blood having previously been pressed out of it.

The common carotid, on the right side, is sometimes absent, its place being supplied by two trunks, which, arising separately from the arch of the aorta, ascend along the neck, assuming the office of the external and internal carotid. When this arrangement exists, which, however, is extremely rare, the order of origin of the branches of the aorta is as follows:—the right subclavian, right external carotid, right internal carotid, left common carotid, and left subclavian. It should also be borne in mind that the common carotid may, on the one hand, bifurcate very low down, not perhaps reaching as high up as the inferior border of the thyroid cartilage, and, on the other hand, it may not separate into its terminal divisions until it gets to the angle of the jaw. Lastly, it may be crossed in front by the inferior thyroid artery, lie upon the vertebral artery as this vessel passes along the spine, and include in its sheath the descending branch of the ninth pair of nerves.

In ligating the carotid, the patient should be recumbent, with the head inclined to the opposite side, and well supported by pillows, the shoulders being at the same time somewhat raised, in order to place the neck in a proper horizontal position. If he do not desire to take chloroform, he may sit on a chair, the head resting against the breast of an assistant.

In the lower part of the neck the artery may be exposed by making an incision, from two and a half to three inches in length, along the inner border of the sterno-

cleido-mastoid muscle, commencing just above the clavicle. The skin and platysma-myoid muscle being divided, a portion of the cervical fascia is pinched up with the forceps, and opened transversely to an extent large enough to admit a grooved director, upon which the membrane is then slit up and down nearly to the length of the outer incision. Two retractors are now inserted into the wound, one being used to draw the sterno-cleido-mastoid muscle outward, and the other to draw the sterno-thyroid inwards towards the trachea. The sheath of the artery being thus exposed, a little piece of it is now raised with the forceps, and divided horizontally, when, the director being introduced, it is slit open so as to denude the artery to a small extent, and enable the operator to isolate it from the jugular vein and the pneumogastric nerve, the ligature being passed from without inwards. Generally a small subcutaneous vein will be found passing along the line of incision, communicating above with the facial vein, and below with the thyroid plexus. This must, of course, be carefully avoided.

The artery being more easy of access in the superior part of the neck than the inferior, this point should always be selected, when this is in our power, for ligating it. To expose the vessel in this situation, an incision should be carried along the inner margin of the sterno-cleido-mastoid muscle, commencing a little below the cricoid cartilage, and reaching nearly as high up as the angle of the jaw. Embracing the integuments, platysma-myoid muscle, and cervical fascia, it

will thus conduct the operator at once down to the sheath of the vessel, which is then to be opened in the same cautious manner as in the previous case; and the artery being gently separated from the accompanying structures is ligated by passing the needle round it from without inwards, so as effectually to exclude the jugular vein. The omo-hyoid muscle which crosses this part of the carotid must be held aside with a hook.

The annexed cut, fig. 273, represents the common carotid as being exposed by a long incision, with a view of showing where it is crossed by the omo-hyoid muscle.

When access to the common carotid, in the inferior part of the neck, is rendered difficult on account of the low situation of the tumor, the best plan is to divide the sterno-hyoid and sterno-thy-

roid muscles, either alone, or jointly with the inner portion of the sterno-mastoid, so as to enlarge the space between the aneurism and the sternum. By observing this precaution, Mr. Porter, of Dublin, was enabled, in one case, to ligate the vessel successfully within the eighth of an inch of the innominate; and examples of a similar character have occurred in the practice of other surgeons.

The carotid is sometimes tied at a very early age. I recollect a case in which I assisted Dr. McClellan, where that excellent and brilliant operator secured this vessel in a child only five months old, on account of an immense nevus of the upper part of the face. I remember, also, that the descending branch of the ninth pair of nerves was divided on the occasion, as it interfered with the passage of the ligature. No untoward symptoms of any kind occurred; the tumor diminished somewhat after the operation, but in less than a month it was larger than ever.

Ligation of the common carotid is occasionally required on account of wounds

Fig. 273.

Ligation of the common carotid.

of the neck involving the external carotid or some of its branches. The operation is often embarrassing in consequence of the confused condition of the parts from the extravasation of blood, and is, moreover, not always successful, owing to the establishment of a return current through the internal carotid into the external carotid. Hence secondary hemorrhage, sometimes of a very profuse character, is liable to ensue, necessitating further proceeding, and that, perhaps, at a time when the wound is in a high state of inflammation. In order to avoid all this, Dr. Gurdon Buck has proposed the simultaneous ligation of the common and internal carotid arteries, and, in the New York Medical Times for November, 1855, he has given the particulars of a case in which the operation was followed by the most gratifying results.

Ulcers of the fauces have sometimes necessitated the ligation of the primitive carotid, as in the cases reported by Luke, Mayo, and Syme, in all of which the operation was successful. The patient of the latter gentleman, however, came very near perishing from secondary hemorrhage.

The common carotid artery has been repeatedly secured for wounds, epilepsy, and erectile and other tumors, as well as for restraining hemorrhage in operations upon and about the jaw, face, and neck. The statistics of these operations present points of much interest, and they have been placed in a very clear light by the tables of Dr. Norris. In 30 cases in which the artery was tied on account of wounds, 15 recovered, and 15 died; in 16 cases in which it was ligated previously to, or at the time of the extirpation of tumors of the jaw, face, or neck, 8 died; in 6 in which it was tied for the cure of epilepsy, all recovered from the effects of the deligation, although in 2 both vessels were secured; and in 42 cases in which it was tied for the cure of erectile tumors and various growths of the diploë, orbit, neck, jaw, and maxillary sinus, 20 were cured, 13 died, and 9 recovered from the effects of the operation without being materially benefited. In upwards of 20 of the 94 cases, more or less severe cerebral symptoms followed the operation.

Dr. James R. Wood, in 1857, published the details of 39 cases in which the primitive carotid was secured by different surgeons of New York, for various affections, as secondary hemorrhage, malignant growths, benign tumors, epilepsy, and aneurism of the branches of the carotid, with a loss only of 6. Of these 6 cases, only 5 were dissected. The cause of death in two was softening of the brain, in one inflammation of the jugular vein, in one pericarditis with abscess in the lung and liver, and in one exhaustion.

A number of cases have been reported in which both these vessels have been tied, either simultaneously or after a variable interval. The following table affords a summary view of nearly all the examples of this kind that have yet occurred.

No.	Operator.	Date.	Age.	Sex.	Disease.	Inter- val.	Result.	
1	Macgill	1823	Adult	f.	Tumors of both orbits		Improved	Vision destroyed; eyes pressed; Pulsation re- was excised; operation.
2	Mussey	1827	Adult	m.	Anastomotic aneurism of scalp	12 days	Failed	
3	Mussey		28		Ditto	28 days	Recovered	
4	Muller	1831	4½		Erectile tumor	4½ mo.	Recovered	
5	Preston	1831	51	m.	Epilepsy	84 days	Failed	Fits had ex- laterly been one side. Convulsions. No. The second during a pu scalp. Th- lowed by a;
6	Preston				Epilepsy	1 mo.	Failed	
7	Kuhl	1834	53	m.	Aneurism of the occiput	72 days		
8	Mott				Disease of parotid	15 min.	Died in 48 hours	
9	Mott				Malignant polyps	Several months	Recovered (?)	
10	Ellis	1844			Secondary hemorrhage	4½ days	Recovered	
11	Velpeau		29		Aneurism of both orbits	3 mo.	Recovered	
12	Warren	1845	23		Erectile tumor	33 days	Failed	Tumor occu neck. Sut diseased st
13	Hamilton		18		Epilepsy	6 mo.	Recovered	
14	Robert			f.	Aneurism	8 mo.	Recovered	
15	Blackman		15	m.	Disease of antrum	21 days	Recovered	Headache; vision. Temporary l
16	W. Parker	1854	42	m.	Malignant disease of nose & orbit	32 days	Died	
17	Weber	1857	20	m.	Epilepsy	17 days	Improved but not cured	
18	Langenbeck				Hemorrhage from superior thyroid	Same day	Death next day	Disease had a attack for ration. F after either
19	Moller		4½		Erectile tumor	4½ mo.	Recovered	

Of the above cases, 19 in number, 16 recovered from the operation, and 3 died. In Dr. Mott's case, where both vessels were ligated, coma soon supervened, and the man died in four days. In the case of Dr. Ellis, of Michigan, the second deligation was performed at an interval of four days and a half, on account of secondary hemorrhage upon a gunshot wound, and no unpleasant symptoms followed an excellent recovery. In Dr. Mussey's case twelve days after the first operation, the second was succeeded by an aneurism of the two arteries on the same subject.

Besides these cases, there is one by Ullmann in which the first operation was successful after an interval of twelve months; one by Buenger, of five months; and one by Dupuytren and Robert, of thirty-six years. Of these two cases, it is obvious that these cases cannot be adduced as evidence of the effects of the ligation of these vessels, inasmuch as the vessels are able to accommodate itself to the changes produced by the first performance of the second.

LIGATION OF THE EXTERNAL CAROTID AND ITS BRANCHES.

The external carotid, extending from the superior border of the thyroid cartilage to the neck of the lower jaw, is situated, just above its origin, in the triangular space formed by the omo-hyoid muscle below, the digastric above, and the sterno-mastoid externally, immediately beneath the integuments and platysma-myoid; but it soon sinks deeper in, passing up under cover of the stylo-hyoid and digastric muscles, and is finally buried in the substance of the parotid gland. It is accompanied by two veins, and is crossed near its commencement by the hypoglossal nerve, and also, in various parts of its course, by branches of the external jugular and other veins. The glosso-pharyngeal nerve is interposed between this artery and the internal carotid, while the superior laryngeal nerve lies under both.

Deligation of the external carotid is seldom required for anything else than wounds and vascular growths about the face and head. The vessel is often opened in attempts at suicide, though less frequently than is generally imagined; for persons intent upon self-destruction usually bend the neck so far back as to place the artery beyond the reach of the knife. Some of its branches are, however, commonly injured under such circumstances, especially the superior thyroid and lingual, and the hemorrhage thus produced may be promptly fatal. A ligature may readily be placed round the external carotid, in the first part of its course, by carrying an incision, about two inches and a half in length, parallel to but about six lines in front of the inner edge of the sterno-mastoid muscle, commencing opposite the middle of the thyroid cartilage, and terminating a short distance below the angle of the jaw. The trunk of the common carotid will guide the finger to its external division. The incision should be made with great care, lest violence be done to some of the numerous offsets of the vessel. The artery, as it lies beneath the digastric and stylo-hyoid, is exposed with difficulty; the incision must be proportionately large, and the muscles just mentioned must be well depressed with the retractor.

The principal branches of this artery, requiring surgical consideration, are the superior thyroid, lingual, facial, occipital, and temporal.

The *superior thyroid artery* is much exposed to injury in attempts at suicide, and may then be easily traced simply by following the wound. If it becomes necessary to ligate it on account of hypertrophy of the thyroid gland, with a view to diminish the supply of blood, it may be laid bare by making an incision across the upper part of the neck, obliquely downwards and outwards from the side of the hyoid bone to the edge of the sterno-mastoid muscle. Or, instead of this, the object may be attained by making an incision, two inches in length, along the inner border of the sterno-mastoid muscle, as in the operation for tying the external maxillary. The skin, platysma-myoid, and cervical aponeurosis having been carefully divided, the superior thyroid will be found deep in the omo-hyoid space, between the sheath of the carotid and the thyroid gland.

The *lingual artery* may be exposed in the same manner as the thyroid, near which it takes its origin; its situation, however, is very deep, and its relations are so complicated that it is generally better to secure the external or common carotid.

If the operation should be deemed necessary, it may be performed as follows, according to the plan laid down by Mr. Skey.

"The head of the patient being placed horizontally, and the neck lengthened

Fig. 274.

Ligation of the lingual artery.

by raising the chin, an incision of about twelve lines in length should be made immediately behind the cornu of this bone, the outline of which should be distinctly ascertained before proceeding to the operation; the incision should be directed downwards and forwards. The skin and platysma being divided, the fascia is exposed, which should also be divided to the length of the external wound. The facial vein, often of considerable size, will be brought into view at the upper part of the wound, in its course downwards to the internal jugular, and should be drawn outwards. The remaining parts should be torn, rather than cut asunder, passing transversely inwards, nearly parallel to the upper edge of the cornu of the os hyoides, when the artery will be exposed. In passing the needle behind it, care must be taken to avoid the superior laryngeal nerve, which descends nearly at right angles behind the artery."

The *facial artery* is frequently concerned in operations about the neck, face, and lips, and may easily be compressed with the finger as it passes over the jaw.

Fig. 275.

Ligation of the facial artery.

If divided, it should immediately be secured. When its ligation becomes necessary, in case there is no wound, its pulsation will point out the proper situation for the incision. When it is desired to secure it just above its origin, the incision should be made as in the operation upon the lingual, its approach being facilitated by drawing the digastric muscle strongly upwards. The vessel is most easily exposed and tied where it lies over the jaw, as in fig. 275.

The *occipital artery* sometimes requires ligation on account of wounds, but its depth in the lower part of its extent is such as to protect it generally from injury involving the cervical region. On the back of the head, however, it is not unfrequently laid open, and usually bleeds very freely. It may be exposed just above its origin by carrying an incision along the inner border of the sternomastoid muscle, in the angle formed by it and

the digastric, the latter of which must be well drawn down. It is in intimate relation here with the hypoglossal nerve, which hooks round it as it passes forwards towards its destination. The artery, after emerging from the splenius muscle, on the back of the head, fig. 276, is superficial, its course beneath the scalp being denoted by its pulsation.

Fig. 276.

Ligation of the occipital artery.

Fig. 277.

Ligation of the temporal artery.

The *temporal artery* is occasionally wounded, and may be secured immediately above the zygoma, by a short vertical incision fig. 277, embracing the temporal

aponeurosis, immediately beneath which it is situated. Lower down, the depth at which it lies is too great to justify an attempt at ligation. Should it be divided in this portion of its extent, the best plan is to tie the external carotid.

The anterior branch of this vessel is the one always selected in arteriotomy, when it is wished to practise depletion on account of affections of the brain or the brain and its membranes. After a sufficient amount of blood has escaped, the artery is cut across, and a graduated compress applied. If this precaution is neglected, a false aneurism will form.

The *internal maxillary artery* is sometimes wounded by a thrust with a sharp knife or dirk. The immediate result, of course, is a copious hemorrhage, for the arrest of which the only remedy is ligation of the external carotid; compression, it is true, now and then succeeds, but the only reliable means is the ligature. When the vessel is wounded in the extirpation of the jaw, it may commonly be seized and tied; when this is impracticable, the bleeding may generally be stopped with the hot iron, or with the tampon, wet with a saturated solution of alum and tannin, or covered with persulphate of iron.

LIGATION OF THE SUBCLAVIAN AND ITS BRANCHES.

The point which is usually selected for tying the subclavian artery is just external to the scalene muscle, in what is considered as the third course of the vessel. One single incision will generally be found to be sufficient for the free exposure of the artery, and this may be strictly horizontal or more or less curvilinear, according to the fancy of the operator. It is only when the tumor is so bulky as to cause great malposition of the shoulder, forcing the collar-bone high up into the neck, that two incisions can really be required, the one extending along the upper border of the clavicle and the other vertically upwards, parallel with the outer edge of the sterno-cleido-mastoid muscle.

Previously to commencing the operation, the patient should be placed in the horizontal position upon a narrow table, with his head and chest moderately elevated, and the face slightly inclined towards the sound side. An assistant taking hold of the hand, keeps the affected limb close to the trunk, at the same time that he pulls down the shoulder as much as possible, in order to draw the clavicle away from the subclavian artery as it passes from the scalene muscle towards the first rib. The surgeon, standing by the side of the patient, above the shoulder, stretches the integuments of the neck upon the upper part of the chest with the fingers of the left hand, while with the other he makes an incision, about two inches and a half in length, directly along the middle of the clavicle, commencing at the sternal origin of the mastoid muscle and terminating near the anterior margin of the trapezius. In this manner he divides the skin, superficial fascia, and platysma-myoid. Letting go his hold with his left hand, the parts will be found instantly to resume their natural situation, leaving thus the incision on a level with the superior border of the clavicle. The next step of the operation consists in detaching from this bone the deep cervical aponeurosis, which may readily be accomplished by a few gentle strokes of the handle of the scalpel instead of the point of the instrument, which would greatly endanger the surrounding vessels and nerves.

VOL. I.—48

Fig. 278.

Ligation of the subclavian artery, in its outer third.

The external jugular vein will be found close to the outer edge of the muscle, and should be held out of the way with a blunt hook. The subclavian artery will also generally appear, at this stage of the procedure, in front of and behind the clavicle, or partially covered by it, and should be secured in a similar manner; or, if divided, it should immediately be tied. At the outside of the incision, bound down by a process of thickening, the operator, using the scalene muscle for his guide, the operator feels for the tubercle of the artery, a little to the outside of which the artery will be found pulsating distinctly, and where it may in general be easily secured by a ligature, from before backwards and from below upwards. Previously to applying the ligature, it should be ascertained that it controls the circulation in the artery, and, above all, that it does not include any of the cords of nerves, a circumstance which has happened in several of the operations of this kind. When the clavicular or subclavian muscle is unusually broad, as it not unfrequently is, it should be divided by the grooved director, as this will greatly facilitate the application of the ligature, particularly when the design is to apply the ligature behind the artery.

In this manner, the subclavian may, in general, be easily secured, without much waste of blood or loss of time. In some instances, however, the operation is rendered extremely difficult, tedious, and embarrassing, on account of the magnitude of the tumor and the consequent elevation of the clavicle, the state of the artery, the unusual course of the vessels of the neck, or the fact that these follow their natural direction, the swollen and distended subclavian vein, the irregularity of the omohyoid muscle, the enlargement of the cervical lymphatic ganglions, or, finally, the great effusion of plastic matter.

1. The elevation of the clavicle is generally in direct proportion to the size of the tumor. Sometimes, however, even when the swelling is diminutive, this bone is situated much higher up than usual, on account of the peculiar conformation of the individual. In either case, the difficulty of the operation will be much increased. In one instance, where the tumor was produced by the enormous development of the disease, Sir Astley Cooper was obliged to abandon the operation altogether. When such a contingency occurs, the operation must be extremely rare, instead of giving up to it, as was done by the English surgeon, the best plan, it seems to me, is to divide the anterior scalene muscle, so as to enable us to apply the ligature what nearer to the heart, or even on the tracheal side of that vessel.

2. The operation is occasionally rendered more or less difficult by the diseased state of the artery. In this case, if the artery cannot be easily enough approached, it is impossible to apply the ligature in its usual situation. To divide the scalene muscle, or to cut down on the side of the neck, for the purpose of securing the vessel at one or other of these points, may here be our only resource. The brachial plexus of nerves may be divided, if necessary, the way of the operator as to render this course necessary, as was the case on the occasion of Dupuytren's operation.

3. The cervical vessels, both arterial and venous, are almost always in the way of the operator, even when they pursue their usual route. The subclavian artery is particularly true of the external jugular vein and of the supra-scapular artery. The former of these vessels, commencing at the angle of the jaw, passes under the neck under cover of the platysma-myoid. In the early stage of the disease, it rests upon the sterno-mastoid; afterwards it gets to the side of the neck, and, finally, at the inferior part of the neck, sinks behind the subclavian vein near its junction with the internal jugular vein. The supra-scapular artery, which it sometimes does by several distinct true branches, the supra-scapular and transverse cervical arteries, runs along the neck in a horizontal direction from without inwards, parallel to the side of the neck. These arteries, as well as their accompanying veins, are at the root of the neck, especially the supra-scapular, which is the

for some distance by the clavicle, on a line with which it runs to reach the root of the coracoid process; it is generally a branch of the thyroid axis, and rests at first upon the anterior scalene muscle, crossing as it passes outwards the subclavian artery. The course of the transverse cervical artery is nearly similar, but it is usually situated somewhat higher up; it is also considerably smaller, and is most frequently derived immediately from the subclavian.

Now, in attempting to reach the subclavian, it is almost impossible to avoid wounding some of the vessels above mentioned. The external jugular vein is particularly in danger, and can scarcely escape without the utmost coolness and dexterity on the part of the operator. As soon as it is recognized it should be separated from the surrounding structures by a few gentle strokes with the handle of the scalpel, and drawn to the outer side of the wound. This plan is undoubtedly always the best and safest when it can be adopted; sometimes, however, it happens that the vessel is so much in our way as not only greatly to embarrass our progress, but absolutely put a stop to it. In this case it must be tied with two fine ligatures, and then divided. Such a procedure not only prevents hemorrhage, but also the introduction of air into the lower portion of the vessel, an occurrence which cannot be too carefully guarded against. The supra-scapular artery, if in the way, should be drawn aside, or, if it be wounded, immediately secured. Any bleeding vessels, indeed, no matter whether arterial or venous, provided they pour out a sufficient amount of blood to interfere with the operation, should at once be tied.

4. The inordinate *swelling of the subclavian vein* is another source of embarrassment which is occasionally experienced in operations of this kind. This vessel is usually situated somewhat below and superficially to the artery, being separated from it by the anterior scalene muscle, upon which it lies. Commencing at the inferior margin of the first rib, where it is continuous with the axillary, it passes horizontally inwards until it joins the internal jugular vein, within a few lines of the sterno-clavicular articulation. In this course, in which it is almost entirely concealed by the clavicle, it receives the small branches which accompany the different offsets of the artery as well as the external jugular, which last enters it, as before stated, nearly opposite the centre of the bone, but sometimes more internally. After the division of the cervical aponeurosis in the lower part of the neck, the operator will occasionally observe this vessel alternately to swell and subside, owing not so much, as some have supposed, to the natural flow of the current within it as to the reflux caused by the action of the right auricle of the heart, aided by the hurried and agitated state of the respiratory movements. The difficulty thus occasioned is not only annoying, but sometimes so embarrassing as to render it almost impossible even to see the artery, much less to separate and tie it. To remedy this, it has been suggested that the operation should be suspended for a moment, and the patient placed in the semi-erect posture to allow him to make several full and easy inspirations, after which, it is said, the tension of the vein will be diminished, and the regurgitation of the blood cease. The surest and most expeditious plan, however, is to hold the vessel out of the way by means of a broad blunt hook, or copper spatula, carried down behind the clavicle. In this manner the vein may be effectually compressed to the extent of half an inch, or more, if necessary, and the artery fairly brought into view.

5. The *omo-hyoid* muscle, instead of forming a triangular space, as it usually does, with the scalene muscle and the clavicle, may run parallel with, and just above, that bone, or even entirely below it. In either case, should it be productive of inconvenience to the operator, he should pass a director under and divide it. Such a proceeding, however, can seldom be called for, as, by laying open its sheath, the muscle may generally be drawn out of our reach.

6. The *lymphatic ganglions*, at the inferior part of the neck, may be so much enlarged as to interfere seriously with the different stages of the operation. When this is found to be the case, instead of trying to save these bodies, they should be carefully dissected out, as we shall thus not only expedite our arrival at the artery, but, what is a matter of no little importance, greatly facilitate the healing of the parts after the vessel is tied.

7. Finally, considerable embarrassment may arise from the *condensed and indurated* state of the parts, caused by an effusion of plastic matter. This may always be looked for when the disease is of long standing, or when the tumor is so large as to excite severe inflammation in the deep-seated structures immediately above the clavicle, thereby obscuring the nerves and vessels.

If, from any of the above causes, it is sometimes difficult to denude the artery, to convey a ligature round it will often be found to be much more so. Indeed, this generally constitutes the most annoying and embarrassing step of the operation. To facilitate this procedure, various mechanical contrivances have been resorted to, some of them so complicated in their character as to be well calculated to enhance instead of diminishing the difficulty. Under ordinary circumstances every indication may be fulfilled with the common aneurism-needle, or even with a common eyed-probe. Whatever mechanical contrivance be employed, the ligature, as a general rule, should be passed from before backwards and from below upwards, as it will be found much easier in this way to prevent injury to the subclavian vein, while there will be no danger whatever of including any of the cords of the brachial plexus of nerves. Owing to the great depth of the wound, not a little difficulty is sometimes experienced in tightening the knot. In this case the ingenious instrument invented by Dr. Hosack, of New York, will be found very useful. By holding the first knot firm it enables the surgeon to tie a second or third with the utmost facility.

Notwithstanding the assistance to be derived from the different instruments that have been invented for that purpose, such has been the difficulty, in some instances, of conveying the ligature round the artery as to lead not only to great delay, but almost to an abandonment of the operation. It has been suggested, under these circumstances, to saw through the clavicle, and to this proposal I can see no objection, provided the shoulder is so much elevated as to offer an almost insurmountable barrier to the passage of the ligature. By this practice, although a compound fracture of the clavicle would be superadded, yet this would be of the most simple kind, while the operation, instead of occupying from one to two hours, as has repeatedly happened heretofore, could be completed in a comparatively short time; the vessel could be much more effectually secured, the risk of wounding the subclavian vein and other parts would be greatly diminished, and the patient would have a much better chance for recovery.

The arteries which are more particularly concerned in maintaining the collateral circulation after the ligation of this vessel, are the supra-scapular, transverse cervical, internal mammary, long thoracic, circumflex, and sub-scapular, the first three being branches of the subclavian, the other three of the axillary. The thoracic artery frequently arises from the aneurismal sac, and is therefore liable to be obliterated for some distance in the progress of the disease.

The subclavian artery has been tied several times in the second course of its extent, but the procedure is very difficult, as well as replete with danger, owing to the proximity of numerous important structures, especially the phrenic nerve, jugular vein, pleura, and thyroid axis. The external incisions are similar to those employed for exposing the artery in the other parts of its extent; as soon as the anterior scalene muscle is fully brought into view, a grooved director is carried behind it, and its lower attachment carefully severed from the clavicle, the phrenic nerve having previously been placed beyond the reach of the knife. The top of the pleura, lying close by, must not be wounded in passing the needle. It will thus be perceived that the operation is one of excessive delicacy, requiring consummate anatomical knowledge and skill for its successful execution. The greatest objection, however, to its performance is that the subclavian is obliged to be tied so close to the superior intercostal and deep cervical branches; a circumstance which must necessarily materially interfere with, if not wholly prevent, the formation of a firm and adherent clot.

The manner of exposing and ligating this artery in the first part of its course has been pointed out under the head of axillary aneurism. From the fact that all the cases in which the operation has been performed have ended fatally, it is questionable whether it should ever be repeated.

The subclavian is occasionally tied for wounds of the axillary artery. In the table of Dr. Norris, comprising 69 cases of operations upon this vessel, 9 were performed for this purpose, and of these, 6 proved fatal. Mr. Guthrie, in his *Treatise on the Diseases and Injuries of the Arteries*, refers to 22 cases in which the subclavian was ligated for a similar object, 11 times above the clavicle, and 11 times below. Of the former cases, 9 recovered, and 2 died; death in one being caused by the bursting of an internal aneurism, and in the other by gangrene after amputation at the shoulder-joint. Of the 11 cases in which the artery was tied below the clavicle, 6 recovered, and 5 perished, three from gangrene of the limb, one from exhaustion, and one from hemorrhage.

LIGATION OF THE VERTEBRAL.

The vertebral artery is the largest branch of the subclavian, and, of course, bleeds profusely when divided, as it occasionally is in wounds of the neck. Taking the opening as the guide, the vessel should be traced to the seat of injury, and a ligature applied to each extremity. The dissection necessary for its exposure should be conducted with the greatest caution, on account of the important and complex relations which the vertebral sustains to the surrounding parts. The best guide to the seat of the vessel is the transverse process of the sixth cervical vertebra, situated about two inches above the clavicle, and now usually known as the carotid tubercle. The artery will be found just below this prominence, deep in the wound, and at the inner side of the anterior scalene muscle.

A case has been reported by Maisonneuve in which he tied successfully the vertebral artery, together with the inferior thyroid, below the sixth cervical vertebra, on account of a gunshot wound. He carried his incision along the anterior edge of the sterno-cleido-mastoid muscle, and exposed the sheath of the common carotid artery, which was then carefully held aside while he denuded and severed the injured vessels. Nuntianti Ippolito has related two cases in which the vertebral artery was successfully tied at its origin.

LIGATION OF THE INTERNAL MAMMARY.

No instance has been reported, so far as I am aware, of spontaneous aneurism of this artery, but of the traumatic form of the lesion, an example has been related by Demontègre as having occurred in a man seventy-six years of age, from the thrust of a sabre. The tumor was two inches in length.

The internal mammary artery is sometimes cut across in gunshot injuries, and it is not unlikely that it might be opened in a bad fracture of the sternum and of the ribs. However this may be, the proper way to secure it, in the event of hemorrhage, is to follow the track of the wound, enlarging it freely, if necessary. The artery with its two veins will be found, in the early part of its course, about three lines from the edge of the sternum, in front of the triangular muscle, which separates it from the pleura. It may readily be reached in the three upper intercostal spaces by a vertical incision, two inches and a half in length, carried in the direction just indicated, through the integuments and internal intercostal muscles, together with some of the fibres of the great pectoral. Below these points the operation will be very difficult, if not impracticable, on account of the great narrowness of the intercostal spaces.

LIGATION OF THE INFERIOR THYROID.

The inferior thyroid has been repeatedly tied for hemorrhage and for the cure of goitre. In wounds of the neck, involving this vessel, the ligation is, in general, easily effected simply by enlarging the existing opening in the direction of the part whence the blood issues; but when there is no such guide the operation is usually one of considerable difficulty, requiring nice anatomical knowledge and careful dissection.

The inferior thyroid artery, in the first part of its course, ascends a little, and

then inclines inwards, passing behind the great vessels and nerves of the neck. The easiest way of exposing it, when there is no wound, is to make an incision along the inner border of the sterno-cleido-mastoid muscle, as in the operation for tying the primitive carotid, the sheath of which should be drawn carefully outwards. The artery will be found to cross over towards the thyroid gland, opposite, in most cases, to the fifth cervical vertebra, and may be readily encircled with a common aneurism needle. Care must be taken not to injure the sympathetic, recurrent and hypoglossal nerves. On the left side the artery lies in close contact with the œsophagus and thoracic duct.

LIGATION OF THE AXILLARY.

Deligation of the axillary artery was first performed by Chamberlayne in 1815. The operation is required chiefly on account of penetrating wounds, or the accidental laceration of the vessel during the reduction of ancient dislocations. Of the latter occurrence, quite a number of cases have been reported by surgical writers. There are two regions where the artery may be secured, either just below the clavicle, or in the hollow of the axilla. In the intermediate point, it is so deeply situated, and is in such intricate relations, as to render its approach very difficult.

As the artery in the first of these regions is very deep seated, it has been advised, instead of tying it, to ligate the subclavian in the third stage of its course. Cases, however, occur, in which it is desirable to secure it soon after its origin, and this can generally be done without any difficulty, provided the surgeon is sufficiently cool and deliberate, and has a thorough knowledge of the anatomy of the parts. The patient being placed in a half-sitting posture, with the arm slightly abducted, an incision is carried along the inferior border of the clavicle, through the skin and platysma-myoid, commencing one inch from the sternum, and extending to within a short distance of the deltoid muscle, care being taken to avoid the cephalic vein, as it lies in the groove between the latter and the great pectoral. The next step consists in dividing the fibres of the great pectoral to the full extent of the external wound. The small pectoral is now seen at the lower portion of the wound, and should be relaxed by bringing the arm close to the trunk. A retractor being inserted, and the divided structures well depressed, the artery will be found at a short distance below the clavicle invested by a dense

fascia, which must be carefully scraped through before the vessel can be fairly exposed to view. The accompanying vein, which often swells suddenly out during expiration, lies below and in front of it, while the brachial plexus is behind, except one of its branches, which is above and in contact with it. The anterior thoracic artery, one of the offsets of the axillary, is also on its anterior surface. The needle is passed from within outwards, in order to exclude the vein. As difficulty is sometimes experienced in distin-

Fig. 279.

Ligation of the axillary, in its inferior division.

guishing the artery from the cords of the axillary plexus of nerves, it will be well, before tightening the thread, to ascertain what effect its application has upon the pulse at the wrist, or in the aneurismal sac. The costo-coracoid ligament sometimes requires division in this operation.

To expose the artery in its inferior section, fig. 278, the arm should be abducted

and supinated, and an incision, nearly three inches in length, made through the axilla, close to the border of the broad dorsal muscle. The cellular and aponeurotic structures being next divided, the median nerve and axillary vein will be brought into view, the two roots of the former embracing the artery on each side, and the latter running along its anterior surface. Cautiously separating these parts with the finger, or the forceps and director, and turning them in opposite directions, the artery is exposed, and tied by passing the ligature from within outwards.

LIGATION OF THE BRACHIAL.

The brachial artery, in consequence of wounds and various kinds of traumatic aneurisms, requires to be ligated more frequently than any other artery in the body. Extending from the lower border of the axilla, on a level with the tendon of the teres muscle, to nearly one inch below the bend of the elbow, it is overlapped above by the coraco-brachial muscle, and in the middle by the two-headed flexor, while inferiorly it is completely covered by a reflexion of the brachial aponeurosis. Its whole course, however, is comparatively superficial, so that it is easy to feel its pulsations in the greater portion of its extent. In attempting to secure the artery high up, near its origin, an incision, two inches and a half in length, should be made along the inner margin of the coraco-brachial muscle, the limb being extended and supinated with the forearm in a state of partial flexion. The artery, accompanied by its two veins, lies here between the median and ulnar nerves, the former being on its outer side, and the latter on the inner. If the artery is sought for at the middle of the arm, the best guide to its seat will be the ulnar edge of the two-headed flexor muscle. The median nerve, in this part of the course of the artery, is usually on the inside and in front of the vessel. At the bend of the arm, the brachial is readily exposed by dividing the brachial aponeurosis in a line with the ulnar border of the tendon of the two-headed flexor muscle. In none of these operations is it necessary to divide any muscular fibres.

Schemes for tying the brachial, radial, and ulnar arteries, are depicted in fig. 280.

In operating upon the brachial artery, it should be borne in mind that this vessel is subject to certain varieties, which may serve both to perplex the surgeon, and mar the result of the undertaking. The most frequent of these anomalies is the high division of the artery into the radial and ulnar, which, on reaching the elbow, either pursue their usual course, or, as is more generally the case, the former proceeds superficially down the forearm, while the latter becomes deep seated; or their course may be reversed, the radial following its ordinary route while the ulnar descends immediately under the skin. Several instances have been met with in which the brachial divided high up into two branches, which subsequently united again a single trunk, as in fig. 281, which afterwards bifurcated regularly into radial and ulnar.

Fig. 280.

Ligation of the brachial, radial, and ulnar arteries; also of the palmar vessels.

Fig. 261.

Double brachial artery.

LIGATION OF THE RADIAL AND ULNAR.

The radial artery, whose course along the forearm is indicated by a line drawn from the middle of the bend of the elbow to the forepart of the styloid process of the radius, may be tied near its origin, at its middle, and at its inferior extremity. When the design is to ligate it above, or in the first of these situations, it may be approached by an incision, about three inches in length, parallel to the inner border of the long supinator muscle, between which and the round pronator the vessel will be found, accompanied by its two veins, the radial branch of the musculo-spiral nerve lying at its outer side, and some distance from it. Care is taken not to wound the basilic vein. In the middle third of the forearm, the artery lies between the long supinator and flexor muscle of the carpus, the spiral nerve descending close along its radial border. In the inferior portion of its extent, the artery is comparatively superficial; its pulsation is very distinct in the greater part of its length, and therefore serves as a ready guide to its course.

The ulnar artery is sometimes divided in the upper part of its extent by a knife or ball, and may then generally be easily found by taking the wound as our guide, enlarging it, if necessary, and tying the vessel at each extremity. When a false aneurism exists in this situation, it is usually recommended to ligate the brachial, but I am satisfied that it would be more safe, in every instance, to tie the ulnar soon after its origin, by cutting boldly through the thick muscular mass at the upper third of the forearm, as we could thus effectually guard against hemorrhage from the recurrent circulation. In the middle of the limb the artery lies along the radial border of the ulnar flexor of the carpus, which should, therefore, be taken as a guide to the knife, and be carefully separated from the common flexor of the fingers. The ulnar nerve here lies on the inner side of the vessel. Near the wrist the artery is generally found with facility, its situation being indicated by its pulsation.

LIGATION OF THE ABDOMINAL AORTA.

Ligation of the abdominal aorta may be required on account of a wound, either of itself or of the common iliac, and in that event the best plan would probably be to enlarge the external opening to an extent sufficient to encircle the vessel with the thread. In ligating the vessel for aneurism, the patient should lie on his right side, and care should be taken to avoid injury to the peritoneum, which can easily be done by adopting the procedure of Dr. Murray, since followed by Monteiro and South, of making a curvilinear incision, with the convexity towards the vertebræ, from an inch above the anterior superior spinous process of the ilium to the cartilage of the tenth rib. It should be fully six inches in length, and should extend, in the first instance, merely through the common integuments. The various underlying structures should then be severally divided until the peritoneum is brought into view, which is cautiously peeled off from the iliac and psoas muscles with the hand a short distance beyond the contemplated point of ligation. The separation of the aorta from its accompanying vein on the right side, and the filaments of the sympathetic nerve in front, constitutes one of the greatest difficulties of the operation, and is generally best effected with a

long director, slightly sharp at the extremity, and the nail of the index finger. The ligature should be passed round the artery from left to right, and from behind forwards, about one inch above its bifurcation into the common iliacs.

LIGATION OF THE COMMON ILIAC.

The common iliac artery was first ligated by Dr. William Gibson, of this city, in 1812, in a case of gunshot wound. His patient died in thirteen days of peritoneal inflammation and secondary hemorrhage. In 1827, it was tied, for the first time, for aneurism, by Dr. Mott. The disease occupied the external iliac artery; the ligature came away on the nineteenth day; and in less than two months the man was entirely well.

This artery has probably been secured altogether nearly forty times. The most extended and reliable statistics of the operation that have yet appeared are those of Dr. Stephen Smith, of New York, published in 1860. He has arranged his cases under four distinct heads, as they relate, first, to the arrest of hemorrhage; secondly, to the cure of aneurism; thirdly, to the starvation of pulsating tumors; and, lastly, to the ligation of the vessel, as a means of avoiding hemorrhage during the removal of morbid growths. Two of the tables are so interesting and instructive that I shall take the liberty of transcribing them.

GROUP I.—*Eleven Cases of Ligation for the Arrest of Hemorrhage.*

No.	Operator.	Sex.	Age.	Side.	Disease or accident.	Result.	Date of death.	Cause of death.
1	Gibson	m.	38	l.	Gunshot wound of external iliac artery	Healed	15th day	Hemorrhage
2	Luton	m.	8	r.	Hemorrhage after amputation of thigh	Died	24 hours	Exhaustion
3	Garvis	Hemorrhage from bursting of aneurism	Healed	4 hours	Exhaustion
4	Pirogoff	m.	—	r.	Hemorrhage after ligation of external iliac	Died	14th day	Hemorrhage
5	Duguise	m.	42	r.	Hemorrhage after ligation of the external iliac	Cured		
6	Post	m.	20	l.	Hemorrhage from an incision into an aneurism	Died	24 hours	Exhaustion
7	Uhde	m.	26	l.	Rupture of internal iliac in applying ligature	Died	4th day	Peritonitis
8	Edwards	m.	27	r.	Rupture of an aneurism of external iliac	Died	25th day	Hemorrhage
9	Holt	m.	24	r.	Hemorrhage from opening a gluteal aneurism	Died	3d day	Exhaustion
10	Parker	m.	20	r.	Hemorrhage from a stab in the groin	Died	10 hours	Exhaustion
11	Buck	m.	40	l.	Hemorrhage after ligation of external iliac	Died	17th day	Hemorrhage

Of the above cases, 10 were fatal, and 1 recovered, being a mortality of nearly 91 per cent. The average period of death was eight days, the cause in 5 being immediate exhaustion, in 4 secondary hemorrhage, and in 1 peritonitis.

GROUP II.—*Fifteen Cases of Ligation for the Cure of Aneurism.*

No.	Operator.	Sex.	Age.	Seat of aneurism.	Result.	Date of death.	Cause of death.
1	Mott	m.	33	Right external iliac	Cured		
2	Crampton	m.	30	Right external iliac	Died	10th day	Hemorrhage
3	Stevens	m.	...	Right external iliac	Died	2d day	
4	Salomon	m.	38	Left external iliac	Cured		
5	Syme	m.	31	Right external iliac	Died	4th day	Gangrene of leg
6	Pease	m.	36	Right external iliac	Cured		
7	Hey	m.	41	Left external iliac	Cured		
8	Garvis	External iliac	Cured		
9	Lyon	m.	53	Left external iliac	Healed	50 hours	Exhaustion
10	Jones	m.	34	Right external iliac	Died	15th day	Erysipelas
11	Wedderburn	m.	25	Left fem. and ext. iliac	Died	4th day	Gangrene
12	Van Buren	m.	46	Right external iliac	Died	4th day	Suppuration of
13	Stephen Smith	m.	33	Right external iliac	Healed	46th day	Hemorrhage
14	Stone	m.	36	Left external iliac	Died	26th day	Dysentery
15	Goldsmith	m.	40	Left external iliac	Died	8th day	Exhaustion

Of the cases comprised in this table, all, except one, were males. The aneurism was located on the right side in 8, and on the left in 6, the seat in one not being given. The mortality was $66\frac{2}{3}$ per cent.

In the third group, Dr. Smith gives 4 cases, in which this vessel was tied by Guthrie, Stanley, Moore, and Meier, on account of pulsating tumors supposed to be aneurismal, but which proved to be malignant. All the patients, except one, died.

The fourth group comprises 2 cases, in one of which the artery was tied by Bushe, for an anastomotic aneurism, in a child six weeks old; and in the other by Chassaignac, in a man, aged 49, to prevent hemorrhage. Both patients died.

Of the above 32 cases, 27 were males, and 3 females, the sex in 2 not being given. The ages varied from six weeks to fifty-nine years, 22 of the cases occurring between the twentieth and fiftieth years. In 17 cases the right common iliac was tied, and in 13 the left. Of the whole number 25 died and 7 recovered, being a mortality of about $78\frac{1}{2}$ per cent. The average period of the separation of the ligature in 12 cases was nearly twenty-three days, the minimum being eight days, and the maximum thirty-six days. In 9 cases the peritoneum was wounded during the operation, and all these, excepting one, died. In 9 cases in which anæsthetics were used, and in 9 in which they were not used, all perished. It would thus seem that the ligation of this artery is one of the most unsuccessful operations in surgery.

The tables of Dr. Smith do not include the case by the late Dr. Luzenberg, of New Orleans, in which the primitive iliac artery was successfully tied in 1846. Dr. Hammond, of San Francisco, in 1861, also ligated this vessel on account of an aneurism of the gluteal artery, but his patient died on the twenty-fourth day.

From numerous trials upon the dead subject, Dr. Smith advises, as the easiest and safest method of approaching the vessel, that an incision be made extending from near the anterior extremity of the eleventh rib to within a very few lines of the internal ring, with a sharp curve inward of one inch. It will thus pass about an inch and a half within the anterior superior spinous process of the ilium, and be about seven inches in length. The curve at the lower extremity of the wound will allow the most perfect freedom in the elevation of the peritoneum, and the complete exposure of the artery.

Ligation of the common iliac, fig. 282, is far from being an easy operation, especially in case of aneurism, attended with a large tumor and morbid adhe-

sions of the peritoneum. The patient lying on his back, with the thighs somewhat relaxed, a slightly curvilinear incision is made along the lower part of the abdomen, about half an inch above Poupart's ligament, commencing at the external ring and passing upwards and outwards a short distance beyond the anterior superior spinous process of the ilium, its length varying from five to seven inches, according to the exigencies of the particular case. The operator should, in every instance, give himself an abundance of room. The first cut extends merely through the skin and superficial fascia. The other structures, beginning with the aponeurosis of the external oblique muscle, are then severally divided upon the director down to the peritoneum, more and more caution being observed in proportion as we approach the deeper parts. The serous membrane is now gently and slowly detached, by means of the finger, from the aneurism and other textures, as high up as the necessities of the case may demand. The artery being thus denuded, is next isolated

Fig. 282.

Ligation of the common iliac.

sities of the case may demand. The artery being thus denuded, is next isolated

from the accompanying vein, and the thread deposited by passing the needle from within outwards, above the middle of the vessel. The different steps of the operation will be greatly facilitated if the patient has previously taken an active cathartic, to unload the bowels. Care must be employed not to wound the spermatic cord.

The primitive iliac arteries extend from the cartilage between the fourth and fifth vertebræ to the sacro-iliac symphysis, diverging from each other as they descend at a somewhat acute angle, their point of commencement being nearly opposite the umbilicus. Each rests on the spine and psoas muscle, and is crossed anteriorly, at its bifurcation, by the ureter. On the right side, the accompanying vein lies, above, behind and external to it, while, lower down, a portion of the vein appears on the inner side; on the left side, the vein passes along the inner side of the artery, both vessels lying under cover of the sigmoid flexure of the colon. Neither artery presents any anomalies of importance in a surgical point of view.

LIGATION OF THE INTERNAL ILIAC.

The ligation of the internal iliac has now been practised in ten cases, the operation having been first performed by Dr. Stevens, of St. Croix, in 1812, upon a negress, for what was supposed to be an aneurism of the gluteal artery, but which was found on dissection, three years afterwards, to have arisen from the sciatic. The tumor had originated spontaneously, and was, at the time of the operation, of the volume of a child's head. Of these cases five recovered, and five died, a result which may well create surprise when we take into consideration the great depth at which this vessel is situated, the injury that must necessarily be inflicted upon the surrounding parts in exposing it, and the exceedingly unfavorable character of most of the cases themselves prior to the operation. The artery, moreover, is very short and disproportionately large, being generally less than two inches in length; it is, besides, in intimate relation with various important structures, thus rendering it extremely difficult of access. Thus, it lies on the internal iliac vein, which, however, on the right side, projects from underneath it over its outer edge; it is crossed above by the ureter, and is overhung by the bladder, while that on the left side lies immediately behind the rectum. Close by are the sacro-lumbar and obturator nerves, the latter, along with the external iliac vein, running in the angle which separates the internal from the external iliac artery.

The manner of exposing the artery is the same as in ligating the common iliac. Dr. White, of Hudson, who tied this vessel successfully in 1827, for gluteal aneurism, made a semi-circular incision on the side of the abdomen, with its convexity to the ilium, seven inches in length, commencing two inches to the left of the umbilicus, and terminating close to the external ring. It is not necessary, however, I conceive, to carry the incision so far inwards, as the object may be just as well attained by the other process, and with less risk of bad consequences. The peritoneum is carefully raised with the fingers, and it is worthy of notice that the membrane, as it is being peeled off, invariably carries with it the ureter, thus placing this duct completely beyond the reach of the ligature. The fascia investing the artery is scraped away with the nail or handle of the scalpel, and, taking the precaution of avoiding the external iliac vein, as it lies in the angle between the internal and external iliac arteries, the ligature is deposited by passing the needle from within outwards.

When the internal iliac artery is very short, or the pelvis unusually small, so as to render the ligation of the vessel very difficult, it would be more prudent to secure the common trunk; the procedure would be attended with less violence to the parts, and with less risk of peritonitis and secondary hemorrhage.

The most common cause of death after this operation is secondary hemorrhage of which one of the patients perished within the first twelve hours. The circulation, after the ligation of the internal iliac, is carried on mainly by the lumbar and sacro-lateral branches.

LIGATION OF THE GLUTEAL.

The gluteal artery has been repeatedly ligated on account of hemorrhage and traumatic aneurism, as, for example, in the famous case of Mr. John Bell, where, to use his own hyperbolical language, the incision was upwards of a foot and a half in length. In exposing the vessel for the relief of hemorrhage, the surgeon is necessarily obliged to take the external wound as his guide, enlarging it, if possible, in the direction of the muscular fibres, and giving himself an abundance of room, especially if the artery is divided just as it emerges from the sacro-sciatic notch. It must be remembered that the vessel is accompanied by a vein and nerve, which must be carefully excluded from the ligature. If the artery is cut off close, it may be necessary to pass the thread with a curved needle, and to include in the noose some of the surrounding tissues, as it will probably be impracticable to raise it with the tenaculum.

In case of traumatic aneurism of this artery, most writers recommend the ligation of the internal iliac; but, when we remember the difficulties and dangers of this operation, and the probable occurrence of peritoneal inflammation and of secondary hemorrhage, it seems to me that it would be better, in every respect, to cut down upon and tie the gluteal itself. The operation will of course be bloody and formidable, but skill, boldness, and promptness may accomplish much, even in a case like this, especially when everything is well ordered beforehand, and the assistants are properly instructed in their respective duties. The incision, made in the direction of a line extending from the posterior superior spinous process of the ilium to a point midway between the tuberosity of the ischium and the great trochanter, must be at least eight inches in length, and should be carried at one stroke down into the aneurismal sac, the contents of which should then be turned out, and the artery instantly secured, as it lies towards the upper part of the wound.

In a case of traumatic aneurism of the gluteal artery, in a boy, aged fourteen years, Professor Campbell, of Montreal, in 1862, secured this vessel at the upper and anterior portion of the sciatic notch, without opening the tumor. Some difficulty was experienced in passing the ligature, but as soon as this was tied all pulsation in the sac ceased, and a rapid recovery was the consequence.

LIGATION OF THE SCIATIC.

The sciatic artery is also liable to be injured, either by sharp-pointed bodies penetrating the gluteal region, or by falls upon the buttock in which the vessel is laid open by a splinter of bone round which it passes as it proceeds forwards. It is situated under the great gluteal muscle, at first posterior and then internal to the great sciatic nerve, and winds round the spinous process of the ischium, near its root, behind the muscles which are inserted into the intertrochanteric line of the femur. It may be exposed by making a similar incision, as in the preceding case, but about an inch and a quarter lower down. When the operator is in doubt as to which artery is implicated, whether the sciatic or gluteal, the incision should be made as nearly as possible in the intermediate space.

The sciatic artery has been tied, in at least one instance, for an aneurism seated upon its own trunk, Dr. Dugas, of Georgia, being the operator. Owing, however, to secondary hemorrhage, caused, apparently, by the patient's own imprudence, the common iliac had to be secured at the end of a week, when the man was almost moribund from the loss of blood. Death occurred four days afterwards.

LIGATION OF THE EXTERNAL ILIAC.

Ligation of the external iliac artery was first practised by Mr. Abernethy, in 1796, in a case of aneurism of the femoral artery, which he had previously tied at the distal side of the tumor; but severe hemorrhage coming on some time after, he found it necessary to apply a ligature above the swelling. The operation, however, failed; and it was not until 1806, after two other attempts, that

his efforts were finally crowned with success. In this country it was first performed by Dr. Dorsey, of this city, in 1811, in a case of inguinal aneurism.

There are several methods in vogue for exposing this artery and encircling it with a ligature, each of which has its advantages and disadvantages, although the results have perhaps not essentially varied in any. That of Abernethy, slightly modified, is perhaps the most unexceptionable. It consists in making a curvilinear incision, with the convexity downwards, along the inferior portion of the abdomen, commencing about an inch and a half above Poupart's ligament, just outside of the external ring, and terminating on a level with the anterior superior spine of the ilium, about two inches on the inner side of this process. Its length should be from three inches and a half to four inches according to the size of the tumor, and the stature of the patient. The first cut, extending through the skin and superficial fascia, will probably sever a few little arteries that should be tied before proceeding any farther. The aponeurosis of the external oblique muscle is now in sight, and should be divided upon the director. Then comes the internal oblique muscle, next the transverse muscle, and, finally, the transverse fascia, readily recognized by its opaque whitish appearance. A small hole having been scratched into this membrane with the nail or scalpel, it is slit open to the full extent of the outer wound. The next step, and one of the most delicate of all, consists in gently and cautiously detaching the peritoneum from its connections in the iliac fossa; an operation which is often attended with considerable difficulty on account of the morbid adhesions. The iliac artery will now be felt pulsating at the bottom of the wound, having the anterior femoral nerve at its outer side and on a somewhat deeper plane, and the iliac vein at first behind, but afterwards, near Poupart's ligament, internal to it. The sheath of the artery is now carefully penetrated, when the instrument bearing the ligature is gradually insinuated round the vessel from its inner side, this procedure being found best to avoid injury to the vein.

There are several circumstances worthy of attention in connection with the ligation of the external iliac. In the first place, the ligature should, if possible, be placed round the vessel about its middle, which will be nearly two inches above Poupart's ligament, the artery being usually from three inches and a half to four inches in length. If the ligature is applied low down, near to the origin of the epigastric artery, there may not be sufficient room for the formation of a coagulum, and the patient may perish of secondary hemorrhage, as happened in a case recorded by Bécларd.

Secondly, care must be taken not to wound the peritoneum. I have witnessed several instances in which it was separated with immense difficulty, in consequence of the great firmness with which it adhered to the aneurismal sac, from the effects of plastic deposits. In a case of Dr. Post, of New York, the membrane was so much thickened and altered by disease that he found it quite impossible to detach it, and was consequently obliged to make an opening into it in order to admit the ligature.

Thirdly, no little difficulty is occasionally experienced in separating the artery from its accompanying vein, owing to their naturally firm union, which is often greatly increased by disease. The object is most easily attained with a grooved director slightly sharpened at the extremity.

Fourthly, should the external iliac be found to be too much diseased, or the tumor so large as to overlap the greater portion of the artery, as it may when the sac extends upwards beneath Poupart's ligament, it will be easy to ligate the common trunk simply by enlarging the wound, especially at its upper angle.

Fifthly, the manipulations will be greatly facilitated if the patient's bladder and bowels are well evacuated a short time previously to the operation.

Lastly, the wound made in the operation should in this, as in the ligation of the other pelvic arteries, be sewed up carefully from the bottom, by carrying the needle close down to the peritoneum; in other words, the muscular and integumental lips should be tacked together separately, the object being the production of firm union, so that there may be no risk of hernia when the patient begins to sit up and walk about.

The ligation of this vessel is not unfrequently followed by secondary hemorrhage, coming out at a period varying from the fifth to the fortieth day, the greatest number of cases occurring from the seventeenth to the twentieth day. Of 14 cases of this accident, analyzed by Dr. James R. Wood, 4 recovered and 10 died.

After the ligation of the external iliac, the collateral circulation is maintained chiefly by the anastomosing branches of the gluteal, sciatic, obturator, and pudic arteries, with the circumflex and deep branches of the femoral.

LIGATION OF THE EPIGASTRIC.

The epigastric artery is occasionally wounded, either accidentally or in operating for hernia, tapping the abdomen, or ligating the iliac. The vessel, although small, may give rise to fatal hemorrhage, the more readily as the bleeding is generally insidious and deep seated, and it should, therefore, be secured without delay. To do this, an incision, about two inches in length, is made just above, and parallel to, Poupart's ligament, in a line corresponding with its centre, cautiously dividing the parts until the artery is reached, as it lies between the transverse fascia and peritoneum. It is accompanied by two veins, which must be carefully excluded from the ligature. The artery arises on the inner side of the external iliac, about three lines above Poupart's ligament, and ascends inwards just within the inner border of the internal ring, where the deferent duct hooks round it on its way to the abdominal canal. Should the vessel be cut off close to the external iliac, it might become necessary to cast the thread round this artery instead of the epigastric.

LIGATION OF THE CIRCUMFLEX ILIAC.

The circumflex iliac artery, given off by the external iliac, usually a little lower than the epigastric, is sometimes wounded, and may, from its large size, cause embarrassing, if not fatal, hemorrhage. It may be secured, in the first part of its course, in the same manner, very nearly, as the epigastric, the incision being made close to, and parallel with, Poupart's ligament, its centre being opposite the internal ring. Farther out, it may be exposed by dividing the tendon of the external oblique muscle within half an inch of the margin of the ilium, where it is firmly bound down by the transverse fascia.

LIGATION OF THE FEMORAL.

The common femoral artery begins on a level with Poupart's ligament, and terminates from an inch and a half to two inches below in the superficial and deep femoral, the former being its direct continuation. The vessel, in all this course, is perfectly superficial, being covered merely by the skin, fascia, and aponeurosis; it is involved, however, in a number of lymphatic ganglions, which, when enlarged, may receive the pulsation of the artery, and so simulate aneurism. The femoral vein lies on the inside of the vessel, in the same sheath, and great care is required in separating it previously to passing the ligature. The femoral nerve lies external to the artery, and is, therefore, not endangered in the operation. Exposure of the artery is easily effected by a vertical incision two inches in length; the needle should be conveyed from within outwards.

Ligation of the superficial femoral artery is often necessary on account of wounds involving its continuity, and, until a comparatively recent period, it was almost exclusively practised for the cure of popliteal aneurism. If the artery is severed by a cut, or pierced by a sharp-pointed body, it is evident that it should be secured at the site of injury, the wound being, if necessary, enlarged, and a ligature applied to each extremity of the vessel.

In aneurism, the artery may be tied at two points of its extent, the superior and middle, the former being, however, by far the more eligible, as the vessel here is comparatively superficial, and therefore easy of access. Its course along the thigh is indicated by a line extending from a quarter of an inch within the centre of Poupart's ligament to the inner margin of the patella. In the upper

third of the limb, it lies immediately beneath the skin and aponeurosis, its pulsation being easily felt as it runs along the inner margin of the sartorius muscle. This space is from four to five inches in length, and is of a triangular shape, its base being formed by Poupart's ligament above, and its apex by the convergence of the sartorius and adductor muscles below. The femoral vein descends along the inner border of the artery, and is inclosed in the same sheath; the connection between them is very firm and intimate, and it therefore requires great caution to effect their separation. The femoral nerve lies on the outside of the artery.

To expose the artery in this part of its course, an incision should be made along the inner border of the sartorius muscle, beginning about two inches and a half below Poupart's ligament, and extending obliquely downwards to the inferior extremity of the triangle through the skin and superficial fascia. A portion of the aponeurosis is now pinched up with the forceps, and a horizontal opening made into it just large enough to admit the point of the probe, upon which the sheath of the vessel is carefully divided for about nine lines. The artery is separated from the vein in the usual manner, but with extreme caution, and the ligature passed from within outwards, close to the former vessel. Injury to the vein would be a serious calamity, as the patient might perish from phlebitis. The occurrence is usually denoted by a gush of black blood upon drawing out the thread. Pressure will readily arrest the flow, and the vessel must on no account be tied, as such a procedure would inevitably give rise to a bad form of suppuration, the ligature acting very much as a seton, exciting and keeping up morbid action. A little nerve occasionally runs down in front of the artery; should this be the case, it must be drawn out of the way.

The femoral artery, in its middle course, as seen in fig. 283, is deep-seated, lying under cover of the sartorius muscle, which must, consequently, be turned to one side in the act of exposing it. The corresponding vein will be found external to the artery. In some instances it is double, and then the artery runs between the two vessels, closely hugged by them. In operating upon the superior portion of this space, just below the triangle above described, the incision should be made along the inner edge of the sartorius, which is then everted so as to afford free access to the vessel as it lies beneath the aponeurosis. If, on the other hand, the lower site be selected, the cut should be made on the outside of the muscle; but no one will be likely to do this if he can avoid it, as the operation will be both tedious and difficult, and possesses no advantages whatever over the more common procedure.

The femoral artery is subject to certain anomalies which should not be forgotten when we undertake its ligation, as they might seriously affect the result. The most important of these anomalies are the following:—First, the high division of the artery, the vessel separating a short distance below Poupart's ligament into two branches, which go to form the posterior tibial and peroneal. Secondly, the artery may be double, the supernumerary one giving off the branches usually furnished by the profunda. Thirdly, it may consist of two equal trunks which afterwards unite to form the popliteal. Sir

Fig. 283.

Ligation of the femoral artery in its middle course.

anomaly in a negro upon whom he operated for popliteal aneurism, the two vessels coalescing as they entered the ham. In this case the blood in the sac had in a great measure coagulated, notwithstanding that the circulation through it had been maintained by the artery, which had not been excluded from the ligature. A similar instance occurred to Sir Astley Cooper. An abscess formed in the sac, after the detachment of the ligature, and the patient died of hemorrhage. The dissection showed that a large branch had been given off by the femoral artery above the point of ligation, and had again united with that vessel just before it terminated in the popliteal, thereby feeding the tumor, and preventing its obliteration. A case of the entire absence of the superficial femoral artery has been recorded by Manec, its place having been supplied by the sciatic which passed down along the back of the limb to become the popliteal.

Compression of the femoral artery is often necessary on account of hemorrhage, either of this vessel itself, or of some of its branches. It is also frequently employed for the purpose of controlling the circulation of the limb in amputations of the thigh and leg; and latterly, it has been much resorted to for the cure of popliteal aneurism, having, in many cases, superseded the use of the ligature. When the object is to arrest the flow of blood, or stanch hemorrhage, the most suitable point for its application is the margin of the pubic bone, which is separated from the artery only by the pectineal muscle, and upon which, consequently, the pressure may be made with great efficiency. The best instrument for the purpose is the thumb of a stout assistant, or the handle of a large key, resting upon a small, thick pad. The more concentrated the pressure is, the more efficacious it will be in stopping the bleeding, and in preventing injury to the accompanying vein and nerves, circumstances that must not be overlooked in such a procedure. If the force is applied with the thumb, it may often be maintained for several successive days without detriment to the parts.

The other situations at which the artery may be compressed are the upper part of the thigh, just below Poupart's ligament, and those portions of the limb where the vessel may be pressed against the shaft of the femur, by directing the instrument outwards and backwards. When the compression is designed to be permanent, as in the treatment of popliteal aneurism, it should be frequently varied, making it now at this point, and then at that, as it may be painful or otherwise; and it is, moreover, of great importance, under these circumstances, that the instrument with which it is applied should not completely encircle the extremity, lest it impede the return of the blood in the veins, and thus occasion swelling and other mischief.

LIGATION OF THE DEEP FEMORAL.

The deep femoral artery has been known to be the seat of spontaneous aneurism, but the occurrence is extremely rare, and very difficult of diagnosis. The profound situation of the tumor, underneath the muscles at the anterior and inner part of the thigh, will usually serve to throw some light upon its character; but the only reliable sign is the continuance of pulsation, thrill, and bellows' sound, with somewhat of an augmented intensity, in the swelling, when firm pressure is made upon the superficial femoral, about two inches below Poupart's ligament, so as to direct the blood with increased force into the deep vessel. The proper remedy, in such a case, as well as in traumatic aneurism, would be ligation either of the affected artery, or of the common femoral, an inch below its origin, where it may be felt beating immediately beneath the skin and aponeurosis. The application of the ligature to this vessel is sometimes required on account of hemorrhage.

The deep femoral is usually given off by the common femoral, from an inch and a half to two inches below Poupart's ligament; sometimes, however, it is detached considerably higher up, and occasionally it is furnished by the external iliac or by the femoral, immediately after the commencement of this vessel. The artery, soon after its origin, passes inwards, behind the superficial trunk, and gradually places itself under cover of the long adductor muscle, between which

and the great adductor it afterwards descends towards the femur, near which it pierces the latter muscle, and finally disappears on the posterior part of the thigh. When this vessel is injured, the wound will, of course, serve as our readiest guide to it; and, in that event, two ligatures will always be necessary to put an effectual stop to the hemorrhage. In case of aneurism, the artery may easily be exposed, near its origin, by an incision similar to that which is made in ligating the common femoral, or the superficial femoral, in the superior portion of its extent, beginning an inch below Poupart's ligament, and descending obliquely in the direction of the inner border of the sartorius muscle. The deep trunk may then be readily traced to the requisite extent, and should be encircled a few lines below the origin of its two circumflex branches.

LIGATION OF THE POPLITEAL.

The popliteal artery, situated deeply in the cavity of the ham, in close relation with numerous important structures, is very difficult of access, especially in fat subjects. Fortunately it is seldom necessary to attempt its deligation, as wounds and traumatic aneurism here are of extremely infrequent occurrence. The artery is in intimate connection by its outer and posterior surface with the popliteal vein, from which it is not always easily detached. Sometimes the vein is double, and then the artery lies between the two trunks, closely and firmly embraced by them. The popliteal nerve is separated from the vessels by a thick layer of fat; superiorly it lies exterior to the artery, but as it descends towards the leg it gradually winds round it to place itself along its internal border.

There are two points at which the popliteal artery may be exposed for the application of the ligature; these are its superior third and its inferior third. The middle portion of the vessel is never interfered with, on account of its great depth, its near proximity to the knee-joint, the unyielding character of its lateral boundaries, and its intimate connection with the accompanying vein and nerve.

The artery may be ligated in the upper third of its extent, where it is more accessible than anywhere else, by carrying a vertical incision along the outer border of the semi-membranous muscle, for about three inches, extending down as far as the popliteal nerve. The muscle is then drawn inwards and the nerve outwards, when, by the cautious use of the forceps and handle of the knife, the vein and artery will be easily found, and must be gently and carefully separated from each other, the needle being passed from without inwards.

Exposure of the artery, in the lower third of its extent, may be effected by a vertical incision between the heads of the gastrocnemial muscle. Care is taken not to injure the posterior saphenous vein and nerve, which lie close by, but to draw them, along with the popliteal nerve, away from the knife. The artery will be found to be deeply imbedded in the ham, partially concealed by the popliteal vein, but projecting somewhat to its outer side.

In our attempts to expose the popliteal artery, care must be taken not to make too free a use of the knife, for fear of wounding the articular branches which are given off at a right angle, and which might, if injured, be a very embarrassing hemorrhage.

Fig. 284.

Ligation of the popliteal at its upper and lower parts. *a*. The popliteal vein *b* The popliteal artery *c* The posterior saphenous vein. The popliteal nerve, on the outside of the artery, has been omitted in the diagram.

LIGATION OF THE ANTERIOR TIBIAL.

The anterior tibial artery may require to be tied on account of hemorrhage or traumatic aneurism, and the best plan always is to take the external wound as our guide to the seat of the injury. The vessel, whose course is indicated by a line drawn from the head of the fibula to the base of the great toe, may be secured at three different points.

The artery, in the superior third of its extent, lies underneath and between the anterior tibial and common extensor muscles, and may be exposed by a vertical incision, four inches in length, carried down in the direction of the line just mentioned. The skin and superficial fascia being divided, the aponeurosis is to

Fig. 285.

be split open upon a director to the full extent of the outer wound; the two muscles are then to be separated from each other along their raphe, and the artery, which lies in close contact with the interosseous ligament, is surrounded with the ligature, in such a manner as not to injure the accompanying veins. The anterior tibial nerve is exterior to the vessels.

In the middle third of the leg, the relations of the vessel are essentially the same as in the upper, except that the long extensor of the toe is interposed between the anterior tibial and common extensor. The artery is still deep-seated, and a long incision is required for its full exposure. A branch of the peroneal nerve sometimes attaches itself to the artery here, and must be drawn away before passing the ligature.

In the inferior third of the limb, the artery lies on the tibia, between the tendons of the common extensor of the foot and the proper extensor of the great toe, the latter overlapping it on the inside. The vessel here is, therefore, comparatively easy of access.

The *dorsal artery* of the foot, the continuation of the anterior tibial, may easily be tied in any portion of its extent, as it runs down across the instep, its course being indicated by a line extending from the centre of the ankle-joint to the posterior extremity of the first interosseous space. It lies under cover of the integuments and aponeurosis, and may readily be exposed by carrying the knife along the outer border of the tendon of the long extensor muscle of the great toe.

LIGATION OF THE POSTERIOR TIBIAL.

The posterior tibial artery occasionally requires ligation on account of wounds, and, if the operation is performed high up, the task is one of the most arduous and perplexing that a surgeon can be called upon to execute. It has fallen to my lot to tie it in this situation in two instances, and the difficulties in

both were very great, having been increased tenfold by the confused condition of the parts, in consequence of the large quantity of extravasated blood. In one of the cases the artery had been laid open by a pistol ball, and in the other by a dirk-knife: the hemorrhage was profuse, and could only be effectually controlled by the ligature.

The situation of this artery is very deep; its course, at first obliquely inwards, and then vertical, is indicated by a line extending from the inferior border of the popliteal muscle to the fossa between the heel-bone and the inner ankle. It is covered in the superior two-thirds of its extent by the gastrocnemial, soleal, and

plantar muscles, but during the remaining portion it lies immediately below the integuments, except at its commencement, where it is slightly overlapped by the tendo Achillis. It is accompanied and embraced by two veins, one being on each side of it. The attendant nerve lies internal to it in the upper part of the leg, but as it descends it crosses the artery superficially, and places itself along its outer margin. The posterior tibial artery is sometimes double.

The artery may be exposed and tied in the upper and middle portions of its extent in one of two ways. The first consists in detaching the gastrocnemial muscle for about four inches along the inner border of the tibia, and cutting across the inner head of the soleal, by reflecting which we come directly down to the posterior layer of the aponeurosis of the leg, the free division of which brings the vessel at once fully into view. Care must be taken to avoid the internal saphenous vein, which runs close along the line of incision. In the other method, originally suggested by Mr. Guthrie, the artery is laid bare by a long, vertical cut, extending through the centre of the muscles of the calf. Its advantages are, first, that the artery being more directly approached, is more effectually under our control, and, secondly, that there is less danger of bagging, if blood and pus are poured out. The length of the incision need not exceed that in the other operation, and the hemorrhage is generally insignificant.

The posterior tibial sometimes requires ligation in the lower portion of its extent, between the heel and ankle. Taking its pulsation for his guide, the surgeon makes an incision, about two inches in length, directly along its track, which is nearly midway between the two points here indicated. The direction of the incision should be somewhat curvilinear, with the concavity towards the inner malleolus. The artery here lies beneath three aponeurotic layers, which must be successively divided upon the director, when the needle is passed under the vessel from behind forwards, care being taken not to include the accompanying veins and nerve.

In consequence of the superficial situation of this artery in the lower portion of its extent, a convenient point is afforded between the inner malleolus and the tendo Achillis for the application of pressure in the treatment of hemorrhage of the sole of the foot. The effect may be greatly increased if the circulation is also arrested in the anterior tibial, as may readily be done by placing a compress over it, just above the joint. A bandage is then extended from the toes upwards as far as the ankle, round which it is to be passed in the form of the figure 8, until the bleeding is completely arrested. Sometimes a metallic arch may advantageously be stretched across the front of the joint, one end resting upon each compress, the object being to ward off injurious pressure.

The two *plantar arteries*, the terminal branches of the posterior tibial, begin opposite the two heads of the abductor muscle of the great toe; they are deep seated, and, when injured, are often a source of troublesome and annoying hemorrhage, owing to the remarkable freedom of their anastomoses. All precepts for exposing and tying these vessels, founded upon their anatomical relations, are useless. The best plan is to make an external wound, and to provide an abundance of room for the ligature, by taking care to cut in the direction of the length of the

Fig. 286.

Ligation of the posterior tibial, at various parts. The wounds are held asunder, and the ligature is under the vessel.

LIGATION OF THE PERONEAL.

The peroneal artery, after running a short distance, passes obliquely downwards and outwards to reach the fibula, along which it descends until it arrives near the outer malleolus, where it divides into its two terminal branches. It may be secured, in the upper portion of its extent, by making an incision, long and vertical, through the bellies of the gastrocnemial and soleal muscles; and inferiorly, as it lies between the outer malleolus and the tendo Achillis, by a cut at least two inches and a half in length, directed upwards and outwards towards the fibula. The vessel here rests upon the interosseous ligament, under cover of the long flexor of the great toe, which must be detached as far as it may be necessary from the bone, and drawn outwards.

CHAPTER VI.

INJURIES AND DISEASES OF THE VEINS.

THE affections of the veins requiring to be noticed under this head are, wounds, hemorrhage, inflammation, varicosity, the formation of phlebolites and the introduction of air.

SECT. I.—WOUNDS.

Of wounds of the veins not much need here be said, as they rarely exhibit any difficulty in regard to their treatment, or much danger in respect to their termination. Like wounds of the arteries, they may be produced by various weapons, and are, therefore, distinguished by different names, as incised, punctured, lacerated, contused, and gunshot. They are always followed by more or less hemorrhage, according to the size of their caliber, the blood issuing from them in a continuous stream, of a dark, purple color. When the division is complete, there is hardly any retraction, or annular constriction, and hence the bleeding often progresses until it proves fatal, especially if the vessel is large and superficial, as in wounds of the jugular and femoral, fainting not materially favoring the formation of a clot. Partial wounds, of whatever direction, will also bleed copiously, if they are at all extensive, and no mechanical obstacle is offered to the flow of blood. If the incision is small, exhibiting the character rather of a puncture than of a cut, the bleeding, after having continued for some time, will gradually cease, in consequence of the formation of a minute, but gradually increasing, clot upon the edges of the wound. These phenomena may often be witnessed in ordinary venesection at the bend of the arm, the clot adverted to constituting one of the impediments to the flow of the blood, and occasionally compelling the operator to open another vein. In gunshot wounds, severing a large vein, the hemorrhage frequently proves as suddenly fatal, or nearly so, as in corresponding lesions of an artery; or, life being preserved by the narrow state of the wound, or the valve-like disposition of its walls, the blood may be extensively, and perhaps most prejudicially, infiltrated into the intermuscular and subcutaneous cellular tissue.

The chief danger from wounds of the veins arises from loss of blood and inflammation of their tunics. The latter occurrence is occasionally observed as a consequence of the operation of bleeding at the arm with a foul or blunt lancet. In ordinary cases, however, there is little risk of this kind, the parts readily uniting by adhesive action, since there is no impediment to this process from the sanguineous current, as there is, under similar circumstances, in an artery; all is

calm and quiet within, and the most extensive wounds are often repaired in an almost incredibly short time.

The *treatment* of a wounded vein is generally very simple, merely by compress and bandage, and attention to position. If seated superficially, the mere bringing together of the edges of the breach generally promptly arrests the hemorrhage without any direct application to the vein itself. In the operation of bleeding, the only dressing commonly employed, after the necessary quantity of blood has been evacuated, is a small pledget of muslin, placed immediately over the part, and confined by means of a roller. The slight inflammation which follows furnishes the requisite amount of plasma, and in less than twenty-four hours the union is generally so firm as to render it difficult to break it. The rule with all good surgeons is never to tie a vein, in any case, or under any circumstances, if it can possibly be avoided; not that such an operation involves any special difficulty, but because of its liability to be followed by severe inflammation, of a diffusive, erysipelatous character, tending to extend into the larger trunks and thence on towards the heart. Cases, nevertheless, occasionally occur, as in wounds and operations about the neck, axilla, groin, and thigh, where, from the extensive character of the lesion, and the impossibility of arresting the hemorrhage by compression, the ligature must be employed at all hazard; and it is gratifying to know that, although such a procedure is perhaps never entirely free from danger, it is often crowned with the most complete success.

Rest is of great moment after wounds of the veins; it should be absolute, for the slightest motion may break up the adhesions, and thus endanger the part by inflammation. Exclusion of the atmosphere is also very desirable, and may be secured by compress and bandage alone, or by these means, aided by collodion.

SECT. II.—DISEASES OF THE VEINS.

Inflammation of the veins, technically called phlebitis, is occasionally an idiopathic affection; most commonly, however, it arises from injury inflicted either directly upon these vessels, or indirectly through other structures. It frequently follows upon severe accidents and surgical operations, and, when this is the case, it is apt to give rise to pyemia, or multiple abscess, a disease which, as stated elsewhere, nearly always proves fatal. Phlebitis is a much more common affection than arteritis, and differs from this lesion still further in its liability to terminate in suppuration, which arteritis seldom does, the ordinary product of the latter being plastic matter, not pus. Another peculiarity of phlebitis is its tendency to extend along the vessels towards the heart, thus greatly increasing its dangers. Recent researches, however, render it probable that this tendency is much less frequent than was formerly imagined. The affection is sometimes confined to one vein; but, in general, it involves a considerable number, either simultaneously or successively. In the former case, it is said to be circumscribed; in the latter, diffused. Finally, it may be acute or chronic.

1. ACUTE PHLEBITIS.

The symptoms of acute phlebitis are not always well marked. When the affected vessels are superficial, their course is generally indicated by the existence of a corresponding number of red lines, which, on applying the finger, feel like hard, rigid cords, exquisitely sensitive to the touch, and reaching from the seat of the injury up the limb as far as the eye can follow them. The discoloration, which varies from a faint, rosy tint to deep red, or even purple, according to the intensity of the morbid action, gradually diffuses itself over the surrounding surface, and eventually exhibits all the characters which distinguish that of erysipelas. Considerable swelling usually attends, not unfrequently pitting on pressure. The pain is of a sharp, smarting, or burning nature, and is generally so severe as to deprive the patient effectually of rest.

The constitution always deeply sympathizes comparatively limited extent. The disease is often,

chilly sensations, if not actual rigors, alternating with flushes of heat; the pulse is frequent, quick, and irritable; the skin hot and dry; the stomach nauseated and otherwise disordered; the bowels costive; the urine scanty and high-colored.

Fig. 287.

Phlebitis; a section of the femoral vein, occupied principally by fibrinous clots.

If the patient was in ill health immediately prior to the attack, the symptoms will usually be of an adynamic character from the beginning; or, if not, they will soon become so. Excessive prostration, delirium, an icterode state of the countenance, gastric irritability, and great restlessness are commonly prominent symptoms in every severe case of phlebitis.

The *anatomical characters* of acute phlebitis are swelling, opacity, and pulpiness of the internal membrane of the veins, with uniform redness, varying from light pink to deep florid. The middle and outer coats soon become profoundly injected, and their proper substance, although at first preternaturally soft and humid, is at length rendered so dense and firm that the vein feels like a hard, contracted cord. The cavity of the inflamed vessel is filled with clotted blood, as seen in fig. 287, sometimes blended with pus or lymph, and in many cases it is lined by a false membrane, susceptible, under certain circumstances, of organization. Instances occur in which the pus is infiltrated into the substance of the vein, or collected into small abscesses beneath the serous lining. The pus of phlebitis is generally an imperfectly elaborated fluid, containing a large quantity of plastic matter, and comparatively few characteristic globules.

Acute phlebitis is always a dangerous, and often a fatal, disease, few persons recovering when the morbid action is well established, or extensively diffused. This remark is true both of the traumatic and idiopathic forms of the disease; also of external and internal phlebitis, or of inflammation of the superficial and deep-seated veins. The pus formed in the affected vessels, commingling with the blood, soon poisons the system, and thus renders the heart, brain, and spinal cord unfit for the performance of their functions.

The *treatment* of phlebitis cannot be conducted with too much caution. When the disease is situated superficially, an attempt should be made, by leeches, blisters, iodine, and nitrate of silver, to circumscribe the morbid action, and thus prevent the formation of pus. Such a result, however, is not to be expected when the disease involves the internal or deeper veins, where the inflammation often makes great, if not irreparable, progress before the surgeon is aware of its true character, and where, consequently, treatment of every kind is of little or no avail. All lowering measures are generally inadmissible, even when the patient is comparatively young and plethoric; debility, great and marked, is sure to arise, and to call imperatively for the use of tonics and stimulants. Purgatives are exhibited to clear out the bowels and correct the secretions; and mercury is given in frequent and liberal doses with a view to early and decisive constitutional impression, the best form being calomel, or calomel and blue mass. The addition of morphia will be required for the threefold purpose of preventing undue purgation, allaying pain, and inducing sleep. The best stimulants are milk punch, quinine, and iron, especially the tincture of the chloride.

If abscesses form, their contents must be evacuated by early and free incisions; the internal organs must be diligently watched, and any complications that may arise must be met by appropriate measures.

2. CHRONIC AFFECTIONS.

The characters of chronic inflammation of the veins differ considerably from those of the acute form. The coats of the vessels are usually so much thickened, hypertrophied, and indurated as to preserve, when cut across, their cylindrical

figure, like an artery. The redness is of a brownish tint, interspersed with numerous shades of gray, violet, or purple; and the inner membrane, which is rough and shrivelled, may easily be raised in large opaque shreds. In some instances, the vein is dilated, or contracted, obstructed with clotted blood, lined by lymph, or filled with pus.

The disease sometimes passes into *ulceration*, but the occurrence is much less frequent than in the arteries. Commencing most commonly at one or more points of the inner membrane, it gradually extends to the other tunics, which it sometimes completely erodes. The immediate effect of this accident is an effusion of blood, which may be so great as to produce fatal results. The ulcers, which affect various forms, are occasionally quite numerous, and spread over a large extent of surface.

Chronic phlebitis is observed chiefly in the veins of the inferior extremity, and in those of the spermatic cord and of the ano-rectal region, as a complication of hemorrhoids. The principal symptoms are pains, of a sharp, pricking, or dull aching character, tenderness on pressure, and a sense of fulness or distension at the seat of the disease. The treatment is gently antiphlogistic, removal of the exciting cause constituting an object of primary importance.

There are certain states of the system in which the veins attain a very great size, and, consequently, carry an inordinate amount of blood. This *hypertrophy*, for so it may be termed, is very conspicuous in chronic affections of the joints, and in various kinds of tumors, both vascular and malignant. It is always conjoined with hypertrophy of the arteries, and forms one of the most serious obstacles to the cure of certain diseases.

Obliteration of the veins is by no means uncommon, and is almost always the result of inflammation. Sometimes it is caused by the pressure of a tumor forcing the sides of the vessel closely in contact, and so converting it into a dense, ligamentous cord. The largest veins are sometimes thus obliterated. Such a condition is extremely apt to be followed by dropsical effusions and other ill effects inimical to health and life.

Loose concretions, *phlebolites* or vein-stones, as they are termed, varying in size from a current to a pea, are occasionally found in the interior of these tubes. Commonly of a yellowish, brownish, or bluish color, they are of a hard, brittle consistence, and of an oblong, oval, or spherical form, with a smooth, even surface. When divided, they are found to be made up of several thin but distinct lamellæ, disposed concentrically around a small delicate nucleus, frequently consisting of fibrin. The number of these concretions is extremely variable; occasionally as many as ten, twenty, or even thirty are observed. They are generally met with in the smaller veins; more frequently, perhaps, in the spermatic, uterine, vaginal, vesical, hemorrhoidal, and splenic, than in any other. In the saphenous and its branches, they often exist in connection with varicose enlargement. Their composition is principally phosphate and carbonate of lime, with a small amount of animal matter, probably albumen, and a trace of oxide of iron.

SECT. III.—VARIX.

A varicose and dilated state of the veins is by no means uncommon, especially in the lower classes of working people, and in mechanics whose avocation compels them to maintain habitually the erect position. The veins which are most liable to suffer in this respect are those of the inferior extremity and of the spermatic cord, but those of the abdomen, scrotum, vulva, trunk, and face are also occasionally implicated, while those of the superior extremity are almost exempt from the disease. Of the deep-seated veins, those most frequently affected are the jugular, azygos, subclavian, and hemorrhoidal. I have met with quite a number of cases where there was apparently a varicose diathesis, almost all the principal veins in the body being abnormally tortuous and dilated.

Age seems to exert a remarkable predisposition to this disease. Thus, varicose enlargement of the spermatic veins is most common in young men soon after the

age of puberty; while, in the inferior extremity, the greater number of cases occur after the thirtieth year. In the hemorrhoidal veins, the malady is most frequent in elderly subjects.

The veins, in this disease, are preternaturally large, tortuous, knotty, and convoluted, or as if they were folded upon themselves, being augmented both in diameter and length, and observing a singularly serpentine course as they proceed to their place of destination. Their coats are hard, dense, and elastic, rolling under the finger like fine cords; with, here and there, a portion that retains its normal characters, or that is uncommonly thin and expanded, as if it

were ready to give way under the slightest exertion. In cases of long standing, they frequently offer a good deal of resistance to the knife, perhaps even emitting a sort of grating noise. On being laid open, they are found to be rough and irregularly sacculated, strong bands being sometimes stretched across their interior, which divide the tube into small cells, occupied by coagulated blood, phlebolites, or fibrinous concretions, in a state of organization. In the advanced stages of the disease, many of the valves are broken down, if not completely destroyed, while in recent cases they are simply thickened, indurated, displaced, or ruptured. These changes, which are generally most conspicuous in the internal saphenous vein and its branches, are obviously brought about by chronic inflammation, or by repeated attacks of the acute form of that disease, and often lead to great and irreparable mischief. Occasionally, the affected vessels are converted into dense, rigid, and impervious cords, altogether disqualified for the discharge of their functions.

The state of the vessels here described is well depicted in fig. 288, taken from a

Varix of the leg

patient of mine, a stout, robust laboring man, upwards of fifty years of age. The enlargement, which was much greater than any of the kind I ever saw before, was principally situated on the inner surface of the limb, and was associated with similar disease of the veins of the scrotum, penis, and abdomen.

The disease in question may be caused in various ways. In the inferior extremities of pregnant females, it is generally induced by the pressure of the distended uterus, creating a mechanical impediment to the return of the blood in the iliac veins, and, indirectly, in the saphenous. Wearing tight garters, drawers, or stockings, may also occasion the disease, and a similar effect is brought about by the habitual maintenance of the erect posture. Hence, the disease is very common in persons who are compelled to stand much. Varix of the hemorrhoidal veins generally depends upon habitual distension of the rectum and frequent straining in defecation. The causes of varicocele are still imperfectly understood, although there is reason to believe that the disease is most commonly developed under the influence of onanism, and other mechanical obstruction calculated to weaken the spermatic veins.

A natural predisposition to varicose enlargement occasionally exists in certain individuals; the veins seem to be unusually large and feeble, and to become tortuous and dilated under the most trifling obstacles to the onward movement of their contents. When this is the case, the disease often occurs simultaneously in different parts of the body, superficial as well as deep.

The effects of varicose veins vary according to the situation of the malady.

In the legs, the pressure of the enlarged and distended vessels is always productive of a good deal of pain, of a pricking or stinging nature, of tumefaction of the skin and cellular tissue, and of more or less tenderness along the track of the affected veins. In the more aggravated cases, ulceration of the integuments is apt to take place, commencing usually at one particular spot on the inner surface of the limb, and gradually progressing until a large sore is established, called, from this circumstance, the varicose ulcer, which is always difficult to heal, and which occasionally extends into the enlarged veins, thus causing copious, if not fatal, hemorrhage. In the spermatic veins, the disease may give rise to atrophy of the testicle, and to distressing neuralgic pains; while in the hemorrhoidal it leads to the formation of piles, and other disagreeable symptoms.

Although the development of varix is generally slow, cases occasionally occur in which it progresses very rapidly. During the latter months of utero-gestation, the veins of the feet, legs, and thighs often attain an enormous bulk in a few weeks, and I have seen repeated instances of a similar kind in the spermatic and hemorrhoidal veins. In the inferior extremity, the disease, after having gone on for some time, often remains stationary for an indefinite period, neither perceptibly advancing nor receding. In some instances, it undergoes a sort of spontaneous cure; that is, inflammation is set up in the affected veins, and, this being followed by the formation of fibrinous concretions, their caliber is ultimately rendered completely impervious, thus compelling the blood to seek other channels. Instead of this favorable result, the inflammation sometimes leads to erysipelas, abscess, and even death. Varicocele never proves fatal, nor does varix of the hemorrhoidal veins, although both are, at times, a source of severe suffering.

Treatment.—The treatment of varix resolves itself into palliative and radical. The former consists, as the term implies, of the removal of the exciting cause of the disease, and the adoption of such remedies as are calculated to relieve the part and system of suffering without positively curing the malady. In varicocele, onanism must be interdicted; in varix of the hemorrhoidal veins, straining and constipation must be counteracted; and in varicose enlargement of the veins of the lower extremity, all sources of constriction must be removed, together with whatever else has a tendency to weaken, irritate, and inflame the diseased structures, and thereby occasion further enlargement. Giving artificial support to the affected veins often has a good effect. Hence the use of the suspensory bag in varicocele, and of the laced-socking in varix of the saphenous vein. In every form of the lesion, great benefit accrues from attention to the general health, and from the occasional administration of an active purgative, which, by clearing out the bowels, thus affords a freer passage to the blood in the diseased veins towards the heart. If the patient is very plethoric, he may sometimes advantageously lose blood. In varix of the legs commonly nothing affords more prompt and satisfactory relief than a good bleeding at the arm; and the same remedy must be called into requisition, along with astringent and anodyne lotions and perfect rest of the parts, when the veins are unusually tender and painful from an accidental access of inflammation.

For the *radical cure* of this disease numerous operations have been devised, a few only of the more important of which need be noticed here, as the rest have either fallen into merited neglect, or are too dangerous to justify their repetition. Besides, the claims of these different operations will more naturally come to be considered when we speak of the several varieties of varix, as varicocele and hemorrhoids. There are really but two operations which, according to my experience, should ever be resorted to for the permanent relief of this disease; these are the ligature and the caustic issue; and if we apply these remedies to individual forms of the lesion, we shall find that the former is exclusively adapted to varicocele and hemorrhoids, and the latter to varix of the feet, legs, and thighs. Both procedures are extremely simple, but, although this is true, they should never be employed without a thorough and protracted preparation of the part and system; and I deem this the more necessary, because, in the great majority of cases upon which we are obliged to operate, the disease is rather an inconvenience than a serious evil, threatening loss of limb and life. I will not pretend to assert

that there are no cases of varix where an operation is not absolutely necessary; to do this would be absurd; what I mean is simply that no man, however skilful or experienced, should endanger his patient's life by rushing headlong into measures which, if injudiciously used, may lead to the worst results. The preliminary treatment should be mild but of longer duration than in ordinary diseases; the object is to remove all irritation that may exist in the affected veins, to soothe and calm them, in order that they may be the better prepared to withstand the rude assault about to be made upon them. To accomplish this object the patient must be subjected to light diet, gentle purgation, and almost absolute rest in the recumbent or semi-erect posture, for at least a fortnight. This is the more important if he is plethoric, intemperate, or very excitable. When it is remembered how intolerant the veins are of injury and of surgical interference, such precautions cannot be considered as idle.

The operation with the ligature is either direct, as in piles, or subcutaneous, as in varicocele, and in either case it is as safe as it is effectual. The principle on which it operates is that of strangulation, by which the enlarged vessels are converted into a slough, which is subsequently detached by ulcerative action. For this purpose it is necessary to draw the cord with great firmness, so as to produce the result in question in the shortest possible period, as well as with the least suffering. When the ligation is direct, as in hemorrhoids, it is always necessary to encircle the base of the tumor, or to tie it as near as practicable to its point of attachment to the bowel. When the base is unusually large, it is sometimes transfixed with a needle armed with a double ligature, one of which is then drawn round each half of the morbid growth, the object being its more effectual strangulation. The subcutaneous operation is particularly applicable to varicocele, to which, in my judgment, it ought to be exclusively limited. It is performed by means of a stout spear-pointed needle and a strong ligature, introduced in such a manner as to avoid the spermatic cord, the instrument making only two punctures, one in front of the scrotum and the other behind, by retracing its steps after it has effected transfixion. The ends of the cord are then firmly tied in the usual manner, the pressure being increased from day to day until the ligature is detached.

In operating upon the veins of the inferior extremities, I am persuaded that the safest plan is the establishment of a series of issues, made with the Vienna paste, the proper mode of applying which will claim special attention in the section on varix in the second volume.

The *after-treatment* is not to be disregarded in these operations. The great danger is a bad form of erysipelas, connected, doubtless, with phlebitis, its tendency being to diffuse itself extensively over the system, and to give rise to typhoid symptoms. I have not myself, however, witnessed any such effects in any of my cases, and I am inclined to ascribe my good fortune more to the pains which I have always taken to prepare my patients than to any particular skill in performing the operation or in conducting the after-treatment, though no one could be more careful about this than myself. If everything goes on well, little else will be necessary than strict attention to the diet and quietude of the part and system, with an occasional purgative; if erysipelas supervene, opium, quinine, and iron will be indicated, along with milk punch, and the application of iodine, astringents, and emollient cataplasms.

SECT. IV.—INTRODUCTION OF AIR.

A fatal, though, fortunately, not a common occurrence, incident to certain operations, is the accidental introduction of air into the veins. It is most frequent in operations about the neck, face, and axilla, and was first noticed, as a distinct event, in 1818, by Beauchesne, in exsecting a tumor from the neck of a young man, in which it was necessary to disarticulate and raise the clavicle. At the moment of effecting this, the patient became faint, and, exclaiming that he was dying, expired in less than half an hour afterwards. The examination of the body revealed the existence of an aperture in the internal jugular vein, at

its junction with the subclavian, through which the air, causing the fatal result, had doubtless entered the circulation. Shortly after this, a similar accident happened to Dr. Mott and Dr. Stevens, as well as to several European surgeons, so that, in due time, the attention of the profession became fully aroused to the nature and importance of the subject.

The disastrous effects of the introduction of air into the venous circulation were known, long ago, to Wepfer, Vander-Heyden, and other physiologists; but they were lost sight of, in great measure, until attention was recalled to the subject by the experiments of Bichat, Nysten, and Magendie, who showed that a very small quantity of this fluid, suddenly injected into the jugular vein of dogs and other animals was sufficient, in most cases, to cause death almost instantaneously. On the other hand, it has been found that a large quantity, as, for example, several cubic inches, will not destroy life, if it is introduced slowly, the air, in this case, combining with the blood in such a manner as to prevent it from producing any serious mechanical inconvenience. Upon dissection, air is readily discovered in the cavities of the heart, as well as in other parts of the circulatory apparatus, thus accounting satisfactorily for the fatal event.

The *symptoms* which characterize the entry of air into the venous system are essentially those of cerebral apoplexy. The patient is generally seized, suddenly and unexpectedly, in the midst of the operation, with a sense of faintness, or a horrible feeling of terror, oppression, and exhaustion, inducing him to believe, and perhaps to exclaim, that he is dying. The countenance, in a moment, assumes a dark, livid hue, the body is agitated with convulsive movements, the breathing is slow, difficult, and stertorous, the muscles are completely relaxed, the pulse is feeble and almost imperceptible, the pupils are dilated, and the individual is wholly unconscious. In short, he dies in a state of profound coma, like a person in a fit of apoplexy. On applying the ear to the cardiac region, the action of the heart is found to be excessively oppressed, the organ struggling powerfully to overcome the mechanical obstruction caused by the admixture of the gaseous and sanguineous fluids, which, swept slowly and heavily along over the fleshy and tendinous columns, occasions a loud, churning noise, synchronous with the contraction of the left ventricle, and at the same time a peculiar thrill, or vibratory sensation, perceptible by the hand as it rests upon the chest.

Such are the effects which are usually observed when air has been introduced suddenly, even in small quantity, into the venous circulation; and there is a strong probability that they will steadily increase in severity until they prove fatal, despite the most judicious and energetic measures that may be employed to counteract them. The period at which death occurs varies from a few minutes to several hours; occasionally life is destroyed almost with the rapidity of lightning, and in most cases in from twenty to forty-five or fifty minutes. The fatal event, if not instantaneous, is always preceded by a rapid reduction of the temperature, and by a diffusion of the lividity over the whole body, the surface being of a leaden hue, as in death from asphyxia. Cases have been noticed where, after the symptoms had continued for some time in a very bad form, the purplish appearance of the cheeks was suddenly replaced by a reddish tinge, affording evidence, although generally of a deceptive character, of speedy reanimation and ultimate recovery.

The immediate cause of death, in this accident, has been variously explained; indeed, it is remarkable what little coincidence of opinion there is upon the subject among writers. From the fact that air has occasionally been found in the right cavities of the heart, after surgical operations in man, and in animals after experiments, it has been assumed that it was the inability of this organ to contract upon its contents, and thus send a sufficient quantity of blood to the lungs and brain for the due performance of their functions. Others have maintained that the primary trouble is in the pulmonary tissues. Thus, Mr. Erichsen supposes that it depends upon the manner in which the air and blood are beaten up together in the right cavities of the heart into a spumous fluid, which is unable to pass through the lungs, thus depriving the brain and spinal cord of their due supply of blood, and inducing fatal syncope, usually attended with convulsions. In

opposition to this view, it may be stated that, if air be injected in considerable quantity into the carotid artery of an animal, all the phenomena of apoplexy, such as stertorous breathing, loss of sensibility, and spasmodic rigidity of the muscles, will instantly be produced, and soon occasion death from obstruction of the cerebral circulation. Whatever of truth these different explanations may embody, it is evident that the secondary effect of the presence of the gaseous fluid, that which really causes the fatal termination, is the want of a sufficient quantity of oxygenated blood in the great tripod of life, the heart, lungs, and brain.

If the patient survive, the transition to health is seldom instantaneous; on the contrary, several hours generally elapse before he recovers his consciousness and strength. In a case mentioned by Dr. Warren, the man, after having lain in a state of insensibility for two hours and a half, awoke as if from a profound sleep, still breathing, however, like an apoplectic. The night was passed without any accident, and, on the following morning, he was as well as usual, except that he had a headache and some soreness in the chest. Sometimes the patient recovers from the immediate consequences of the accident, but dies afterwards from pneumonia, produced, probably, by the irritating effects which the fluid exerts upon the pulmonary capillaries, and through them upon the air-vesicles. Such an occurrence, however, is infrequent.

The local phenomena accompanying the introduction of air into the veins are of great interest, particularly in their diagnostic relations. In general, there is some noise, or sound, so loud and distinct as to be plainly perceived by the operator and his assistants, and which, occurring in combination with the sudden distress of the patient, is of the utmost value as a means of discrimination. In some cases, the sound is of a hissing nature, like that arising from air rushing into a narrow and exhausted receiver; in some, it is bubbling, clucking, or lapping; in some, gurgling, sucking, or licking. The immediate causes of these variations are, the size, shape, and situation of the opening in the injured vein, the quantity of blood in the wound, and the volume of the vessel and the relation which it bears to the surrounding parts. Whatever may be the nature of the sound, or the degree of its intensity, it cannot, when once heard, be forgotten, and is always clearly characteristic of the accident. In addition to this phenomenon, there is occasionally, but by no means constantly, an appearance of bubbles of air about the wound in the vein, especially if it is somewhat deep seated.

The veins through which air is usually spontaneously admitted in surgical operations are those about the neck, particularly the external and internal jugular and their immediate branches. It may also enter by the veins of the face, the axilla, and the chest. Thus, in one of Dr. Mott's cases, it passed in through the facial vein during the extirpation of an enlarged parotid gland. Dr. Warren met with an instance in which it was introduced by the subscapular vein; Clemot saw it enter by the veins of the chest; and Delpech had a case where it gained admission by the axillary vein. In operations on the trachea, and in the removal of tumors from the anterior part of the neck, the veins lying in this region might easily be wounded so as to let in air.

A case in which the introduction of a seton in the forepart of the neck was followed by the entrance of air into the veins occurred to Dr. Willis, of England, in 1848. The patient had labored under chronic laryngitis, and died in seven hours after the operation. The large cervical vessels were found, on the dissection, to be uninjured, but the right auricle and pulmonary artery were distended with frothy blood, and the lungs were emphysematous.

The reason why the veins in the localities here enumerated are alone subject to this accident is that they are under the influence of a suction action during inspiration, owing to a tendency to the formation of a vacuum within the chest during the expansion of the lungs. This action is naturally limited to the veins at the root of the neck, and it is here, therefore, that air is most liable to be introduced spontaneously; it may, however, as has already been stated, pass in through the veins of the face, axilla, and thorax, but in order to do this it is necessary that these vessels should be in the condition of rigid tubes, or in a state of

canalization; for if they are merely collapsed, flattened conduits, it is evident that the air will not be able to enter them, however freely they may be punctured. There are various circumstances which may induce this accidental canalization of a vein, of which the principal are the adhesion of its walls to the parts through which it passes, and the manner in which it is held during the operation, rendering it open-mouthed and gaping when divided. Sometimes the introduction takes place in a perfectly healthy vessel at a considerable distance from the root of the neck, in consequence of the tension into which it is thrown by the position of the head and arm, as happened in one of Warren's cases, where the air was admitted by the subscapular vein. The probability of this occurrence is much increased when operations are performed upon the neck, face, and axilla, for the removal of large tumors, especially such as are of a glandular nature, including veins of considerable size. In injury of the jugular veins the accident will be most likely to happen if the wound is made just above the clavicle, where the suction action is naturally strongest. Air thrown into the veins in remote parts of the body will destroy life as promptly and effectually as when it enters in the localities above alluded to, and the only reason why the accident does not occur in them is that the vessels are not under the immediate influence of the respiratory organs, as they are about the neck and chest. Legallois witnessed three cases of instant death in female animals from the introduction of air into the inferior vena cava and heart by the uterine veins.

Treatment.—The treatment of this accident is preventive and curative. For the former, different plans have been suggested, most of which may occasionally be adopted with advantage. In the first place, the operator should remember where, and under what circumstances, such an occurrence is most likely to happen; for, being thus put upon his guard, he will be more cautious in the movements of his knife, and thereby, in all probability, altogether avoid the much dreaded mischief. Secondly, when he is about to begin his incisions, he should request an intelligent assistant to compress at the root of the neck any veins that may be within reach, and, consequently, in danger of being injured in the early stage of the procedure. In conducting the deep dissection, he should make careful use of the handle of the scalpel, as well as of his fingers, to detach the morbid structures, or to separate the sound, as the case may be, and if he finds that any veins are included within them, so as to require to be severed, he should secure them at once with the ligature at the cardiac side of the tumor. Sometimes a temporary ligature may be proper, to be removed, or tied, after the completion of the operation, according to the exigencies of the case. It has been recommended that, when we are compelled to divide any of the vessels about the neck, the patient should be desired previously to make a full inspiration; such a procedure, however, would hardly be safe unless the vessel should become instantly collapsed, and remain so afterwards. Thirdly, in operating in the different regions under consideration, care must be taken to avoid those positions of the head and arm which are calculated to produce tension and canalization of the veins. Fourthly, it having been found that the entrance of the air into the veins can be prevented in the inferior animals by compressing the chest and abdomen, Mr. Erichsen strongly insists upon the propriety of swathing the body as tightly as the comfort of the patient will admit, with the view of compelling respiration solely by the diaphragm. Such a plan I should think of questionable utility, especially if the patient requires the use of an anæsthetic during the operation. Lastly, should the accident happen, notwithstanding every possible precaution, as indicated by the occurrence of the peculiar hissing, clucking, lapping, or gurgling noise, previously mentioned, or by the appearance of bubbles about the wound in the vein, compression must instantly be applied, and all further proceeding abandoned until the trouble is effectually remedied.

To recover a patient from the effects of this accident, various methods of treatment have been proposed, some of which are, to say the least, anything but philosophical. Thus the idea of sucking out the air from the injured vein, a plan proposed by a French surgeon, by the introduction of a suitable instrument, such as a silver canula or catheter, amounts to little less than positive absurdity;

for, independently of the difficulty and tediousness of such an operation, it would be far more likely to be followed by an additional entrance of air than the abstraction of that which has already been admitted. But, even granting, for the sake of argument, that a tube could readily be passed into the vein without the risk of letting in more air, it would not be practicable to remove the fluid from the lungs, which it must necessarily reach within a few seconds after the occurrence of the accident. Once admitted, no skill can dislodge it, either by this or any other means. When the patient is plethoric, and has lost but little blood during the operation, it has been recommended to open the temporal artery, on the ground that it might have the effect of removing cerebral and pulmonary congestion, and thus favoring the restoration of the circulation. The utter futility of such a procedure must be apparent, when it is recollected that this congestion depends, not merely upon an imperfectly aerated blood, but upon the presence of a spumous fluid, which the capillaries are incapable of propelling onward. The same remarks are applicable to the section of the right jugular vein, which, it has been alleged, might prove beneficial by unloading the corresponding cavities of the heart.

The fact is, all that can be done in any case of this kind, is to make an effort to support the system. With this view, the treatment should be conducted very much upon the same principles as in syncope from the loss of blood, or in asphyxia from drowning. The patient is laid at once recumbent, with the head and shoulders even lower than the rest of the body, and, if the circulation is still going on, firm pressure is immediately applied to the axillary and femoral arteries, for the purpose of allowing as free an access of blood to the heart and brain as possible. Sinapisms of the most powerful kind are applied to the extremities, the spine, and the precordial region, and the body is wrapped up in blankets, wrung out of hot water, at the same time that cold air is freely admitted to the nose and mouth. Brandy and ammonia are freely given, if the patient can swallow; otherwise these fluids must be promptly injected into the rectum. Finally, as a dernier resort, artificial respiration should be established, by means of a tube, introduced through the glottis, or through an opening in the larynx, and steadily and faithfully maintained, if necessary, until some time after all signs of breathing and circulation have disappeared.

CHAPTER VII.

AFFECTIONS OF THE CAPILLARIES.

THE capillaries are liable to enlargement, consisting of a species of hypertrophy of their tunics, with more or less dilatation of their caliber. The disease may be limited to the arterial capillaries, or to the venous capillaries, or it may involve both classes of vessels, constituting thus a kind of compound affection. However this may be, the consequence of the enlargement is the formation of a distinct tumor, which may eventually acquire a large bulk, and seriously compromise the safety of the patient, especially when it is of an arterial character. In many cases, if, indeed, not in all, the disease is congenital, having, perhaps, already made considerable progress at birth.

SECT. I.—ARTERIAL TUMORS.

The only arterial tumor, properly so-called, that can be recognized, in a practical sense, is that which was originally so ably and graphically described by

John Bell, of Edinburgh, under the name of aneurism by anastomosis. His account of the disease is by far the most clear and elaborate that has yet appeared, and it is remarkable that hardly anything of importance has been added to it by subsequent observers, either as it respects its anatomy, etiology, or mode of treatment. The only error which the Scotch surgeon committed was the assertion that the lesion was peculiar to adults, and that it was a perfect aneurism.

The most common sites of the arterial tumor are the scalp, lip, nose, orbit, eyelid, cheek, and chin; it may, however, occur in any part of the body, and I have repeatedly met with it upon the shoulder, trunk, fingers, and foot. Some years ago, I removed a considerable tumor of this kind from the big toe of a young man of twenty-two. I have also seen examples of the disease in the vulva of young girls. The texture in which it is usually situated is the cellular, especially the subcutaneous and submucous; I do not recollect ever to have seen it anywhere else, though its occasional occurrence has been noticed in the liver, spleen, and kidney.

This tumor is essentially composed of a network of arteries and veins, closely connected together by cellular or cellulo-fibrous tissue, as exhibited in fig. 289. It is, in fact, originally nothing but a species of hypertrophy of the capillary vessels, commencing in a little speck, perhaps, not larger than the head of a pin, and going on gradually enlarging until, at length, it acquires an enormous volume.

The arteries, which are free from the earthy and fatty degeneration, have a singularly convoluted arrangement, and, in cases of long standing, or of extraordinary bulk, some of them are often as large as a small goose quill; their walls are disproportionately thin and diaphanous, and from being pressed out laterally into short, blind pouches, it is very common for them to have a sacculated appearance. This increase in the caliber of the arteries is not limited to the tumor, but always extends some distance beyond its proper boundaries, as can readily be ascertained by a careful examination with the finger; in fact, it is sometimes easily detected with the naked eye. The general disposition of the veins is similar to that of the arteries; they are, however, usually less capacious, relatively considered, and hence the blood returns with less facility than in parts naturally constituted.

The tissue by which the vessels are connected together is, in the first instance, nothing but ordinary cellular substance, naturally existing in the part where the tumor is developed; it is perfectly soft, spongy, and extensible. In time, however, it necessarily undergoes important changes, brought about by the pressure exerted upon it by the impetuosity of the inflowing blood, and by its temporary sojourn in the midst of the morbid mass. Hence it is that, while in some situations it exists most sparingly, so much so, indeed, as to be hardly demonstrable, in others it is preternaturally abundant, and truly cellulo-fibrous.

Such are the grosser elements of this form of tumor. Examined more minutely, it is found to consist of a kind of areolar structure, the cells of which, varying in size from that of the smallest pin's head to that of a pea, freely communicate with each other, not unlike those of a sponge, by means of lateral pores. These cells, which exhibit every diversity of shape, are formed apparently by the ampullar expansions of the coats of the arteries, and bear, in their general character, a considerable resemblance to those of the erectile organs, as the penis and clitoris. In old tumors of this description, some of the sacs occasionally become closed, thus assuming, as it were, an independent existence. The cause of this occurrence is probably inflammation, leading either to direct adhesion of the contiguous surfaces of the arteries, or to the formation of coagula. The contents of these cysts are either sero-sanguinolent, or sanguineous. In the latter case they are generally solid.

Finally, the arterial tumor has no distinct, separate envelop; the only covering which it has is derived from the superincumbent structure, as the skin or mucous membrane, which, in time, becomes atrophied by the incessant beating of the blood.

Fig. 289.

Anastomotic aneurism.

beneath, and ultimately gives way by ulcerative action. In of the tumor is of a reddish scarlet hue, with, here and there so transparent as to allow many of the enlarged vessels to be seen. Occasionally a few granules of adipose matter overlie the tumor through its substance.

It will thus be perceived that this tumor is in reality not preceded and accompanied by the fibrous, earthy, or atheromatous, but simply an abnormal dilatation of the capillary arteries, the larger arteries in their immediate vicinity, and attended by a less developed state of the capillary and adjacent veins. It is clearly and distinctly, in a hypertrophied condition of these vessels, as was previously remarked, in a gradual evolution and growth, and veins from tubules that are imperceptible by the naked eye to an extraordinary size. There is no addition of new vessels, but the vessels formed out of those which naturally exist in the part, enlarge in length as well as in diameter, under the pressure of the afflux of blood. The coats of the vessels are not, it is true, as those of the arteries and veins, properly so-called, usually of great capacity is so much greater than what the part naturally must be regarded as a product of supernutrition, and nothing more.

The origin of the arterial tumor is often ascribed to the violence, as a blow or fall, and that it may occasionally be a probable; in general, however, it arises without any assignable cause or mother's mark. Indeed, I am inclined to think that the tumor is always congenital, even in those cases in which it is said to be acquired. This may be accounted for on the assumption that the tumor is usually so exceedingly minute as to have entirely escaped attention to assume an active character. However this may be, the disease is usually a little reddish speck, not larger than the head of a pin, perfectly free from pain, and seated just beneath the skin, or at least partly in the subcutaneous cellular tissue. Its growth is gradual, so that a number of months, and perhaps even several years, before it attains the volume of a pigeon's egg. Occasionally it increases with great rapidity, and soon acquires a frightful bulk. I had a striking illustration, not long ago, in a female child, at birth a reddish spot, as large as a dime, was observed on the left cheek. At the end of five weeks it had nearly doubled in size. A charlatan now applied some caustic substance, eventuating in a sore, which was the seat of occasional hemorrhage, healed in two months, leaving an unseemly scar, upwards of two inches in diameter, red, spongy edges. A year after the use of the escharotic, the child, the tumor was of immense volume, horribly disfiguring, occupying the whole of the left side of the face, extending forward to the mouth, upwards to the eyelid and temple, backwards to the neck, its antero-posterior diameter being half an inch, and the vertical six inches. The tumor, of a bluish color, and of a soft consistence, sensibly increased whenever the child cried, laughed, or coughed. At its lower and back part it had a peculiar bruit, synchronous with the action of the heart. During the day the inside of the cheek had become much enlarged, and now presented a red and bluish appearance. The upper jaw, along its alveolar process, evidently from the same cause, and was beginning to swell upon the mouth. The swelling was free from pain, and there was no derangement of the general health.

In general, however, the tumor proceeds more slowly, and is met with cases, in which, after having made some progress, it becomes stationary. When it begins as a nevus, it is not unusual as a little reddish spot for several years, when, its activity being why we know not, it grows with unwonted vigor, and soon ac-

The tumor has generally an irregular outline, and rarely projects more than six or eight lines beyond the level of the surrounding parts. It is soft and compressible, the finger sinking into it as it would into a wet sponge, but the moment the pressure is removed it immediately regains its former situation. Its color varies in different cases; when it occurs in the skin, or skin and cellular tissue, it is generally of a reddish hue, inclining to scarlet, especially in its earlier stages; but in old cases, and when it lies beneath the mucous membrane, it is more commonly of a bluish or purplish color. It beats and throbs synchronously with the contraction of the left ventricle of the heart, and imparts a peculiar aneurismal thrill to the finger. Its movements are often perceptible at a considerable distance, and are always sensibly augmented under the influence of mental emotion. When of considerable volume, the tumor may produce severe pain and other inconvenience by its pressure, but in most cases there is little local suffering or constitutional disorder.

Such a tumor sometimes ulcerates and sloughs, causing more or less hemorrhage, and ultimately perhaps death. Some years ago, I saw a female child, aged ten months, who had a congenital arterial nevus upon the right shoulder and arm, which gradually extended down towards the elbow; it was of a dark purple color, and of a soft, spongy consistence, throbbing and beating violently. The general health was good, but after some time ulcers began to form on different parts of the tumor, which now became very painful and inflamed; in a few weeks more gangrene set in, and, gradually progressing, soon destroyed the little patient. The hemorrhage which succeeds the ulceration of this tumor, although sometimes very profuse, seldom proves fatal; after the bleeding has continued for some time, the blood coagulates upon the abraded surface, and thus affords the vessels an opportunity of preventing further effusion. In the female, the hemorrhage is occasionally vicarious of the menstrual flux; the tumor becomes full and tense at the return of each period, and, giving way at the top, allows the blood to drain off, without serious injury to the part or system. It has been asserted that such a growth may degenerate, changing its primitive character, and assuming one of a worse kind, as the medullary or melanotic. Without altogether denying the possibility of such an occurrence, I have never seen anything to justify the conclusion.

Treatment.—The treatment of this form of tumor may be conducted by excision, escharotics, strangulation, injections, starvation, and, lastly, by amputation, as when the disease occupies one of the extremities. Besides these methods, there are several others of a more doubtful and less trustworthy character, which will be briefly noticed in their proper place.

a. Excision is chiefly adapted to small arterial tumors, before they have acquired much functional activity, or given rise to any marked enlargement of the neighboring arteries. The operation is then perfectly safe, easy of execution, and likely to be entirely successful. But if we wait until the tumor has attained a large bulk, beating and throbbing violently at every pulsation of the heart, as if it were ready to burst, the attempt, besides proving one of immense difficulty, may be attended with so copious a hemorrhage as to cause speedy exhaustion; we have then a formidable enemy to deal with, and we may consider ourselves happy if we do not let our patient perish from the loss of blood, gushing forth, as it will, in torrents, at every stroke of the knife. In such a case the prudent surgeon weighs well, before he begins his perilous operation, the chances of his success; he measures every inch of the unexplored territory, and equips himself thoroughly, at every point, for the trials and perplexities of his portentous undertaking.

When excision is determined upon, the rule of practice is, as John Bell long ago so correctly observed, not to cut into the tumor, but around it, and yet not so widely around it as to include an unnecessary quantity of sound tissue. The operation is performed rapidly, the finger of a good assistant quickly following the knife in order to compress any important artery that may be divided, until the whole mass is completely extirpated; and it will be wise, if practicable, always to arrest the circulation in the main artery leading to the tumor before we begin

the incisions. Removal being effected, upon the the principle here enjoined, the ligature may often be entirely dispensed with, all bleeding ceasing the moment the operation is over; or as soon as the edges of the wound are thoroughly approximated by the twisted suture, a mode of dressing peculiarly adapted to this form of disease, on account of the hemostatic influence exerted by its compression.

b. Small arterial tumors may often be readily destroyed by *escharotics*, of which I have found the Vienna paste to be preferable to any other, used as in making an ordinary issue. The paste is retained for fifteen minutes, being spread out sufficiently to cover the whole of the affected surface; the application is followed up by an emollient poultice, and when the slough is detached the sore is treated upon general principles. When the tumor is very large, and so situated as not to involve any important structures, interference with which might prove prejudicial, it may be attacked, either simultaneously or successively, at several points of its extent, for the purpose of converting the whole mass into an eschar. For obvious reasons the caustic should not be used upon those parts of the body which are habitually exposed, as the face and neck.

c. *Strangulation* may be effected by transfixing the base of the tumor with one or more pins, and then drawing a ligature firmly around them, so as to cut

Fig. 290.

Erectile tumor. The integument, uninvolved, has been reflected by flaps. Transfixion is being completed, previous to deligation. a The larger ligature, in the act of being pulled through. It fills the aperture of puncture, preventing bleeding, and, besides, bears a stronger strain on tying.

off at once, and effectually, its sanguineous supply. Or, instead of this, a stout double thread may be conveyed beneath and around it by means of a spear-pointed needle, provided with an eye, one cord being tied upon one side of the swelling, and the other upon the opposite side. If the integument be sound, the ligation is preceded by its careful division and reflection, as in fig. 290, in order that, when the morbid growth has been removed, it may be replaced, and thus serve to protect the parts from an unseemly cicatrice.

When the tumor is so flat and elongated as not to admit of inclusion by the quadruple ligature, recourse may be had to the ingenious expedient of Erichsen, which combines the great advantage of thorough strangulation with a small ultimate cicatrice, it being unnecessary to embrace an undue quantity of integument for the eradication of the disease. The operation is performed in the following manner:—"A long triangular needle is threaded on the middle of a whip-cord, about three

yards in length; one half of this is stained black with ink, the other half is left uncolored. The needle is inserted through a fold of the sound skin, about a quarter of an inch from one end of the tumor, and transversely to the axis of the same. It is then carried through, until a double tail, at least six inches in length, is left hanging from the point at which it entered; it is next carried across the base of the tumor, entering and passing out beyond its lateral limits, so as to leave, as shown in fig. 291, a series of double loops about nine inches in length on each side. Every one of these loops should be made about three-quarters of an inch apart, including that space of the tumor, and the last loop should be brought out through a fold of healthy integument beyond the tumor. In this way we have a

series of double loops, one white, and the other black, on each side, as in fig. 291. All the white loops should now be cut on one side, and the black loops on the other, leaving hanging ends of thread of corresponding colors.

Fig. 291.

Fig. 292.

Erichsen's mode of ligating vascular tumors.

"The tumor may now be strangulated by drawing down and knotting firmly each pair of white threads on one side and each pair of black ones on the other. In this way the tumor is divided into segments, each of which is strangulated, by a noose and a knot: by black nooses and white knots on one side, by white nooses and black knots on the other, as in fig. 292."

d. Starvation may be attempted in one of two ways; either by tying the arteries which immediately feed the tumor, or else by occluding the main vessels which lead to the parts where the tumor is located. Of these two methods, preference should always, if possible, be given to the former, on account of its having a more direct and controlling influence upon the arrest of the morbid growth; when the swelling is very large, the two plans may sometimes be advantageously combined. Ligation of the arteries in the immediate vicinity of the tumor should be performed at several points at once, otherwise but little impression will be likely to follow; and care is taken, in performing the operation, not to interfere with the proper substance of the tumor, lest embarrassing hemorrhage ensue.

Deligation of the main artery leading to the parts upon which the morbid growth is situated has hitherto been practised chiefly upon the common carotid, in aneurism by anastomosis of the orbit, face, and scalp. The success has been variable, but, in the main, not very flattering, and yet I conceive that the procedure may be very proper when no other treatment is available. The misfortune, perhaps, is, that it is always employed as a dernier resort, and it is, therefore, not surprising that it should have so often failed. Dr. Mott, many years ago, tied the common carotid artery on account of a large arterial tumor, involving both orbits, the nose, and part of the forehead, in a child only three months old; the mass gradually diminished in size, and became so much consolidated as to lead to the belief that it might afterwards be extirpated, if such a measure should be deemed expedient. The final result of the case has not been reported. In 1828, I assisted Dr. George McClellan in taking up the right common carotid for the cure of an aneurism of the corresponding side of the face and orbit, in a child five months old. The operation seemed to arrest the growth of the tumor for a fortnight, but, at the end of that time, its activity was again aroused, and it went on gradually and steadily increasing until it caused death by hemorrhage and constitutional irritation. Dr. Mussey, Dr. J. Mason Warren, and others, both of this country and of Europe, have tied both carotids for the cure of this disease. The first of these surgeons applied the second ligature, after an interval of twelve days, without the occurrence of any untoward symptoms. In the

case of Dr. Warren, a little upwards of a month elapsed between the first and second operations; no unpleasant effects supervened, and the patient, a man aged twenty-three years, made a rapid recovery, although the arterial tumor was of enormous size, involving the mouth, face, and neck. Professor Kuhl, of Leipsic, tied the left carotid in a man of fifty-three, and, in forty-one days afterwards, the right carotid, on account of an extensive arterial disease of the scalp. The patient recovered, but not without considerable cerebral disturbance and repeated hemorrhages from the tumor. In tying two such large arteries for the cure of this affection, it is important to allow a sufficient period to intervene between the two operations for the dilatation of the collateral vessels which supply the brain, so as to enable this organ to obtain the requisite supply of blood for the proper execution of its functions. Several cases, it is true, have lately been published, in which the ligation was performed after a very brief interval, without any serious detriment to the cerebral circulation, but this fact does not invalidate the necessity of this precaution in the class of maladies in question.

Mr. Oliver Pemberton, in a paper in the London Lancet, for May, 1860, has adduced some valuable statistics upon this subject. Of 35 cases in which the ligature was applied to the principal trunk of the artery leading to the tumor, 14 were cured, 10 died, 9 were unsuccessful, and in 2 the result was imperfectly given. In 6 of these 35 cases the operation was performed for vascular growths of the orbit, and, of these, 5 were cured. In 10 other cases in which the branches of the main artery were ligated, not one was permanently relieved.

e. Of the various *injections* that have been used for the relief of this tumor, the principal are nitric acid, creasote, iodine, and perchloride of iron, introduced in small quantity, either pure or diluted, with a delicate syringe, similar to that spoken of under the head of aneurism. These fluids are all more or less irritating, while several of them are capable of exciting high inflammation; hence it is hardly necessary to add that they should be employed with the greatest possible care and gentleness. At least one case is upon record, where a drop of nitric acid, injected into a small arterial growth of a child, caused death by convulsions.

The only really unobjectionable injection, for the cure of this disease, is a strong solution of persulphate of iron, a few drops of which may be deposited in different parts of the tumor, by means of a delicate syringe, the nozzle of which, introduced subcutaneously, is moved about in such a manner as to break up the coats of some of the capillary vessels. Coagulation occurs almost instantaneously, and in the course of five to ten days the whole growth drops off in the form of a slough, leaving a sore which gradually heals by granulation. By means of this salt, which is now rapidly coming into use as a hemostatic, I am satisfied that any case of arterial or venous tumor, unless very bulky, may be promptly and effectually cured.

f. Finally, among the subordinate and less certain remedies may be mentioned the use of heated needles, the seton, vaccination, and compression.

The introduction of *heated needles* into the midst of the morbid growth was strongly recommended, some years ago, by several American surgeons, who followed up the suggestion by the publication of a number of cases illustrative of its efficacy. On the strength of these reports, I was induced to make trial of the remedy in a number of instances which fell into my hands shortly afterwards, but such was my disappointment that I soon abandoned it altogether. My opinion is that few practitioners now employ it, or have any particular confidence in its efficacy. In performing the operation, which is adapted only to very small arterial tumors, a number of slender, sharp-pointed needles, generally as many as three, four, or five, inserted into a wooden handle, and heated red, are thrust into different parts of the morbid growth, where they are retained until they become cool, when they are withdrawn, the introduction being repeated every three or four days, the object being to provoke an effusion of plasma. Besides the pain attending this procedure, such is its uncertainty, that it is questionable whether it deserves a place among the regular and accredited remedies for the cure of this disease.

A few cases of cure of the arterial tumor by *vaccination* have been reported. The remedy is, of course, applicable only to persons whose system has not been previously protected by this operation; and it is necessary, in order to be successful, that the virus should be inserted at different points, so that the effects of the resulting inflammation shall be deeply felt by the whole growth. The operation is sometimes followed by violent inflammation and high constitutional disturbance, threatening convulsions, and other serious accidents.

The *seton* is, perhaps, on the whole, more reliable than any other of these subordinate remedies; introduced underneath the tumor, and left there until suppuration is fully established. If the growth is small, a single thread may suffice, otherwise three or four may be necessary, or, perhaps, even a larger number. A small needle, inserted into a handle, is used, the cord being dragged through so as to fill the puncture made by the instrument, thereby preventing hemorrhage. I have treated three cases of small arterial tumors on the scalp successfully by this method.

Compression is sometimes employed, generally through the medium of the pad of a truss, or of a piece of ivory, coin, or sheet lead, confined by adhesive strips and a roller. To prove efficient, it must be made in a steady, uniform manner, the cases to which it is chiefly adapted being those in which the tumor is diminutive, and situated upon a hard, bony surface. The procedure is exceedingly unsatisfactory.

g. When the tumor is irremediable by the various measures now described, and is so situated as to admit of it, *amputation* may become necessary. Much as such a step is to be regretted, no one should hesitate to take it when the disease occupies a finger, hand, arm, foot, leg, or thigh.

SECT. II.—VENOUS TUMORS.

Under this head may be described a morbid growth, composed chiefly of dilated and varicose veins, held together by connective tissue; situated, for the most part, upon the scalp, cheek, lip, and chin, but also liable to occur in other regions, as the trunk and extremities. The submucous cellular substance of the mouth, tongue, and vulva may, likewise, be mentioned as occasional seats of the disease, and there is one form of hemorrhoidal tumor which evidently closely assimilates itself to it in structure. Varying in size and prominence, it may, originally, not be larger than a small pimple, which, gradually spreading in different directions, may ultimately acquire an extraordinary bulk, forming a considerable projection, and occupying a diameter many inches in extent. Its color is usually purple, or claret, either continuously, or intermixed with various shades of red; occasionally it is dark-mottled, especially when the enlarged veins lie nearer the surface at one point than at another, thus rendering their contents distinctly visible through the attenuated integument. In its consistence it is soft and spongy, diminishing sensibly under pressure, but speedily regaining its former bulk when the pressure is removed. It is free from pulsation, bruit, and expansion, and is comparatively little influenced by mental emotion. Sometimes the growth is tardy, at other times rapid; it is usually congenital, but may occur at any period of life; sometimes, and most generally, without any assignable cause, and at other times as a consequence of external injury. At first there is commonly no cutaneous involvement, the tumor being strictly limited to the cellular tissue; by and by, however, the skin becomes uniformly attenuated, or thickened at one spot, and atrophied at another, and thoroughly incorporated with the morbid structure. As the disease advances, but generally not until the tumor has attained considerable bulk, ulceration may take place, followed by occasional hemorrhage, chiefly of a venous character, and easily checked by pressure.

The venous tumor consists of a network of dilated capillaries, not of new development, but simply an exaggeration of those which are peculiar to the part where the morbid growth is situated. They are connected together by loose cellular tissue, are more or less tortuous in their disposition, and have exceed-

ingly thin, delicate walls, so that, when a body of this kind is excised, they immediately collapse, the structure, which previously formed a large mass, shrinking away into a little, spongy remnant. In the specimens which I have had an opportunity of examining, no abnormal vascular cells or fibrous bands were distinguishable; and, as the operations performed for their removal were almost bloodless, it is evident that the arteries which entered into their composition must have been exceedingly small and few in number. In very old and large growths of this kind, some of the individual veins are occasionally of enormous size, as well as remarkably tortuous, and contain fibrinous and earthy concretions, lodged in separate compartments. Such occurrences are most frequently met with in venous tumors on the trunk and buttocks.

The venous tumor is most easily dealt with by excision, and, unless the growth is of inordinate volume, such a procedure will be almost bloodless. Should any considerable artery be embraced in the general mass, it must, of course, be secured, either during the dissection, or immediately after it has been completed. The same rule of cutting round the tumor, and not into it, should be observed here as in the removal of arterial growths.

When the knife is objectionable, a venous tumor, if small, may readily be destroyed by the subcutaneous injection of a few drops of a strong solution of persulphate of iron. The procedure is perfectly safe, and productive of little suffering. I have performed the operation in several cases with very gratifying results. The diseased tissues usually slough off in from five to eight days. Such growths may also be readily destroyed by strangulation, either with the ligature alone, or with the ligature and needle, in the form of the twisted suture; if very large, however, they must not be meddled with in this way, otherwise, violent inflammation arising, the operation may prove fatal.

CHAPTER VIII.

DISEASES AND INJURIES OF THE BONES AND THEIR APPENDAGES.

THE bones, being organized upon the same principles as the soft structures, are liable to similar diseases, both of a benign and malignant nature. The presence of earthy matter, however, to which they are indebted for their solidity and strength, so as to render them fit organs for locomotion, exerts a modifying influence upon their diseases, not only as it respects their frequency, but also their progress, the character of their products, and the mode of their termination. This influence is particularly noticeable, on the one hand, in the difficulty with which inflamed osseous tissue suppurates, and, on the other, in the facility with which it becomes softened and deprived of its vitality, even, apparently, under very slight action. Inflamed soft texture generally suppurates with remarkable readiness, and often becomes the seat of large abscesses; in pure osteitis, on the contrary, pus is rarely seen in any form, much less in that of abscesses, such an occurrence being usually impossible, first, on account, probably, of some peculiarity in the habits of the discernent vessels, and, secondly, because of the absence of free cellular substance, which, in the soft tissues, always serves as a bed for the reception and accommodation of the purulent fluid. Bones inflame with difficulty, but when the morbid process is once fairly lighted up, it is sure to produce the most serious structural disorder, often followed by the worst consequences, as softening, protracted ulceration, hypertrophy, fragility, and even necrosis. In tertiary syphilis, gout, rheumatism, and scurvy, the bones frequently suffer im-

mensely, receiving and harboring disease with great facility. They are a common seat of various kinds of tumors, especially the benign, some of which, as the exostoses, are very similar to, if not identical with, their own structure, while others are essentially different in most particulars. The heterologous formations have all been observed in the skeleton, but their great rarity has been a subject of remark by every systematic writer. The most common of these formations is the tubercular, which plays so important a part in caries of the carpal and tarsal bones, in Pott's disease of the spine, and in certain affections of the larger joints of the extremities.

SECT. I.—PERIOSTITIS.

The occurrence of periostitis is by no means infrequent, its causes being those of osteitis, with which, especially in its acute form, it is usually associated. Among the most common of these causes are various kinds of external injury, as fractures and dislocations, blows, contusions, gunshot wounds, and the application of escharotic substances; and the effects of gout, rheumatism, and syphilis, operating upon a disordered and dilapidated state of the system. There is one form of whitlow which consists essentially of periostitis, attacking usually one of the fingers, and liable, if neglected or improperly treated, to terminate in extensive suppuration and necrosis of the distal phalanx. Inflammation of the periosteum, of a very severe and destructive nature, is occasionally produced by deep-seated abscesses, extending to, and irritating that membrane, as sometimes happens, for example, in phlegmonous erysipelas, where the matter burrows extensively among the surrounding tissues. Two forms of the disease are met with, the acute and chronic, the latter being the more common.

ACUTE PERIOSTITIS.

In the acute form of inflammation, the fibrous membrane is commonly of a reddish, pink, or lilac hue, its vessels are loaded with blood, and its substance is sensibly softened, as well as slightly thickened from interstitial deposits. Its attachment to the bones is also considerably diminished, so that it may be pretty readily peeled off, and the cellular substance immediately over its outer surface is generally infiltrated with sero-albuminous matter. These changes, which are present, in greater or less degree, in all cases of periostitis, are often very conspicuous upon the fragments of a broken bone, and in incised wounds of the muscles, involving the membrane in question.

The disease not unfrequently passes into suppuration, the occurrence being particularly liable to happen in the periosteum of the bones of the inferior extremity, as the femur and tibia, and in the phalanges of the thumb and fingers; in the former as a consequence of cold acting upon a strumous constitution, or of the effects of mercury, or of mercury and syphilis, and in the latter as a result of whitlow. Much diversity exists in regard to the progress of the suppurative action; most generally it is rather tardy, but there are cases in which it proceeds with extraordinary rapidity, committing excessive ravages in a few days. However this may be, the pus is rarely of a healthy, laudable nature, but almost always very thin, bloody, and offensive, with flakes of curdy matter and the debris of broken-down, softened tissue.

Mortification is another termination of this disease. The occurrence is characterized by a dirty, ash-colored appearance of the affected membrane, which is, at the same time, very much softened in its texture, and saturated with a foul offensive fluid, emitting an unmistakably gangrenous odor. Such an event is necessarily associated with necrosis of the corresponding bone, and frequently, also, with mortification of the endosteum, all perishing together in consequence of the destruction of their vascular connections. The best examples of this mode of termination occur in the periosteum of the alveolar processes of the jaws, from the abuse of mercury, and in that of the tibia from the effects of syphilis. The sloughs, which are always tough and shreddy, are usually thrown

off with considerable difficulty, owing to the tardy and imperfect action of the circumjacent structures.

Symptoms.—The symptoms of periostitis are such as usually attend inflammation of the deep-seated structures generally, the pain being of a violent and pulsatile character, and the swelling of the soft parts diffuse and œdematous, with excessive heat of surface, and more or less constitutional disturbance. The occurrence of suppuration is announced by a marked increase of suffering; and as the pus accumulates the superincumbent integuments assume a shining, glossy, erysipelatous aspect, pitting under pressure, and imparting a distinct sense of fluctuation. Both in suppuration and mortification the pain is exquisite, and the patient generally labors under high fever and often also under delirium.

In periostitis consequent upon a syphilitic taint of the system, the suffering is always worst at night, the pain being of a severe, aching, or gnawing character, and invariably aggravated when the patient becomes warm in bed. Small, circumscribed swellings, or nodes, frequently exist, and are exquisitely tender on pressure and motion, the skin over them being red, inflamed, and œdematous. The contents of these swellings are generally of a thick gummy character, possessing none of the properties of genuine pus.

In gouty and rheumatic periostitis the pain is deep-seated, wandering, or migratory, and generally very severe; the soft parts over the seat of the disease are discolored, glossy, and puffy; slight effusions of sero-plastic matter often exist beneath the affected membrane, forming small, rough, and irregular swellings, which are easily detected by the finger; the system is disordered by fever; the perspiration is acid and copious; and the urine is scanty and high colored, depositing a large quantity of lateritious substance upon the bottom of the receiver. The most reliable symptoms, in a diagnostic point of view, are, the shifting character of the disease, the involvement of the joints, and the history of the case.

Treatment.—In the treatment of periostitis, a primary object is to seek for the cause of the disease, and, if possible, to remove it. The traumatic form is to be managed upon ordinary antiphlogistic principles. Idiopathic periostitis is often a self-limited affection, tending to terminate in suppuration, despite the best directed efforts of the surgeon. Examples of this constantly occur in whitlow and in some varieties of necrosis, in which periostitis commonly plays an important part, the morbid action being apparently dependent rather upon some inscrutable constitutional trouble than any special local cause. General treatment can seldom be altogether dispensed with in any case, while in many it constitutes our most valuable resource, no progress of a favorable character being made without it. In the more severe forms, bloodletting, active purgatives, and the saline and antimonial mixture, will probably be required, along with anodynes, to allay the excessive pain which is so often present. The most important topical remedies are leeches, iodine, blisters, and saturnine lotions with laudanum. If great tension exist with a tendency to suppuration, deep incisions are made, without waiting for fluctuation, which is often extremely difficult of detection, unless the affected structure is very superficial, as, for example, in periostitis of the tibia. The necessity of this operation cannot be too strenuously insisted upon, as it is the only way in which we can afford prompt relief to the suffering, and obviate extensive and irremediable mischief, as must inevitably happen when the matter is permitted to burrow. When mortification takes place, the same treatment must be adopted as under ordinary circumstances.

In syphilitic periostitis the best remedy is iodide of potassium, in doses of five to ten grains three times a day, either alone or in union with bichloride of mercury. If nodes form, they will generally disappear under the influence of iodine, blisters, or mercurial inunctions, and will seldom demand interference with the knife.

Periostitis caused by rheumatism and gout requires the use of colchicum, with systematic purgation, and occasionally, perhaps, slight ptyalism, with leeches, fomentations, and alkaline and anodyne liniments.

CHRONIC PERIOSTITIS.

The periosteum is often the seat of chronic inflammation, its substance becoming thickened and indurated from the effusion of plastic matter. The hypertrophy—for so it may be termed—often involves a considerable extent of surface, forming a diffuse, incompressible swelling, fibrous, cartilaginous, or even osseous in its character. Sometimes, on the other hand, the enlargement is very small and circumscribed, not exceeding, perhaps, the end of the little finger or half a dime. It may be caused by some specific constitutional poison, especially the syphilitic, or by external violence, as a blow, fall, or kick, as is often the case when it exists on the skull. However induced, its development is attended with a constant, deep-seated, gnawing pain, which is usually most severe at night when the body becomes warm in bed, and which occasionally assumes a true neuralgic character. After continuing for an indefinite period, it often remains stationary, or it gradually disappears by absorption, or it excites suppuration in the superimposed tissues.

These chronic affections of the periosteum are generally peculiarly obstinate and intractable, requiring specific remedies, frequently varied and long continued, for their cure. Iodide of potassium and mercury, Donovan's solution, and the different preparations of arsenic, with blisters, iodine, leeches, the vapor bath, and mercurial fumigations, are the means most likely to prove beneficial. In obstinate cases, resisting the ordinary remedies, free incisions, extending through the substance of the thickened and indurated membrane down to the bone, will afford more relief than anything else, especially if the wound is made to suppurate abundantly.

Bony tumors, growths or deposits of this membrane are to be treated upon the same principles as exostoses, properly so termed. When small, not painful, or not inconveniently situated, they will probably require no attention. Occasionally they disappear spontaneously, or under the influence of very simple remedies. Such formations are nearly always caused by the effects of the gouty, rheumatic, or syphilitic poison, and are, therefore, generally greatly benefited by iodide of potassium and a mild course of mercury.

Finally, the periosteum is sometimes the seat of the heterologous formations, as the melanotic and tubercular. In carcinoma of the bones, the membrane is now and then implicated secondarily, but is rarely, if ever, the primary seat of this malady. In a number of dissections which I have made of encephaloid disease of the bones and soft parts, I have found it entirely intact, not even thickened or indurated.

SECT. II.—ENDOSTEITIS OR OSTEOMYELITIS.

Under this name may be described a disease of the medullary membrane, now known as the endosteum, possessing all the characters of true inflammation. It may be either acute or chronic, and almost invariably coexists with more or less osteitis.

The *causes* are generally of a traumatic nature, consisting of fractures, gunshot wounds, the lodgment of foreign bodies in the substance of the bones, violent blows, contusions, concussion of the spongy tissue, and laceration of the endosteum by the saw in amputation of the limbs, of which the lesion is by no means an uncommon consequence, as is shown by the suppuration and necrosis which so often follow this operation. There can be little doubt that the disease is frequently produced by the mere concussion of the limbs, transmitting its injurious effects along the canals of the long bones, thereby, perhaps, partially detaching portions of the lining membrane, and so inducing serious disruption of the circulation. Cold is another cause of endosteitis, and there is reason to believe that many of the cases of necrosis of the shaft of the femur, tibia, and other long pieces of the skeleton, originate in this manner. Occasionally the malady depends upon some constitutional taint, as the syphilitic, strumous, or

scorbutic, awakening inflammation consentaneously in the endosteum, osseous tissue, and periosteum.

The *morbid anatomy* of the disease is best studied in one of the long bones, as the femur or tibia, after amputation. If several days have elapsed since the operation, the membrane will be found to be of a pale pink hue, more or less injected, and apparently a little thickened; the marrow is abnormally soft; and the cells of the spongy structure of the canal are pervaded by a sero-sanguineous fluid. At a later period, when the inflammation is more fully established, the discoloration of the endosteum is of a more decided character, being of a deeper red with a shade of brown or purple, the fatty matter is broken up into a semi-liquid substance, and, in addition to the bloody sanies just alluded to, evident traces of pus are seen, forming numerous little points, of a yellowish aspect, which, gradually coalescing, at length assume the character of small abscesses. When the disease is uncommonly violent or protracted, portions of the endosteum are converted into real eschars, of a brownish color, and of a characteristically fetid smell; the periosteum opposite the seat of the morbid action is detached, and the intervening part of the bone, thus deprived of its vessels, speedily perishes.

In the chronic form of the disease, which sometimes lasts for years, the osseous structure is rendered abnormally hard, dense, and heavy, the medullary canal is in great measure, if not entirely, obliterated, and the endosteum at the seat of the morbid action is completely destroyed. Small cavities filled with a soft oily material, or fatty gelatinous substance, and surrounded by softened, vascular, reticulated tissue, are not unfrequently found; and cases are occasionally met with, although rarely, in which there are small abscesses and dead pieces of bone. When the disease is of long standing, the affected bone is generally more or less changed in its form, rough on the surface, and remarkably compact and heavy.

The *symptoms* of endosteitis are so vague and unreliable as to render it very difficult, if not impossible, to distinguish them from those which attend inflammation of the bones and their fibrous envelop. Indeed, it is only when the disease occurs as the result of injury, as after amputation, that anything even like a plausible conjecture can be formed as to its real nature. Under such circumstances, upon taking off the first dressings, the wound opposite the end of the bone will probably be found to be gaping and filled with pus, the bone itself being either entirely denuded, or only slightly covered with lymph below, while the medullary membrane is of a reddish or brownish color, and more or less vascular. If six or eight days have elapsed since the operation, the exposed medullary surface will be likely to be studded with pale, flabby, unhealthy granulations, somewhat sensitive to the touch, if not decidedly painful, and discharging an abundance of thin, sero-sanguinolent fluid. Around this red and inflamed circle, the compact layer exhibits an unusually white, glistening appearance, without any trace of reparative action; in fact, the bone is divitalized, or, if not actually dead, it soon will be. Superadded to these phenomena, there is occasionally an escape of marrow, with or without fragments of the medullary membrane; a sure sign of the inflamed and disorganized state of the parts.

Endosteitis is always attended with considerable swelling and puffiness of the soft structures immediately over the affected parts, but there is not necessarily any discoloration of the surface, or any unusual pain. Considerable irritative fever is commonly present; the skin has a peculiar sallow hue; and there are apt to be rigors, alternating with flushes of heat, and followed by copious sweats, generally of a disagreeable acid nature. When the disease is idiopathic, there may be tumefaction and pain, deep-seated and throbbing, at the site of inflammation, but neither of them of so distinctive a character as to be of any service in a diagnostic point of view.

Endosteitis cannot be considered otherwise than as a dangerous malady; for when severe or wide-spread, it is apt not only to cause extensive necrosis, but it may destroy the patient by the induction of phlebitis in the principal veins of

the corresponding limb, and abscesses in the different viscera, especially the lungs and liver. Occasionally, it would seem to be capable of assuming a kind of endemic tendency. Thus, in 1814, nearly all the patients at the Hôtel Dieu, in Paris, who died after amputation, and the number was quite considerable, were observed to have suppuration in the medullary membrane of the long bones.

The *treatment* of endosteitis must be conducted upon general antiphlogistic principles, local and constitutional, in the hope of limiting morbid action and preventing the occurrence of suppuration and gangrene. If the medullary canal is exposed, some mildly stimulating injection, such as a very weak solution of nitrate of silver, tannin, or acetate of zinc, may be useful, the part being protected from the atmosphere by lint wet with a similar fluid, or an emollient cataplasm. When the membrane is affected in its continuity, and there is much swelling of the soft structures, free incisions may be necessary in order to relieve tension and promote the escape of effused fluids. If there is reason to apprehend the existence of medullary abscess, as there will be if there is deep-seated, aching, gnawing, or boring pain, with œdema of the subcutaneous cellular tissue, the surgeon must not hesitate to cut down upon the matter with a small trephine as the only chance of averting still more serious consequences.

In the strictly chronic form of the disease, our chief reliance is upon iodide of iron and potassium, with minute doses of bichloride of mercury, tonics, cod-liver oil, change of air, and counter-irritation. In the more hopeless cases it may be necessary to trephine the affected bone, or even to resort to amputation.

SECT. III.—OSTEITIS.

Osteitis is a very common occurrence, especially in early life, owing, doubtless, to the great vascularity of the osseous tissue at that period rendering it more susceptible of disease than in old age, when many of the vessels shrink and disappear. It may be primitive or consecutive, acute or chronic; and in either case it may be limited to a particular portion of a bone, or pervade its entire length and breadth, although this is unusual. The spongy tissue suffers more frequently than the compact; and what is remarkable is that in the first the disease often passes into ulceration, while in the latter it more frequently causes necrosis, or mortification, the two structures being evidently endowed with different powers of resisting the effects of inflammation. The pieces most liable to be affected are those which are naturally the least covered by soft substance, as the tibia, fibula, ulna, clavicle, and frontal bone. The disease is generally slow in its progress, and a considerable period may, therefore, elapse before there is any very appreciable alteration of tissue. Cases, however, occur, where it proceeds with immense and overwhelming rapidity, suppuration, ulceration, and even mortification appearing in less than forty-eight hours from the commencement of the attack.

If a bone laboring under inflammation is carefully examined, it will be found to exhibit several important structural changes of great interest. At first it is simply enlarged, although less so than is usually imagined, because much of what appears to be an increase of volume is due rather to swelling of the periosteum, than to any actual expansion of the osseous tissue itself. Gradually the affected bone loses its density, becoming softened, and infiltrated with a sanguinolent fluid, of a sero-plastic nature, and assuming a bright reddish hue, the capillaries being very numerous, turgid, and distinct. As the disease advances, the osseous fibres separate from each other, and the widened intervals are immediately filled with inflammatory deposits, often intermingled with little clots of pure blood. These alterations are always attended by an absorption of earthy matter, which has the effect of rendering the bone both soft and spongy, at the same time that it causes an actual diminution of its weight. The lamellæ of the compact substance are resolved, as it were, into their primitive distinctness, the Haversian canals are greatly enlarged, and the cells of the areolar texture are remarkably rarefied. When the disease has reached its maximum, the osseous tissue is frequently so soft as to be easily bent and cut. When the inflammation is super-

ficial, affecting the outer layers of a bone, it always promptly extends to the periosteum, which, in consequence, becomes red, swollen, and infiltrated with serous and plastic matter. If, on the other hand, the inner structure is involved, the endosteum is sure to suffer, assuming a discolored, bloodshot appearance, while the adipose matter is either rapidly absorbed, or converted into a soft diffuent mass, of a light reddish hue, and of a peculiarly fetid character. When the inflammation of the bone is at all extensive, both periosteum and endosteum participate in the morbid action, and it is in these cases, more especially, that, the circulation being cut off by fibrinous exudations, necrosis is liable to arise.

Osteitis may terminate in resolution, the morbid phenomena gradually disappearing, and the affected structures regaining their primitive texture; or the disease may cease, and the bone become indurated and enlarged by interstitial osseous deposits; or, lastly, the inflammation may pass into suppuration, ulceration, softening, or mortification, the results resembling those of inflammation of the soft parts. It is seldom that a bone, after having been inflamed for any

Fig. 293.

Hypertrophy of the tibia from inflammation.

length of time, will not, upon recovery, remain somewhat hypertrophied, or larger and harder than it was before the attack, as seen in fig. 293. It is, in fact, nature's mode of cure, the process which she employs for repairing the mischief committed by the disease.

Causes.—The causes of osteitis are either traumatic or constitutional, the former consisting of injuries inflicted in surgical operations, fractures, contusions, and wounds, especially gunshot and punctured, and the latter of a syphilitic, strumous, scorbutic, rheumatic, or gouty taint of the system, together with the operation of cold. The disease may begin directly in the osseous tissue, or this may be involved secondarily, from extension of the disease from the surrounding parts. Thus, in dislocations, particularly compound, and also in simple dislocations of the larger hinge-joints, as the elbow and knee, the inflammation consequent upon the accident is nearly always communicated to the contiguous extremities of the bones, rendering them soft and brittle, and liable to give way under the slightest influences. In like manner the periosteum often becomes the propagator of the morbid action; for, although, in general, this membrane serves to ward off disease, forming a kind of wall between the soft structures and the bones, yet this barrier is not unfrequently overleaped, and inflammation kindled up in the very centre of these pieces. A great similarity is thus found to exist between the bones, periosteum, and endosteum, on the one hand, and the lungs, pleura, and bronchial mucous membrane, on the other, experience having proved that disease cannot be present in any considerable degree, or for any length of time, in any one of these component elements without being propagated to the rest, which subsequently have often to bear the chief brunt of the incited action.

Symptoms.—The symptoms of osteitis bear a great resemblance to those of periostitis and endosteitis, and therefore the most adroit diagnostician often finds it difficult to discriminate correctly between them. Practically, an error of this kind is of no special moment, as the treatment is essentially similar in the three affections, but as a matter of science it is very desirable in every instance to ascertain, if possible, in what structure the disease is located, or, if all are implicated, in what degree. There is really, however, no one symptom, or group of phenomena, upon which the least reliance can be placed in this respect. It may be said that the pain in osteitis is more intense, agonizing, and deep-seated, than in inflammation of the periosteum and endosteum, and yet this is so only

as a general rule; in many cases the difference is too slight to be appreciable. The same is true in regard to the swelling of the soft parts, and the constitutional disorder, which are often very great in all these affections, but, as they do not possess any distinctive features, are of no value in a diagnostic point of view.

Acute osteitis is generally attended by the same symptoms as acute inflammation of the soft structures. The pain is excruciating, the part feeling as if it were torn, or bored, or as if insects were feeding upon it; it is deep-seated, more or less circumscribed, and increased by motion, pressure, and damp states of the atmosphere; it is also usually more violent at night when the patient becomes warm in bed, especially when it recognizes a constitutional origin. The swelling is extensive, firm, and almost inelastic, pitting, perhaps, after a time, under the application of the finger; the skin has a glossy, shining appearance; and there is intense heat of the surface, conjoined, in most cases, with an erysipelatous blush. The constitution sympathizing powerfully with the local disorder, there is high fever, with excessive thirst, a full, bounding pulse, and great dryness of skin, with all the minor phenomena of general incited action. If the disease is not promptly restrained, the soft parts suppurate, the event being announced by rigors and delirium, followed by copious sweats.

Although acute osteitis is seldom dangerous, it may, nevertheless, occasionally prove fatal, especially if it is extensive, or complicated with other maladies, by the induction of erysipelas, pyemia, or constitutional irritation. Such an event will be most likely to happen in young scrofulous subjects, or in persons worn out by the effects of syphilis. The malady often terminates in serious and irremediable structural disease of the affected part, as softening, caries, and necrosis, requiring important operations, which are themselves frequently a source of much risk. Recovery, in any event, is generally extremely tedious.

The symptoms of *chronic osteitis* are usually well-marked. The bone is the seat of more or less pain, circumscribed, increased by motion and pressure, and aggravated at night, often depriving the patient of sleep and appetite. Enlargement of the affected part, with swelling and induration of the overlying tissues, is commonly a prominent phenomenon. Sooner or later suppuration occurs, followed by the formation of sinuses, difficult to heal, and the seat of a constant discharge of thin, ichorous, sanious, or unhealthy matter, occasionally mixed with osseous particles. The constitution frequently sympathizes with the local disorder, as indicated by the pallor of the countenance, the gradual emaciation, and other evidences of failing power.

Treatment.—The most important elements in the treatment of osteitis are bleeding, tartar emetic, purgatives, calomel, and opium, with perfect rest both of the part and body. The prompt abstraction of blood by the lancet, or by leeches from the affected structures, will generally prove of marked benefit in cutting short the disease, or, rather, in limiting the sphere of its action. Calomel should be given as soon as the patient has been well bled and purged, and should be steadily continued until gentle ptyalism is induced. There is no remedy which, after proper depletion has been premised, exerts so powerful and controlling an influence over inflammation of bone as this; and, although it should not be used causelessly, or without due precaution, there are few cases to which it is not applicable. To prevent it from running off by the bowels, and, at the same time, to mitigate the excessive general and local distress, it should be administered in combination with large doses of opium, repeated as frequently as the exigencies of the case may seem to require.

The best local remedies, besides leeches, are warm anodyne fomentations, light medicated cataplasms, dilute tincture of iodine, and blisters, the latter being applied in such a manner as to cover in the whole of the affected surface, and allowed to remain on until thorough vesication has been produced. If matter form, or even if there is merely great tension, the knife must be used, the incisions being long and deep, extending down to the very substance of the bone. Without such an expedient relief is impossible. If the pus is allowed to accumulate, it will be sure to burrow, insinuating itself freely among the muscles, and per-

haps even between the periosteum and bone, thereby detaching these parts from each other, and thus inducing extensive necrosis. What is done for the soft tissues, under such circumstances, should also be done for the affected bone, although practitioners are generally agreed to let it take care of itself. Is this good practice? The surgeon makes it a rule in inflammation of the soft structures to relieve pain and swelling by early and free incisions, and he finds that the procedure is usually followed by the most happy results, texture being saved and much suffering avoided. Why should he not adopt a similar treatment in osteitis attended with swelling and excruciating torture in consequence of effused fluids? Several openings might very easily be made into the affected bone with the crown of a very small trephine, the soft tissues being carefully divided as a preliminary measure. The operation never fails to be beneficial, and there is reason to believe, from what I have seen of it, that if it were more frequently resorted to than it is there would be much fewer cases of necrosis and caries than are now seen to follow this disease.

In chronic osteitis our chief dependence is upon alterants, purgatives, and counter-irritation, of which the best form is an issue made with the hot iron as near as possible to the seat of the disease. A free discharge should be established and steadily maintained until the morbid action is effectually broken up. The most reliable alterant is iodine of potassium in union with mercury, carried, in obstinate cases, to gentle and somewhat persistent ptyalism. Such a course is particularly indicated in syphilitic osteitis, but is hardly less beneficial in the rheumatic, gouty, and strumous varieties of the malady.

There is a peculiar affection of the bones of *children* deserving of passing notice in connection with osteitis. It consists, not in inflammation of the osseous tissue itself, but of the soft, pulpy, vascular substance which serves to unite the epiphyses to the shafts of the bones; and frequently sets in at an early period of life, either spontaneously or as the result of external injury, as a sprain, blow or contusion. The disease is generally acute, and is characterized by great swelling, intense pain, and violent constitutional disturbance, often attended with delirium. If active measures are not adopted for its relief, an abscess soon forms, preceded by rigors and followed by hectic irritation. More or less of the bone commonly dies, especially that part of it which is connected with the shaft, and finally comes away either as an exfoliation or a sequester. Convalescence is tedious, and recovery seldom occurs without partial ankylosis of the contiguous joint, and a slight arrest of development of the affected limb, below the epiphysis, the latter of which, as it possesses an independent vitality, continues its accustomed growth.

SECT. IV.—SUPPURATION AND ABSCESS.

Suppuration of the external surface of bone is a very common occurrence, and may arise from various causes, as fracture and other external injury, or a syphilitic taint of the system. As the morbid action, however, which precedes and accompanies the suppuration, is usually associated with inflammation of the periosteum, it is difficult, in most cases, to determine which structure is really the source of the purulent matter. When the osteitis is of long standing, or characterized by inordinate severity, the pus is occasionally diffused through the proper substance of the bone, but such an occurrence can only happen in the event of the osseous tissue having undergone previous softening, the removal of the earthy matter being followed by the formation of cells or cavities for the lodgment of the fluid. If a vertical section is made of a long bone, as the tibia, in an advanced state of inflammation, it will be found that the pus, presenting itself in small globules, will be scattered both through the Haversian canals and the cells of the areolar substance, no disposition being manifested in the little depots to arrange themselves into abscesses. The intermediate structure is of a reddish color, filled with fibrinous exudation, and so soft as to be easily divided with the knife. This punctiform variety of suppuration is seldom so conspicuous as in inflammation of bone complicated with endosteitis.

Abscess of bone, distinct, circumscribed and well-defined, such as is seen in phlegmonous suppuration of the soft parts, and as is represented in fig. 294, is a very uncommon affection. The formation takes place slowly, an unusual degree of chronicity being one of its natural concomitants. The most frequent seat

of the disease is the head of the tibia, or the head and lower extremity of that bone, the expanded and rarefied tissue of which is peculiarly well adapted to such an occurrence. The abscess ranges in size from that of a pea to that of a pigeon's egg; is generally solitary; is lined by a thin, though distinct, membrane; and is occupied by a dark-colored, ill-elaborated pus, more or less fetid, and intermingled with aplastic matter or curdy flakes similar to those observed in strumous pus. The surrounding tissues are softened, congested, and infiltrated with sero-sanguinolent fluid. The manner in which the abscess terminates is variable; when seated near the extremity of a bone, it sometimes manifests a disposition to discharge its contents into the contiguous joint; at other times, and more generally, it maintains

its position, becoming as it were encysted by a deposit of new bone around it, as delineated in fig. 295. Finally, in a third class of cases, the matter continues to accumulate, apparently for a long time, and, pressing upon the osseous tissue in every direction, gradually expands the bone into a large shell, capable of holding several ounces, and so thin and soft as to be bent and cut like cartilage.

The symptoms denotive of the formation of pus are usually such as characterize this event in the other tissues, only that the local suffering is generally much more intense, especially if the matter has no free vent. The existence of abscess in the interior of a bone is indicated by a dull, gnawing, heavy pain, circumscribed, deep-seated, remittent, and more like a violent toothache than anything else to which it can be compared. In many cases it is of a throbbing, boring, tearing, or lacerating nature. It is always worse at night than in the day, and is usually so intense and exhausting as to make serious inroads upon the general health, the patient soon becoming wan, sallow, and hectic. Occasionally the pain completely intermits, the parts being wholly free from suffering for many hours, and even days together; more generally, however, it is continued with partial remissions. The soft structures, at the seat of the abscess, are always exquisitely tender, especially at one particular spot directly over the matter, more or less tumefied, glazed, and œdematous, often pitting on pressure. The formation of matter is generally announced by rigors, alternating with flashes of heat; and similar attacks are very common during the progress of the disease, particularly in the early part of the night, the body being usually drenched towards morning with acid, offensive perspiration.

Although the symptoms of abscess are in general well marked, yet, as they are liable to be simulated by other affections, they cannot be said to be characteristic. The principal affections with which they are liable to be confounded are necrosis and deposits of matter in the soft parts, which are liable to be confounded with abscess, and irritating the parts so as to keep up intense inflammation by collections of pus in the neighbourhood.

Fig. 294.

Abscess in the head of the tibia.

Fig. 295.

Large chronic abscess, with a thickened, expanded wall.

is of little consequence in these cases, as the treatment is essentially the same, whether the symptoms arise from abscess, the lodgment of dead bone, or interstitial osseous deposits. The discrimination between abscess and neuralgia, which often closely imitate each other, is of more importance, on account of the difference of treatment, but so far as I know there are no diagnostic signs by which the distinction can be effected.

Abscess of the osseous tissue admits of relief only by efficient evacuation with the trephine. In no other manner can the pent-up fluid be reached. The operation is not always as easy as might at first be imagined, owing to the excessive

Fig. 296.

Trephine.

firmness of the affected bone, in consequence of interstitial deposits, which often give it the closeness and density of ivory. The best instrument is a common trephine, fig. 296, from three to four lines in diameter, with sharp, well set teeth, and fluted at the surface, so as to make a wide track. The surgeon, taking the site of pain and swelling, or the "tender spot," as his guide to the seat of the abscess, exposes the bone by a free incision, either single, T like, curvilinear or crucial, as may be deemed necessary, and then turning aside a small portion of periosteum, applies the instrument. Its arrival at the abscess is generally denoted by a sudden cessation of resistance, and by the escape of a few drops of pus mingled with blood. If no matter is found after sinking the instrument to a considerable depth, it is applied at some other point, in the vicinity of the former, in the hope of a more successful result, for it is often quite impossible, in these cases, to hit the precise spot where the fluid is located in a first or even a second

attempt; on the other hand, however, care must be taken not to make too many perforations, lest the bone be thereby unduly weakened or suffer other injury. Moreover, it is not to be inferred by any means that, although no pus has been detected, the operation will, therefore, be a failure; perhaps the instrument may have come in contact with a small sequester, lying loose in the cellular tissue of the articular extremity of the bone, and by removing this, rapid recovery may take place; or, instead of this, the pain and other symptoms may have been occasioned by the pressure of interstitial deposits, and the excision of a disk of bone may afford relief on the principle of taking off tension, as a free incision does in deep-seated purulent collections in the soft structures.

The abscess having been opened, the cavity is washed out with the syringe, as much to get rid of the sawdust as to clear away pus and stimulate the pyogenic sac. A narrow tent is then inserted into the bottom of the opening, and the wound gently supported with adhesive strips, the after-treatment being conducted upon strictly antiphlogistic principles. The relief from the operation is often immediate, and there is no class of cases in which the efforts of the surgeon are generally rewarded with more unalloyed satisfaction. The patient, tortured for months with pain and sleepless nights, is suddenly translated from torment into Elysium.

SECT. V.—CARIES OR ULCERATION.

Caries is a disease of the osseous tissue, strictly analogous to ulceration of the soft parts. It is essentially of an inflammatory type, and is characterized by an increase of vascularity, softening, and disintegration, the earthy matter being separated from the animal, and eliminated along with the discharges, which are often quite profuse, especially when the malady has made considerable progress. Caries differs from ordinary osteitis chiefly in this, that it is attended with actual loss of substance, the affected tissue being gradually broken down, excavated, or destroyed, whereas, in the latter, it retains its various elements, although in an altered condition, the principal changes consisting in congestion, softening, and

sero-plastic infiltration. There are other points of difference, as the seat of the two diseases, the age at which they respectively occur, and the nature of the concomitant secretions, as will be rendered evident by a careful study of the subject.

Caries is most liable to occur in those pieces of the skeleton which are distinguished by the abundance of their areolar tissue. Hence it is most common in the vertebræ, the sternum, the innominate bones, the bones of the carpus and tarsus, and the articular ends of the long bones, especially of the femur, tibia, and humerus. The compact tissue is more frequently the seat of necrosis than of caries; indeed, the affection cannot occur here unless this tissue has previously undergone a certain degree of softening, so as to prepare it, as it were, for the disintegrating process which characterizes it.

Young persons are most subject to caries, particularly children under ten years of age; it is seldom that it is met with even so late as middle life, and then chiefly as a result of some specific taint of the system, more especially the syphilitic. I am not aware that sex exerts any material influence upon its production, for I think it has occurred in my own practice with nearly equal frequency in males and females. Temperament and occupation may predispose to it, but if this be so we have no positive proof of the fact. Strumous children are particularly obnoxious to caries, and this circumstance, of which daily observation furnishes abundant evidence, long since created a doubt in my mind whether the disease is not really, in a great majority of cases, of a tubercular nature. The further I examine the subject, the more I am satisfied of the truth of this opinion. Most of the children that are brought to me with this disease, as it occurs in the spine, the hand, foot, and ends of the long bones, present all the characteristic features of the scrofulous diathesis; and I am quite sure that this experience, instead of being peculiar to myself, must be common to all practitioners. I do not, therefore, throw out this view as a mere conjecture, but as a conviction, and shall speak of it hereafter as the basis of important therapeutic indications.

Causes.—The causes of caries are of two kinds, local and constitutional, of which the latter are by far the more common and influential. As appertaining to the first, are various injuries, as blows, kicks, falls, fractures, contusions, and concussions, disturbing the circulation and innervation of the osseous tissue, or depriving it of its fibrous covering, and thus modifying its nutritive action. In the bones of the foot, especially those of the tarsus, the disease is sometimes induced by the penetration of a foreign body, as a nail, or splinter of wood. The sawing of the bones in amputation and resection, and their accidental division by sharp instruments, is occasionally followed by caries, both extensive and protracted. Cases occur where the disease is produced by the pressure of an aneurismal tumor, and by the application of escharotic substances.

Among the internal causes of caries may be cited whatever has a tendency to induce general debility, or to impoverish the fluids and solids, and, consequently, to exhaust the constitution. Hence we may place at the head of the list severe and protracted courses of mercury, the operation of the syphilitic poison, a gouty or rheumatic state of the system, scurvy, scrofula, profuse loss of blood, and severe attacks of dysentery, diarrhœa, typhoid fever, and eruptive diseases, as scarlatina, measles, and smallpox. All these circumstances are capable of producing ulceration both in the skeleton and the soft parts, as is proved by the numerous sores which so often arise in different regions of the body, as the sequelæ of these affections, and which we usually find so difficult of cure.

Of all the internal causes, however, of caries, there is none which exercises so powerful an influence as scrofula. I do not mean by this remark that there is always necessarily a deposit of tubercular matter; on the contrary, I am satisfied that there is, in most cases, nothing of the kind, but merely a tubercular diathesis, predisposing the part to the disease, and thus rendering it less capable of resisting its effects when once it is established. As in strumous ophthalmia there is often serious disease, without any evidence of tubercular deposit, so in strumous caries a bone may be completely softened and disintegrated, without any secretion of *strumous matter*, properly so termed. In both cases the diathesis exists,

but not the tubercular matter. As this is the most frequent cause of caries, so is this form of the affection also one of the most difficult to remove.

Morbid Anatomy.—If a carious bone is subjected to careful examination, it will be found to exhibit marked differences in its appearances, according to the duration of the disease and the nature of the affected piece. In the earlier stages, the osseous tissue is merely inflamed, as is evinced by its vascular and softened condition; its spongy texture is rarefied, and occupied by a serous, oily fluid, intermixed with a good deal of the coloring matter of the blood, thus giving it a reddish aspect. It may be cut with the knife, or even indented with the finger, especially if the bone is a carpal or tarsal one, and, upon macerating it, the water soon becomes covered with a layer of fatty matter. Exposed to the air, it dries with difficulty, and assumes a pale, yellowish hue, verging slightly upon greenish. When the disease has reached its more confirmed stages, the bone is found to be excavated, or riddled with cavities, of variable size and shape, sometimes lined by a kind of pyogenic membrane, and filled with thin, sanious, and offensive matter, without any of the characteristic properties of landable pus. Occasionally small fragments of bone lie loose in these cavities, unable to escape on account of their disproportionate dimensions. The osseous tissue is now extremely soft and brittle, breaking down readily under the finger; it is still more porous than before, and is of a grayish, brownish, or blackish color. It is apparently destitute of vessels, and yields a considerable quantity of oil on maceration. In a chemical point of view, the only notable difference between carious and healthy bone is the greater amount of cartilage and fat in the former than in the latter, the quantity of cartilage often forming as much as thirty-seven per cent., while the amount of fat is upwards of three. This quantity of fat, although much greater than normal, is not sufficient to justify the opinion expressed by some that this disease essentially consists in adipose degeneration of the osseous tissue.

The substance immediately around the softened and disintegrated structure is always more or less inflamed, red, and vascular; the periosteum is thickened, spongy, and injected; and the endosteum exhibits all the phenomena of an active

participation in the disease. The compact lamella has often a worm-eaten appearance, and it is not uncommon to find it partially incrustated with bony matter. The soft parts around are infiltrated with sero-plastic matter, indurated, closely matted together, and otherwise altered. In articular caries, there is always more or less involvement of the cartilages, which are gradually softened and disintegrated, as in fig. 297, large pieces often coming away with the discharges.

The ravages of caries, consequent upon tertiary syphilis, are well displayed in fig. 298.

The disease commenced in the soft palate, from which it gradually extended to the bones of the cranium and face, causing a free communication between the mouth, nose, orbits, and frontal sinuses. Fig. 299, from a specimen in my collection, affords a good illustration of caries of the head of a bone.

Symptoms.—The symptoms of caries are usually obscure, especially in its earlier stages, as there is no line of demarcation between it and osteitis. It is only when the affection has terminated in suppuration, ulceration of the soft parts, as in fig. 300, or the formation of sinuses, that its real character can be fully made out. Prior to this the nature of the disorder may be suspected but cannot be certainly determined. All the symptoms, in the first instance, are those simply of osteitis. There is a dull, heavy, aching pain, which appears to be deeply seated in the substance of the bone, and which gradually increases in extent and severity with the progress of the morbid action; the part is exquisitely tender to the touch; the skin has a glazed, reddish aspect; and there is marked tumefac-

Fig. 297.

Caries of the scapula, with softening and incipient separation of the cartilage.

tion, particularly at the focus of the inflammation. The local phenomena gradually augment in intensity, the pain assumes a throbbing disposition, the swelling

Caries of the head of the humerus.

becomes more pointed, and presently the loose, flabby integuments give way by ulcerative action, thus allowing the contents of the abscess—for such in fact the

Fig. 300.

Caries of the tibia, with an ulcer in the skin

case is—to drain off. The bone thus laid bare has a foul, corroded appearance, at the same time that it is rough and so soft as to be easily penetrated with the probe.

The sinuses leading to the seat of the disease are either straight or tortuous, and vary in length from a few lines to several inches, according to the depth of the affected bone and, above all, the place of opening of the abscess. In general they are multiple, and have separate orifices, so as to give the cutaneous surface a cribriform appearance. In chronic cases the sinuses are lined by a species of false membrane, and the situation of each is indicated by a mass of reddish granulations, somewhat mammillated in shape, in the centre of which the aperture of communication is generally easily detected with the point of the probe. This nipple-like body, which is often entirely insensible, and almost always bathed with pus, projects considerably above the surrounding level, and is of great diagnostic value, as it is invariably denotive of carious or necrosed bone. The sinuses do not commonly all form at once; perhaps there may be only one or two at the beginning, the rest being superadded during the progress of the disease, or, perhaps, as one closes another appears. However this may be, the parts around are always more or less indurated, inflamed, and tender on pressure.

The discharge is commonly of a thin, ichorous, sanious, or bloody character, loaded with earthy matter, more or less fetid, and so irritating as to erode the parts with which it comes in contact. It usually tarnishes silver—a circumstance

which shows that it contains sulphuretted hydrogen gas—and is often so profuse as to cause serious exhaustion. The earthy matter, which is easily detected by its gritty character, by rubbing the fluid between the thumb and finger, frequently amounts to two per cent. of the entire discharge. Sometimes the pus is of a laudable nature, but when this is the case it may generally be assumed that it is furnished by the adjacent soft parts rather than by the bone itself. It is not uncommon for it to contain flakes of lymph, the debris of cellular and aponeurotic substance, and even considerable fragments of bone and cartilage; the latter being most apt to show themselves when the sinus penetrates a neighboring joint.

The constitutional disturbance is not always proportionate, so far as we can judge, to the amount of the local disorganization. The general health is often but little affected, especially in the early stages of the disease; by degrees, however, it begins to give way, and ultimately suffers severely. The patient loses flesh and strength, the countenance is wan and pallid, and the sleep and appetite are destroyed. If the disease is at all extensive, or if, even when it occupies but a small compass, it opens into a large joint, as, for example, the knee, hectic irritation soon sets in, and, making rapid inroads upon the system, speedily reduces the patient to death's door. The pain is often excruciating, particularly at night and in damp states of the atmosphere, and is one of the principal sources of exhaustion.

Diagnosis.—The diagnosis of caries can, in general, be determined only by a careful consideration of the history of each individual case. Until ulceration of the soft parts occurs, the nature of the disease must almost necessarily remain an enigma. The only affection with which it is liable to be confounded is necrosis, but from this it may usually be easily distinguished, before the skin has given way, by the comparatively small amount of the attendant pain, as well as by the lesser degree of constitutional disturbance, and by the fact that caries is usually met with in the short bones, while necrosis mostly occurs in the shafts of the long. When sinuses have formed, the eye, finger, and probe will usually be able to determine the diagnosis, by the appearance and feel of the affected structure. In both cases the bone is roughened, but usually much more so in necrosis than in caries; in the former it always retains its original consistence, whereas in caries it is so much softened as to be readily penetrated by the probe. Nothing of a definite character can be learned from the nature of the discharge, since it is nearly identical in the two maladies. Occasionally valuable information may be obtained from a consideration of the exciting cause. Thus, osteitis from syphilis terminates more frequently in necrosis than in caries, the reverse being the case when the inflammation is dependent upon a scorbutic or strumous taint of the system. To this statement, however, numerous exceptions occur, and the diagnosis must, therefore, at least in most cases, be a matter of time and of repeated critical examinations.

Prognosis.—The prognosis of caries is generally unfavorable, a spontaneous cure, although not impossible, being an extremely uncommon occurrence. When the disease is of limited extent, a cure may often be promptly effected by operative measures directed against the affected parts, but under opposite circumstances nothing short of resection or amputation holds out the slightest prospect of relief. In many cases the affection continues for years, apparently neither advancing nor materially receding, the general health in the meantime experiencing but little change; on the other hand, however, its progress is sometimes very rapid, and the constitutional disturbance proportionately great, hectic irritation, loss of strength, and emaciation setting in early, and steadily proceeding until the patient dies completely exhausted. As a general rule, it may be stated that caries is less likely to terminate favorably when it assails the vertebræ and the articular ends of the long bones than when it appears in any other portions of the skeleton, except, perhaps, the carpal and tarsal bones, in which the malady is often so extremely obstinate as to require the removal of the limb in order to save life. The prognosis is, of course, other things being equal, more unfavorable in sickly

and debilitated persons than in such as are healthy and robust at the time of the attack.

Treatment.—The treatment of caries should always, if possible, be conducted with strict reference to the nature of its exciting causes. When the disease has been induced by a syphilitic, strumous, or scorbutic taint of the system, remedies calculated to meet these respective contingencies will of course promptly suggest themselves, as most likely to fulfil the particular indication of the case; but where no such affection is visible, and where, in fact, nothing whatever of an appreciable character exists, the surgeon must disregard all rules, and limit himself to the application of general principles. The diet should be very plain and simple, but at the same time nutritious, so as to build up the system, and create a better state of the blood, which is generally so much at fault in caries of nearly all portions of the skeleton. Chalybeate tonics, quinine, nux vomica, and cod-liver oil are the most valuable internal remedies; aided, as occasion may seem to demand, by blue mass and alkalies, to modify and improve the secretions. Active purging must be avoided, as it would inevitably prove prejudicial by its debilitating effects. Exercise in the open air is often of great service, but to render it efficient care must be taken not to move or irritate the diseased bone while it is being employed. Salt bathing, followed by dry friction, will be of benefit in imparting tone and vigor to the cutaneous capillaries; and in many cases the general health is immensely improved by a residence at the sea-side.

In commencing the local treatment, the first object should be to allay the irritation of the soft parts by attention to rest and position, and by the application of leeches, fomentations, and poultices, or warm water-dressings, medicated with laudanum and acetate of lead. When there is much induration from plastic deposits, the skin should be freely painted twice a day with dilute tincture of iodine, and if the case prove obstinate, a large blister should be used, experience having shown that, in superficial caries, this is more effectual in arresting the inflammation and bringing on the suppurative crisis than any other remedy. Even in deep-seated caries it frequently answers an excellent purpose, promptly arresting the excessive pain, and promoting the absorption of effused fluids. As soon as evident fluctuation exists, or even before, if there is inordinate tension and throbbing, a free incision should be made, extending, if possible, into the very depths of the bone, so as to admit of the most thorough drainage. To allow the matter to remain pent up always proves excessively injurious, from its tendency to burrow among the surrounding structures, detaching them from each other, and leading, in the end, to the formation of numerous sinuses. Besides, the early evacuation of the matter greatly abridges the suffering, constitutional as well as local, and thus prepares the system better for the future struggle. Whenever pus is retained, whether among the soft parts, in the osseous tissue, or within a joint, it must necessarily act as a foreign substance, maintaining local and constitutional irritation, and should therefore be got rid of as promptly and effectually as possible. These remarks are applicable to caries of the deep-seated as well as the superficial pieces of the skeleton. When the matter is lodged in the interior of a bone, as, for instance, the extremity of the femur or tibia, evacuation should be effected with the trephine.

The means now described are all merely of a palliative nature; they relieve pain, swelling, and constitutional disturbance, but are entirely incapable of curing the disease, however slight. To fulfil this indication other remedies are necessary; some for modifying the affected tissues, so as to afford them an opportunity of regaining their normal characters, and others for effecting riddance of the diseased bone, either in part or in whole.

Under the first head may be mentioned various detergent and acidulated preparations, as the solutions of the chlorides, creasote, nitrate of silver, and acetic, nitric, and hydrochloric acid, their strength varying with the age and constitution of the patient, and the state of the parts, the contact being effected by means of a large glass syringe, two operations being sufficient in the twenty-four hours.

They are particularly serviceable in these cases on account of their

cleansing and deodorizing effects, while the acids act more directly upon the osseous tissue, stimulating the capillary and absorbent vessels, and thereby promoting a more healthy tone, at the same time that they produce disintegration of the earthy matter of the diseased bone. These remedies, and all others of a kindred nature, are certainly not without some benefit in the milder and more accessible cases of caries, but they all have the disadvantage of being difficult of application, as well as uncertain in their results, and can rarely be relied upon for a cure. I have, therefore, of late years, entirely abandoned their use with this intention, and now employ them only with a view to their detergent and deodorizing effects, preferring, of course, the chlorides to any of the other articles for this purpose.

The actual cautery, formerly so much vaunted in the treatment of certain forms of caries, especially in that of the carpal and tarsal bones, is obnoxious to the same objections as the remedies just mentioned. In applying it, it is necessary not only to divest the affected bone pretty thoroughly of its soft parts, but to employ the greatest circumspection, otherwise a much larger amount of tissue may be destroyed than is desirable. Moreover, the eschar is always a long time in coming away, and the iron has generally to be used again and again before a cure is finally effected.

Under the second head are included the operations necessary for scraping or cutting away the diseased structure, excising the affected bone, either in part or in whole, and amputating the affected limb, when the case is unmanageable by other means.

As a general rule, all operative interference, having for its object the removal of the carious matter, is carefully abstained from until the disease has become strictly chronic, or, in some degree, ceased to spread. If this injunction be disregarded, injury, and not benefit, will be certain to follow our efforts, the irritation excited by them giving new impetus to the morbid action. The precise time for interference cannot, of course, be specified, but it is evident that no attempt should be made to scrape or cut the bone so long as the superimposed parts are in a highly tender, tumid, and inflamed condition. The proper treatment, under such circumstances, consists in the use of leeches, medicated fomentations, and other antiphlogistic measures calculated to soothe the irritated structures, and prevent the spread of the disease.

When the caries is of small extent, it may generally be got rid of by means of a burr-head drill, similar to that used by the dentist for removing caries from decayed teeth previously to plugging. With such an instrument, of which the adjoining sketch, fig. 301, affords a good idea, the whole of the diseased substance may often be cut away in a few minutes, with little pain to the patient, and no detriment whatever to the neighboring parts, which should always be

Fig. 301.

Bone-drill.

Fig. 302.

Gouge.

Fig. 303.

Scraper.

turned aside immediately prior to the operation. Every bone-case should have from three to six drills, of varying size and shape, so as to meet every contin-

gency that may arise in practice. Several trephines, pliers, gouges, chisels, and scrapers, should also be at hand. In operating upon the tarsal and carpal bones, I have generally derived material service from the use of a short, stout scalpel, with a semi-sharp convex extremity, and a large handle. Such an instrument is peculiarly advantageous in paring the surface of deep-seated cavities. When the ligaments and cartilages are involved, the operation can hardly be completed in a satisfactory manner without a pair of blunt-pointed scissors, with long, thick, narrow blades. The raspatory is useful in smoothing carious cavities after the removal of the disorganized substance. During the operation the diseased cavity is kept free from blood, by means of sponge mops.

When all the diseased structure has been removed, free use should be made of the syringe in order to effect thorough clearance of the affected cavity. Unless this is done, more or less of the bony matter will be left, thus keeping up irritation and discharge, and interfering with the reparative process.

Considerable *hemorrhage* often attends these operations, the blood sometimes proceeding from small arteries, but more generally from numerous points, as if it came from the pores of a sponge. In the former case, the ligature will usually be required, more particularly as the vessels are unable to retract on account of the indurated condition of the surrounding parts, while in the latter the temporary application of the sponge, wrung out of cold water, will commonly speedily arrest the flow. Should this, however, not answer the purpose, the bleeding cavity should be stuffed with lint, soaked in a strong solution of alum, or of persulphate of iron, the plug being retained no longer than may be absolutely necessary.

Doubt is often experienced, in these operations, as to the amount of substance to be removed, the precise line of demarcation between the sound and diseased structures not being always easy of determination. A good diagnostic, under such circumstances, is to wash the fragments in water, when, if they are carious, they will exhibit a whitish, grayish, greenish, or blackish appearance; whereas, if they are healthy, they will be found to be vascular and red, and to retain their normal consistence, presenting none of the fragile and porous characters which distinguish them in the former case.

Bleeding having been arrested, the edges of the wound are loosely approximated by suture; and the limb, placed in a favorable position for drainage, is wrapped up in a bandage, extending from the distal extremity upwards beyond the seat of operation. Water-dressing is afterwards used, either cold or warm, as the case may seem to demand, and strict attention is given to antiphlogistics generally. Occasionally it is found requisite to insert a tent, to conduct off the matter, and prevent premature closure; and for some time the bony cavity should be injected twice or thrice daily with tepid water and Castile soap, or some gently detergent lotion. The great sources of danger after the operation are erysipelas and pyemia.

The *healing process*, after such an operation, exhibits itself by the development of granulations, which, under the microscope, display very much the same appearance as those of the soft parts. The vessels, as shown in fig. 304, from a drawing made for me by Dr. Packard, have a remarkably looped and varicose arrangement. It was taken from an ulcerated patella, which was covered with an immense number of the most beautiful scarlet granulations, not as large as the smallest pin's head, closely grouped, and exceedingly tolerant of rude manipulation. The section was magnified sixty diameters.

Excision of an entire bone is sometimes necessary for the relief of this disease. Such a procedure is most frequently required on account of caries of the

Fig. 304.

Structure of a granulation in a bone.

carpal and tarsal bones, upon which it may frequently be performed with great advantage, a useful limb being generally left even after the removal of several of these pieces. In the long bones, the operation is usually limited to the articular end, or to this and a portion of the shaft. Respecting the manner of executing this operation, and the estimate to be placed upon it, in a curative point of view, special mention has been made in the chapter on excision, so that any further discussion of the subject here is unnecessary.

When the disease is so extensive as to be uncontrollable by the means now described, and the attendant discharges are so copious as to give rise to profuse night-sweats, marasmus, and colliquative diarrhœa, *amputation* of the limb, comprising the carious bone, will afford the only chance of safety, and should be performed without delay. It is surprising how the system usually rallies after such an operation. The patient, in the course of a few days, generally looks like a new being; his sweats and diarrhœa soon leave him, and he rapidly improves in health and spirits, making often an excellent recovery.

SECT. VI.—NECROSIS OR MORTIFICATION.

The word necrosis denotes the death of a bone, and is strictly synonymous with mortification, gangrene, or sphacelus, used to designate the death of a soft structure. The immediate cause of the occurrence is inflammation, eventuating in an arrest of the circulation and innervation of the osseous tissue.

Necrosis is most common in the superficial bones, or in those which lie immediately beneath the integuments, as the tibia, ulna, lower jaw, clavicle, the inferior portion of the femur, and the phalanges of the fingers. The long bones suffer more frequently than the short, and the short than the flat, the reverse being the case in caries, for the reason that, in the former, the compact tissue is most commonly affected, and in the latter, the spongy.

Children under fifteen years of age, of a strumous diathesis, are the most common subjects of this disease. Of the influence of sex, climate, and occupation, upon its production, nothing satisfactory is known. It has generally been supposed, and not without reason, that it is most common in cold, damp, and variable regions, on the assumption that the inhabitants of these countries are particularly prone to suppression of the cutaneous perspiration, which, in individuals predisposed to disease, may, it is alleged, readily cause death of the more superficial bones. Persons engaged in the manufacture of lucifer matches are liable to necrosis of the jaw, from the contact of the fumes of phosphorus with the interior of decayed teeth; and it is not improbable that there are other pursuits which may conduce to destructive inflammation of the osseous tissue, although of their precise nature and mode of action we are not informed.

Causes.—If we inquire into the idiopathic form of necrosis it will be found, as has just been intimated, that it is most common in young strumous subjects, having either well marked evidence of scrofula in other parts of the body, or, at all events, signs of a strumous predisposition, as evinced by the delicacy of the skin, the languid circulation, the tumid belly, and the deficient temperature of the extremities. This has certainly been the case in the great majority of instances that have come under my own observation, and I believe that my experience, in this respect, in the main, agrees with that of other writers. It is in persons of this description, more particularly, that we so frequently meet with the worst species of necrosis of the tibia, femur, and humerus, telling so fearfully upon the constitution, and so often requiring amputation in order to save the patient's life. The most common cause of the disease, in this class of subjects, is exposure to cold, as when a boy, overheated by play, sits down in a current of air, and thus suddenly repels his perspiration; or when, under similar circumstances, he strips himself and plunges into cold water. He is not made aware, perhaps, for several days that he has received any injury; but, all of a sudden, he is seized with violent pain in one of his limbs, attended with severe rigors alternating with flushes of heat, and, upon examining the affected part, he observes that it is exquisitely tender on pressure, more or less swollen, and covered

with an erysipelatous blush. The local and constitutional symptoms progressing, matter soon forms deep beneath the muscles, the swelling becomes more and more circumscribed, and, ulceration taking place, the contents of the abscess thus gradually find their way to the surface, leaving the bone dead below. Such is the manner in which necrosis is generally produced in weakly, scrofulous subjects, and it is hardly necessary to add that all the attendant phenomena are indicative of a rapidly destructive osteitis, or osteitis and periostitis.

Tertiary syphilis is another cause of necrosis, and the history of this disease has shown that the osteitis growing out of it is more apt to occasion death of the bone when the patient has been subjected to free courses of mercury for its cure, than when the malady has been treated on general antiphlogistic principles. The two poisons coming together, and mingling their baneful influence, induce a form of inflammation which is extremely prone, especially in persons of a worn-out, debilitated constitution, to terminate in gangrene of the bones, particularly those of the nose, palate, upper jaw, leg, and arm.

Protracted courses of mercury, especially in young subjects of a strumous diathesis, or exhausted by diarrhoea, cholera, or eruptive diseases, often cause necrosis of a frightful character, generally of the maxillary bones, but sometimes, also, of other pieces of the skeleton. What is termed dry salivation is frequently more destructive to the gums, teeth, and jaw-bones than salivation accompanied by profuse discharge. The debility provoked by the injudicious use of drastic purgatives and tartar emetic has occasionally eventuated in necrosis of the bones of the head, trunk, and extremities. Scurvy has been known to produce similar effects, although more commonly it causes caries. In short, there is reason to believe that idiopathic necrosis may be induced by whatever has a tendency to bring about an impoverished condition of the blood and solids.

Among the local causes of necrosis may be enumerated wounds, contusions, fractures, amputations, and chemical irritants. In the tibia and femur, the probability is that mere concussion, as happens when a person falls from a considerable height and alights upon his foot, is often sufficient to produce a destructive form of osteitis. Gunshot injuries are a common source of the occurrence, whether the bone is merely grazed by the passage of the projectile, or whether the ball lodges in its substance and acts as a foreign body. Mere denudation of a bone, however occasioned, is frequently followed by its death, especially when the loss of periosteum is very considerable, or if, even when it is comparatively trivial, it is accompanied by the laceration of the nutrient artery, or extensive destruction of the soft parts generally. Under such circumstances, the necrosis is usually limited to the outer compact structure, the part ultimately coming away in the form of an exfoliation. Such an event, however, is by no means inevitable. The periosteum may be stripped off to a considerable extent, and yet, if the bone is in other respects healthy, or enjoys a tolerably active circulation, granulations will spring up, and thus gradually repair the breach. It is only when the vascular connection between the two structures has been materially impaired, or totally destroyed, that necrosis will be likely to ensue, the bone becoming white and dry, and ultimately dark and even black. These appearances are well illustrated in what so often happens in compound fractures, attended with protrusion of the end of the bone divested of its fibrous covering, and in the phalanges of the fingers in whitlow.

It will thus be perceived, without going into further details, that death of the osseous tissue may be produced by constitutional or local causes, and that these causes differ in no respect whatever from those which induce mortification of the soft parts. Furthermore, it may be stated that they are such as usually give rise to inflammation generally in all structures without exception.

Extent.—Necrosis may be partial or complete, simple or complicated, superficial or deep; that is, it may affect merely a portion of a bone, or it may pervade its entire structure; it is said to be simple when it is limited to a single piece, and complicated when it attacks several, either simultaneously or consecutively. It is seldom that an entire bone perishes. Such an occurrence is sometimes observed in the pieces of the carpus and tarsus, in consequence of external

injury, but it is extremely uncommon in the long bones; in these the shaft alone generally suffers, the articular ends retaining their vitality. Necrosis of the whole lower jaw has been repeatedly noticed as a result of the action of phosphorus, and some interesting cases in which the entire bone was successfully removed on account of this disease have been related by Dr. Carnochan, Dr. J. R. Wood, and others. Finally, necrosis may be limited to the outer surface of a bone, involving merely its superficial lamellæ, the dead portion being ultimately detached in the form of a thin scale or plate; or it may invade its entire thickness, and it then not unfrequently begins in the very depths of the cancellated tissue, generally from injury or disease of the medullary membrane.

The occurrence of necrosis, the elimination of the dead bone, usually called the sequester, and the formation of new bone as a substitute for the old, or that which has died, involve some very curious pathological and physiological processes, and therefore deserve attentive consideration. The symptoms which immediately precede, and those which accompany the death of the bone, are generally such as are denotive of violent inflammation, deep-seated, attended with excruciating pain, and rapidly tending to the suppurative crisis, the mischief being often done in a few days, or even in a few hours. Action, general as well as local, is excessive, and both the part and system occasionally fall a prey to its devastating influence, especially when there is involvement of a large neighboring joint, as now and then occurs when the necrosis attacks the inferior extremity of the femur, and extends into the knee. Progress, however, is not always so swift and overwhelming; often it is quite the reverse, the part and system suffering but little, and the malady pursuing apparently a chronic course.

A very common way in which the occurrence of gangrene of a long bone is announced is as follows. The patient, usually a lad from six to ten years of age, after having been overheated or exposed to severe cold, retires at night apparently perfectly well, but towards morning he is aroused by pain in the thigh or leg, deep-seated, circumscribed, of a sharp, aching character, and so excessively severe as to deprive him of further sleep and rest. The soft parts over the seat of the disease soon become exquisitely tender to the touch, swollen, and discolored, the surface having a glazed, dusky, reddish, or purplish tint, and pitting under pressure from the infiltration of the subcutaneous cellular tissue. These local phenomena are always attended by severe constitutional disturbance. There is high raging fever, with a tendency to delirium, and excessive restlessness; the pulse is full, hard, and frequent; the skin is hot and dry; the thirst is incessant; and the urine, thick and scanty, is surcharged with urates. By and by, violent rigors set in, succeeded by flushes of heat, the pain assumes a tensive, throbbing character, the swelling becomes more diffuse, extending often to a great distance up and down the limb, as well as widely circumferentially, the discoloration acquires an erysipelatous blush, and a careful examination soon detects, what, indeed, the existing symptoms sufficiently declare, the presence of pus, deep-seated, lying partly between the affected bone and the periosteum, and partly on the outside of the membrane, in the cellular tissue of the muscles and aponeuroses, which it often extensively dissects and separates from each other, forming large pouches from which it is frequently difficult to dislodge it. Sometimes the abscess opens into a neighboring joint, and thus becomes a source of additional mischief, exciting inflammation in the synovial membrane, perhaps ultimately followed by destructive softening of the cartilage, and caries or necrosis of the end of the bone.

The quantity of matter at this stage of the disease varies from a few ounces to upwards of a pint, and is mostly derived, not from the affected bone, or bone and periosteum, but from the soft parts in their immediate vicinity, which always greatly participate in the morbid action. In spontaneous necrosis, it is usually of a strumous character, of a yellowish color, verging upon greenish, more or less fetid, especially if long retained, and of a thick, cream-like consistence, interspersed with curdy substance, and, not unfrequently, also with shreds of dead cellular tissue. Occasionally the matter is thin, ichorous, or sanious, but such an occurrence is unusual until after the bursting of the abscess, and the evacuation of its contents.

When the matter has been discharged, whether spontaneously or artificially, there is always a marked improvement in the symptoms, both local and constitutional, and an opportunity is now afforded for a thorough examination of the parts. The best instrument for this purpose is the finger, or, when the opening is very small or devious, the probe. With either of these it is generally easy to determine the extent of destruction of the periosteum, and the amount of injury sustained by the bone, the surface of which will always be found to be more or less rough, and of a whitish, grayish, or ashy hue, without any appearance whatever of vascularity.

Such is a succinct account of the circumstances which precede, accompany, and follow the ordinary occurrence of necrosis. The first stage of the disease is over; the matter consequent upon the inflammation has been discharged; and the inflammation itself has measurably subsided, although the soft parts are still swollen, indurated, tender, painful, and disabled. Nature, never idle, now begins the double work of elimination and repair, both usually very tardy, often imperfect, and sometimes altogether unsatisfactory, the powers both of the part and system being inadequate to accomplish the object. In gangrene of the soft structures, the separation of the eschar is generally an easy matter compared with that of a bone, provided the patient's strength holds out; the process, once fairly commenced, proceeds rapidly and energetically, the surgeon each day seeing decisive evidence of the fact; soon the line of demarcation between the dead and living parts is perceived; then granulations spring up in the intervening chasm; and, finally, the reparative efforts still advancing, the breach is gradually closed over with new skin, a circumstance clearly denotive of the completion of the cure. But it is altogether different in necrosis; here the detachment of the slough is a matter of time, requiring many weeks, if not several months, for its satisfactory conclusion, and even then generally demanding the interference of art before it can finally be effected. The cause of the difference is sufficiently obvious. In the one case there is an active circulation and an energetic system of absorbents, the former furnishing an abundance of plastic material for the repair of the lost tissues, and the latter exerting themselves to cast off the dead substance; in the other, on the contrary, everything is the reverse, and the parts labor under the additional disadvantage of being loaded with earthy matter, which is obliged to be softened and disintegrated before it can be removed by the vessels whose duty it is to get rid of it.

The necrosed substance may, as has already been seen, embrace merely a portion of the periphery of a bone, as, for example, its outer layer; or it may include its entire thickness, and also the greater part of its length. In the former case it constitutes, when detached, what is called an *exfoliation*, in the latter a *sequestrum*, a distinction of considerable importance, not so much on account of the extent of the dead substance, as of the manner in which the breach of continuity is repaired, or a new bone formed.

An exfoliation is commonly merely a thin scale, plate or lamella of the outer, peripheral portion of a long bone, of variable color and consistence. In general, it is either whitish, grayish, or of a light brownish hue, rough, more or less porous, and so brittle as to break under very slight pressure. No vessels are perceptible in it, and in most cases the animal matter seems to be almost completely abstracted. Maceration deprives it of its dark color, while immersion in dilute nitric acid for a few days completely destroys its proper texture, converting it into a soft, gristly substance.

The *sequestrum*, properly so called, varies much in size and shape, consisting, at one time, of a part only of the circumference or length of a bone, and, at another, of its entire shaft, with perhaps a portion of its articular ends. A rather common form is that represented in the adjoining sketch, fig. 305, from a preparation in my collection;

Fig. 305.

Sequestrum of the tibia.

it was a part of the body of the tibia, in which all the spongy structure was completely destroyed, while the compact was remarkably hard and firm. The dead bone is always rough, pitted, excavated, or spiculated; it is of a grayish, brownish, or blackish color, and emits, when struck with a probe or piece of metal, a peculiar hollow sound, by which it is usually readily distinguished from sound bone. In the cylindrical pieces, as in the femur and tibia, it is generally dense and dry; in the short and flat, on the contrary, it is porous, moist, brittle, and easily crumbled. The analyses of Von Bibra have shown that there is a very great reduction of organic matter in necrosis with a corresponding increase of earthy, the latter being as much as eighty per cent. of the entire mass. The same experimenter has proved that the difference is considerably less in the traumatic variety of the lesion than in the idiopathic.

Mode of Repair.—While the absorbents are engaged in detaching the dead bone, with a view to its ultimate expulsion, the capillaries take upon themselves the duty of throwing out material for the formation of the substitute or new bone. The process by which this is accomplished is similar to that which presides over the creation of the original structure. The first step consists in a deposit of plasma, the result of the incited action of the vessels caused by the irritation of the necrosed bone, and this substance, becoming organized, is gradually converted into fibro-cartilage, which, in turn, gives way to cartilage, as this ultimately does to osseous matter, the period required for the completion of the development varying, according to the age and vigor of the patient, and the character and amount of the local disease, from a few weeks to several months. The new bone is at first a mere shell encasing the old, and thus serving to separate it from the surrounding parts, which ill brook its presence. In time, however, it increases in thickness, being often from three to six lines in depth, and occasionally, though not generally, it is fully as large as the original

piece. Its surface is usually somewhat rough, and it is not uncommon to observe upon it considerable eminences and depressions, owing evidently to the irregularity of the developmental process. The new substance, too, has comparatively little areolar tissue, and, therefore, especially if some time has elapsed since its formation, it is always cut with great difficulty, the resistance offered by it being much greater than that of the pre-existing structure. In cases of long standing, indeed, it often acquires the solidity and density of ivory, so that it requires great patience and perseverance to penetrate it with the saw and pliers. The vessels, in this event, are always very small and sparse, and the Haversian tubes are traced with difficulty. In the long pieces, after the death and removal of the shaft, there is never a complete reproduction of the medullary canal and its lining membrane, or of the endosteum. In fact, the new bone, although it possesses all the essential attributes of the osseous tissue, is, nevertheless, a very imperfect type of the original, and therefore much less capable of resisting the effects of disease and accident.

The appearances of the new bone, encasing the old or dead, are admirably depicted in *fig. 306*, taken from a specimen in the collection of Professor Pancoast.

In viewing the new bone as it

old, its surface is found to be pierced by several apertures,

Fig. 306.

Necrosed tibia, the dead bone lying loose within the new.

Fig. 307.

Encase in a necrosed tibia.

fancied resemblance to the rectal pouch of a bird, the term *cloacæ*, fig. 307, is usually applied. These openings, which play an important part in the expulsion of the dead bone, owe their existence to a deficiency of periosteum, or of secreting structure, as is proved by the fact that, when the formation of new osseous tissue goes on uniformly round every portion of the periphery, the old bone will be completely imprisoned, thus not only obscuring the diagnosis but rendering the removal of the sequester a matter of great difficulty and perplexity. The size of these cloacæ varies in different cases, from that of a three cent piece to that of a quarter of a dollar, their shape being generally rounded, or somewhat oval. Not unfrequently, however, they present themselves in the form of long, irregular fissures, or slits. Their number is indefinite; sometimes there is but one, while at other times there may be as many as half a dozen, the latter number being by no means uncommon in necrosis of the shaft of the tibia. However this may be, they always communicate with the surface of the limb in which the affected bone is situated, the passages between them constituting so many channels for the discharge of matter and the ultimate elimination of the sequester, although this, owing to the inadequate dimensions of the cloacæ, is seldom effected without the intervention of art. It is an interesting fact, and one of no little practical value, that these openings are always situated in that portion of the new bone which is least covered by soft parts.

There has been much dispute among pathologists as to the agents by which the new bone is produced, and the question can hardly be said to be even yet definitively settled. Without entering into any details, I may state, as the result of personal observation, that the perfection of the new bone will generally be in proportion to the integrity and activity of the periosteum. I have always found that, when this membrane has suffered much during the inflammation which precedes and accompanies the necrosis, the reproductive process, or new osseous epigenesis, is tedious and difficult, and often extremely inadequate, the new bone being comparatively small and stunted, and, therefore, ill adapted to the purpose of a substitute bone. The part which the periosteum plays in the development of the new bone is well shown in the formation of cloacæ, which, as already stated, is clearly dependent upon the partial destruction of that membrane. If the periosteum everywhere retained its integrity, the new bone would be without a solitary opening, and the consequence would be that the sequester, or slough, would always be an encysted body, imprisoned, as it were, in a shut canal. When this membrane has perished along with the bone, as occasionally happens in the shaft of the tibia or femur, the new bone will be formed by the surrounding structures, whatever these may be, but under such circumstances it is so imperfect, short, and thin, as hardly to deserve the name of substitute, to which, in general, it is so well entitled.

When the eschar presents itself as an exfoliation, or thin superficial scale, the breach is repaired through the medium of granulations, which, being derived from the old bone, are extremely vascular and sensitive, and soon assume the ossific process, throwing out an abundance of proper material for the accomplishment of the object. A similar process appears to be set up when the central portion of a bone perishes; for here the endosteum being also destroyed, it can have no agency in the reproductive act. When this membrane retains its vitality, it must necessarily exert an important influence as an osteogenic agent.

The idea has been broached, and warmly defended, that when the shaft of a bone is necrosed, so as to leave merely its articular ends, the new bone is formed exclusively by these ends, the osseous matter extending gradually towards the middle of the chasm, and ultimately coalescing there. Such a theory, however, is altogether untenable, as it is contrary to what occurs in the growth of the original bone, which always takes place by several distinct points, one of which is invariably central. However well the surviving extremities might perform their duty, yet, as there is no central nucleus, serving as a point of departure for the ossific matter, it is easy to conceive that the bone would always necessarily
 articular spot as to disqualify it materially for the per-
 tions.

The osteogenic properties of the periosteum have lately been placed in a very satisfactory light by the experiments of Dr. Ollier, of Lyons. He found that, in rabbits, portions of this membrane, completely detached from the bone, might be pushed into the soft structures, and still preserve their power of generating osseous matter. In some cases, indeed, this faculty was not lost when the periosteum was transplanted to remote parts of the body, or from one animal to another. The results of these researches, however, although pathologically interesting, possess little, if any, practical value, inasmuch as they cannot be rendered available in the human subject.

Symptoms.—The symptoms which attend necrosis, in its earlier stages, have already been pointed out; those which accompany the separation of the old bone and the formation of the new, are, in general, sufficiently characteristic. The most important of these are, little ulcers, surrounded by large unhealthy granulations, arranged in a papilla-like manner; sinuses leading from these ulcers down to the dead bone; and a discharge, more or less constant and copious, of thin, fetid, sanious matter, or of thick, white, inodorous pus; accompanied, in all cases, by a certain amount of hardness and swelling, pain and tenderness on pressure, wasting of the soft parts above and below the seat of the disease, and marked impairment of the functions of the neighboring joints. The general health always suffers; the patient is wan and emaciated; and, if the irritation is at all extensive, he will usually have hectic fever. In some cases the end of the sequester sticks out at one of the cloacæ, thus at once declaring the real nature of the complaint; but more commonly the dead bone is completely imprisoned by the new, and can only be reached by the probe or finger, carried along the sinuses leading from the surface to the cloacæ. In order to ascertain whether the separation has been effected, or whether the dead bone still maintains its relations, in some degree, with the living, the surgeon may often advantageously use two probes, introducing one at each extremity of the eschar, and moving them alternately in different directions, as may frequently be easily done when the detachment is complete. In general also useful information, in this respect, may be obtained from a consideration of the history of the case, as the size of the affected bone, the age of the patient, and the commencement of the attack. Thus, other things being equal, it will usually be found that a small bone will be more readily separated than a large one, and the bone of a young subject than that of an old one, while in every instance the process may be supposed to be more advanced in proportion to the period that has elapsed since the death of the bone.

Prognosis.—The prognosis of this disorder is variable. In general, it may be considered to be favorable when it is owing to external or local causes; when it is confined to the outer portion of a bone, the necrosis occurring in the form of an exfoliation; when it is simple and of moderate extent; and when the patient is young, robust, and of good constitution. On the other hand, the cure is difficult, and the issue doubtful, when the disease is extensive and complicated with other affections; when it attacks pieces which are of high importance on account of their function or situation; when it occupies the interior of a bone, and involves several parts of it; when it arises from an internal or constitutional cause, as struma or syphilis; when it extends into the adjacent joints, especially when these joints are of large size; and, lastly, when the patient is enfeebled by age, long suffering, or previous disease.

The time required for the development of the substitute bone will depend, as already stated, in great measure, upon the situation and extent of the disease, the age, health, and condition of the patient, and various other circumstances. That the whole of a necrosed bone may be regenerated is a fact so well established as no longer to admit of any doubt. The new bone, however, as intimated elsewhere, is always, at best, only an imperfect copy, although, as it respects its functions, it usually answers the purpose well enough.

Treatment.—The treatment of necrosis must of necessity depend very much upon circumstances. There are three indications, however, which deserve special attention; the first is to limit and moderate the inflammation which is the immediate cause of the mischief, the second, to watch nature during the separa-

tion of the old bone and the formation of the new, and the third, to promote the removal of the sequester, slough, or eschar.

The first of these objects is to be attained by the proper employment of antiphlogistic remedies; by the lancet, if the patient is plethoric, purgatives, the antimonial and saline mixture, light diet, repose, and the free use of opiates to allay pain and induce sleep. The affected parts, placed in an easy, elevated position, are leeches and fomented, or, what is particularly serviceable, painted with a strong solution of iodine at least three times in the twenty-four hours, the surface being protected in the intervals with an emollient anodyne cataplasm, or medicated water-dressing. In some instances, great benefit is derived from the application of a blister large enough to encircle nearly the whole of the affected limb, and kept on sufficiently long to produce thorough vesication. By these means, the surgeon not only limits the inflammation, but promotes the absorption of effused fluids, and hastens the suppurative crisis, which is always inevitable, to a greater or less degree, in every case of this kind. As soon as fluctuation is perceived, or even before, if there be inordinate pain and tension, or deep-seated matter, a large incision is made at one or more points, in the direction of the long axis of the bone, in the hope of saving osseous as well as soft tissue, especially the periosteum, the integrity of which is so essential to the development and formation of the substitute bone. In making the opening, due attention is, of course, had to drainage, and to the prevention of its premature closure.

The second indication is to watch the part and system during the sloughing process and the stage of reparation, in order that they may be enabled to perform with facility the arduous and important duties before them. The case requires active vigilance rather than active treatment; care, on the one hand, that the disease do not spread, and, on the other, that the debility consequent upon the drainage and irritation do not obtain the mastery, and so bring on fatal exhaustion. A certain amount of inflammation must necessarily attend both operations, and, therefore, action must not be too much repressed, lest nature be thwarted in her efforts. A nutritious diet will generally be required, and the patient will often be immensely benefited by animal food and milk punch, ale, porter, or wine, and the use of quinine, iron, and aromatic sulphuric acid, especially if he has hectic fever and night-sweats. If he can move about on crutches, he should take gentle exercise daily in the open air; or, if this is impracticable, he should be pulled about in a hand-car, or swung upon a hammock. Attention is of course paid to the bowels and secretions. Pain is allayed by anodynes. The principal local remedies are leeches, provided there is any disposition to over-action, the daily application of iodine, and the use of the bandage to support not merely the affected parts, but also the distal portion of the limb, which, when this precaution is neglected, has usually a tendency to become œdematous. Fœtor is allayed, and discharge moderated, by the chlorides, introduced by the syringe and sprinkled upon the dressings. Much has been said about the employment of solvents, thrown in through the principal sinuses upon the dead bone, in the hope of promoting its gradual disintegration and elimination. Special stress used to be laid upon various acid solutions, particularly the nitric, hydrochloric, and pyroligneous; but experience has proved that they are always productive of harm, from their irritating effects upon the new bone and the soft parts, whilst, unless they are intolerably strong, they can exert no destructive influence upon the sequester itself. If such lotions be employed at all, they should, therefore, be employed in the mildest possible form, simply with a view to their detergent and alterant effects, which are often very salutary, expediting the sloughing and restorative processes. In general, however, all the good that can be expected to result from such remedies may be accomplished by injections of tepid water, impregnated with Castile soap, a little potassa, or common salt, followed, if there is much fœtor, by a weak solution of carbolic acid and soda. If new abscesses form, attention.

During this stage, a stage, I repeat, into special diatheses, or states of and, therefore, be in need of special

inquiry is made of the strumous, and

with the syphilitic poison, and a course of mercury, or of iodide of potassium, may be required. It must be obvious that no satisfactory progress can be made, in any case, towards a cure so long as the system is borne down by the pressure of a vitiated state of the solids and fluids.

The third indication is to get rid of the sequester, for so long as this remains it must necessarily keep up inflammation and discharge. It was generally supposed, until recently, that the dead bone, during its sojourn among the living tissues, was acted upon by the absorbent vessels, so as materially to diminish its size and weight, the idea having apparently derived support from the altered and pitted condition of the surface of the affected piece. The notion, however, has been completely dispelled by the experiments of Mr. Gulliver, who has ascertained, as might, indeed, have been anticipated, that such an occurrence is altogether impossible. Portions of necrosed bone, carefully weighed before and after exposure, were confined on suppurating surfaces, in the medullary canal, and in the subcutaneous cellular substance for months, and in one instance for upwards of a year, without undergoing the slightest alteration whatever.

Inasmuch, then, as the dead bone acts as an extraneous body, and is in nowise amenable to the agency of the absorbents, the indication plainly is to remove it by operation. Such a step is the more imperative because of the manner in which it is imprisoned, the substitute bone forming a firm and solid case around it, and thus effectually preventing its extrusion. The only circumstance which should make the surgeon at all hesitate is the doubt that may arise in his mind respecting the probability of the dead bone being completely detached, and the new one sufficiently advanced to enable it, after the removal of the sequester, to maintain its position without bending under the weight of the limb, in turning in bed, walking, or sitting. If he is satisfied of this, as he usually may be after a careful examination, the operation should at once be proceeded with. The instruments that will be required are several scalpels, a trephine, a Hey's saw, an elevator, pliers, chisels, and stout forceps, with a good syringe for washing away osseous debris. The adjoining cuts represent some of the more important of these instruments.

The incisions should be made in the direction of the long axis of the bone, out of the way of the great vessels and nerves. The best plan usually is to select one of the principal cloacæ, or, when two or three are close together, especially if they are on the same plane, to connect them, thereby affording more room to work in. When the soft structures are much diseased, they may be included in an elliptical incision, as, in this event, it may be best to get rid of them. When it is deemed advisable to connect two or more cloacæ, the object may easily be attained by a Hey's saw, or, if the new bone is not very thick and firm, by the pliers. The trephine is chiefly of use when the openings in the substitute bone are very small, or when this bone possesses unusual density and thickness, rendering its division extremely difficult by the more ordinary instruments. Access having thus been obtained, the sequester is to be seized by one of its extremities, with a pair of forceps having long, thin blades, serrated on their inner surface, and from a third of an inch to half an inch in width, the handles being well curved, so as to facilitate prehension and maintenance.

When the sequester is unusually long, it may be necessary to divide it at the middle, and extract each piece separately; an operation which is always easily performed with the pliers or chisel.

The dead bone having been extracted, the next step is to wash out the canal left by its removal with a syringe and cold water to clear away any little pieces, fragments, or debris that may have been left. Attention to this injunction will greatly expedite recovery by facilitating the growth of healthy granulations. The hemorrhage attending the operation is often quite free, the blood oozing out at every point, in consequence of the great vascularity of the parts, both osseous and soft, and occasionally requires plugging of the cavern with lint steeped in some styptic lotion, as a saturated solution of persulphate of iron, alum, or alum and tannin. It is seldom that any arteries require to be tied.

The edges of the wound are drawn lightly together with adhesive strips; the

limb, placed in an easy position, is bandaged from the distal end upwards; and the parts more immediately affected are kept constantly wet with cold water

Fig. 308.

Fig. 311.

Fig. 312

Instruments for removing dead bone.

medicated with laudanum and acetate of lead. The dressings are removed in forty-eight hours, when the wound is well syringed, and covered with an emollient poultice, to favor the granulating process. The only general means usually required are light diet and a little attention to the bowels, with a full anodyne after the patient is put to bed. If the new bone is not sufficiently strong to prevent the limb from bending or breaking, it must be supported by appropriate splints, or, what is better, a case made of sole-leather, gutta-percha, or trunk-maker's board.

Soon after the sequester has been removed, whether by nature or art, the new osseous shell begins to contract, and by degrees assumes the shape of the old bone, which it is designed to replace. While this change is going on externally, osseous matter is deposited upon the inner surface of the shell, as well as upon the articular ends of the surviving portions, thereby gradually filling up the cavity, the period required for this being generally in proportion to the size of the eschar. The medullary canal, in case there has been one, is, as already stated, seldom re-established.

It is not often that the surgeon is not able to effect a good cure in necrosis; in general even with little deformity and loss of function. Cases do, however, occur, where, from neglect or injudicious treatment, the neighboring structures are so extensively and ruinously involved as to render it difficult, if not impossible, to save the affected limb. Such an event will be particularly liable to happen when a large joint is implicated, as, for instance, that of the knee in necrosis of the thigh, or of the ankle in necrosis of the tibia. Under such cir-

circumstances, hardly anything short of amputation will be likely to answer; and a similar procedure may become necessary when the patient's constitution is so much shattered by previous or concomitant disease as to preclude the possibility of its holding out during the time that may be required for the separation of the dead bone. In other cases, again, amputation may be demanded on account of hemorrhage from some large sinus, presenting itself either as a general oozing, or as a flow from an artery of considerable size, opened by ulcerative action at a period when the loss of a few more ounces of blood might prove fatal. It is impossible, however, to exercise too much caution in attempting to decide so grave a question. In weighing the several points involved in its consideration, we must not lose sight of the fact that cases, apparently of the most forlorn character, where life literally hangs, as it were, by a thread, will sometimes promptly recover upon the removal of the dead bone. Finally, it must not be forgotten that excision of an entire bone has often been advantageously performed, especially of late years, recovery taking place with comparatively little deformity.

SECT. VII.—SOFTENING.

The essential characteristic of osteomalacia, *mollities ossium*, or softening of the bones, is a diminution of the firmness and solidity of the osseous tissue de-

Fig. 313.

Madame Supiot, in a posture quite practicable in the advanced stage of the disease.

pending upon the gradual removal of its earthy constituents, and the deposition of a reddish sero-albuminous, oily, or greasy substance. The malady is often confounded with rickets, but differs from it in the circumstance, first, of its being a disorder of adult life, and, secondly, in being always attended with severe pain; whereas rickets is peculiar to infancy, and free from local suffering.

Softening of the osseous tissue varies in degree and extent, occurring at one time as a very slight affection, with hardly any appreciable change of structure, and at another as a most serious lesion, in which it is difficult to distinguish any trace of the normal substance. In regard to its extent, it may be general or partial; in the one case

pervading the entire skeleton, while in the other it is limited to particular bones, or portions of bone. Of general osteomalacia, the case of Madame Supiot, which has long since become classical, and which has been so minutely described by Morand, the younger, in the *Memoirs of the Academy of Sciences of Paris*, for 1710, affords a characteristic, as well as a most extraordinary example, as shown in fig. 313. This female, who was thirty-seven years of age at the time of her death, had her bones so completely softened that they could be bent like wax, and put in almost any position, although she herself had lost all control over them, her head and left arm being the only parts she could move. Most generally the disorder is confined to particular bones, especially the ribs, sternum, vertebrae, and pelvic pieces. The latter are especially liable to suffer in child-bearing women.

Morbid Anatomy.—The osseous tissue in this disease gradually loses its firmness and solidity, becoming ultimately so soft and pliant that it may be easily bent, if not cut. It is of a pale reddish color, often inclining to yellow, is specifically lighter than the healthy structure, and is infiltrated with a turbid, viscid serum, removable by pressure. Occasionally the osseous fibres are widely separated from each other, so as to leave large cells, which are filled with a bloody-looking, adipose substance, as seen in fig. 314. When this is the case, the bone is sometimes remarkably pliant, bending like semi-concrete wax. Boiling completely dissolves it; and exposure to the air, by abstraction

diminishes its weight. Such are the principal changes observable in the osseous tissue. The periosteum over the affected part is abnormally thick, rough, and feebly adherent; it is of a grayish hue, deeply infiltrated, and, like the bone, infiltrated with sanguinolent fluid.

Upon being macerated, however, it is found to consist of a fibrous structure. The marrow is converted into a reddish, greasy sanies; and the medullary membrane is wasted away to a few soft, cellular shreds. The cancelli sometimes participate in the softening, while the trabeculae are pale, atrophied, and infiltrated with a fluid.

In the advanced stages of the disease, the bone is deprived of its laminated structure, the osseous corpuscles are greatly changed in their shape, as well as in their number, and the Haversian canals are greatly swollen and distended. The red grumous matter, so abundantly diffused through its interior, is shown by Dalrymple to consist of granular nucleated cells, and caudate corpuscles, similar to those of cancer.

Softening generally involves the whole thickness of the bone; but cases occur in which the outer table is unchanged, consisting of a thin, brittle shell. The order obviously consists either in an inordinate deposition of the phosphate of lime, upon which the strength of the osseous structure naturally depends, or in the deficient deposition of this matter into its meshes.

Dr. Rees, from a careful analysis of three diseased bones, taken from the same adult subject, obtained the following results, which he has compared with those furnished by healthy bone:—

	Diseased		Healthy.	
	Earths.	Animal matter.	Earths.	Animal matter.
Fibula	32.50	67.50	60.02	39.98
Rib	30.00	70.00	57.49	42.51
Vertebra . . .	26.13	73.87	57.42	42.58

Examining this table, it will be observed that, in the diseased as well as in the healthy state, the fibula contains more earthy matter than the rib, and the rib more than the vertebra. In health, the vertebra and rib approach very nearly in the proportions of animal and saline ingredients, whereas, in softening, a considerable difference obtains.

Dr. Rees, who has very recently investigated this subject, has found a specimen of softened bone to be composed of 18.75 of animal matter, 29.17 of phosphate of lime, and 52.08 of water.

What are the causes of this remarkable disease, or the circumstances which influence its origin and development? Upon this subject, unfortunately, we are almost completely silent. A great variety of causes have been accused of producing it, more especially a gouty, rheumatic, syphilitic, or scurvy state of the system; but, in admitting such an agency, it should be forgotten that vast numbers of persons labor under such a taint, and yet are the subjects of osteomalacia. That it may occasionally induce softening of the osseous tissue is extremely probable; but that this occurrence is frequently plainly contradicted. The whole course of the disease shows it is essentially connected with a vitiated and depraved condition both of the blood and fluids; but whether the disorder of the one precedes that of the other, or they have a simultaneous origin, and afterwards keep steady and unaltered, are questions which our knowledge is inadequate to solve. However, it is sufficiently apparent that the structures

Fig. 314.

Section of a softened femur; the medullary and cancellous structures are occupied by a transparent jelly-like fat, of various colors.

which are its seat are in a state of inflammation, and that this inflammation plays an important part in the production of the changes which characterize it. We cannot as rational pathologists assume any other ground; for, how else can we account for the excessive vascularity of the affected tissue, the sanguinolent nature of the infiltrated fluids, the thickened, spongy, and congested condition of the periosteum, and, finally, the atrocious and constant pains which form so notable a feature in the history of osteomalacia? All these circumstances unerringly point to inflammation as the great agent in the production of these changes; changes which, when existing in the soft structures, are invariably referred to this cause, and to none other. The morbid action, whatever it may be, is always of a chronic character, and is attended with important lesion of nutrition, leading to the removal of the earthy matter of the bones, and the excretion of it from the system, or its deposition among parts where it does not naturally occur. Or, what is more probable, there is both absorption of the original solid structure and a want of secretion of new, thus causing a complete disintegration, or decomposition, of the osseous tissue. All these circumstances are sufficiently obvious and tangible; but if we attempt to go beyond them, we involve ourselves at once in difficulties from which it is impossible to extricate ourselves.

Age and Sex.—Osteomalacia is rarely seen before the age of puberty; its favorite period of attack is between the thirtieth and fiftieth year. Another singular feature in its history is that it takes place much more frequently in women than in men, in the proportion, it has been said, of ten to three. It is most common in females who have borne several children; and it not unfrequently begins either during pregnancy, or within a short time after parturition. Cases have been reported where it was hereditary, having been distinctly traced through three generations, but in none of the offspring did it show itself until after puberty.

Symptoms.—The invasion and progress of this disease are generally very insidious. The earliest, and, for a long time, the most prominent, symptom is pain in the limbs, spine, and pelvis, of a wandering, shifting character, which the patient usually supposes to be of a rheumatic nature, and which is often so severe as to cause immense distress, especially at night, and in damp, chilly states of the atmosphere. By and by, dyspnoea sets in, with palpitation of the heart, and a sense of constriction across the chest, and the patient is seized with an overwhelming feeling of prostration, which utterly unfits him for business, and usually compels him to keep his bed. If he attempts to walk, his limbs bend under him, and if the effort is often repeated, they soon become badly curved; should his toe catch in the folds of the carpet, or should he be so unfortunate as to trip, or fall, or give his body a sudden twist, he will probably hear some of his bones crack, and yield under the superincumbent weight. Emaciation gradually takes place, the appetite is deranged, the skin is bathed with clammy perspiration, the tongue is foul, the bowels are irregular, being either costive or too loose, and the urine, surcharged with earthy phosphates, is very thick, heavy, of a whitish aspect, and frequently also albuminous. In the latter stages of the malady the saliva, tears, and sweat often contain similar ingredients. Great distortion frequently occurs; and the bones, bent in every direction, are effectually disqualified for the performance of their functions. The chest projects like that of a pigeon, the spine is bent laterally, as well as backwards, the pelvis is twisted, or rotated upon its axis, and the whole stature of the individual is sensibly diminished, the head being thrust down between the shoulders, which are unnaturally arched and prominent. Amidst all this disturbance, however, the intellect is unclouded, menstruation is perfect, and even conception is still possible. The period at which death occurs varies from a few months to several years, its approaches being usually very gradual, and the consequence of sheer exhaustion.

Diagnosis.—Osteomalacia is liable, as already stated, to be mistaken for rachitis. While it cannot be denied that the two diseases have several features in common with each other, it is equally certain that they possess sufficient

points of dissimilarity to justify us in considering them as separate affections. The chief differences are the following: Osteomalacia is rarely seen before the age of twenty-five or thirty, while rachitis is altogether peculiar to infancy and childhood, the disease in the former attacking the bones after the completion of ossification, whereas, in the latter, it assails them before they are fully developed. In softening, the patient is harassed with excessive pain and an overwhelming sense of exhaustion; in rickets, on the contrary, there is a total absence of pain, and the little patient generally retains a good share of strength. In osteomalacia there is more deformity than in rachitis; the disease is also of a more fatal character, few persons getting well, whereas in rachitis recovery is the rule, death the exception. Softening is much more common in women than in men, especially in such as have had several children; rachitis, on the contrary, is nearly equally frequent in both sexes. In softening the urine always contains a large quantity of earthy matter, whereas in rickets this excretion is unusually lateritious. Finally, the two affections are signalized by marked differences in their anatomical characters. In osteomalacia the osseous structure is completely disintegrated and decomposed; in rachitis, on the other hand, it is merely modified, and therefore susceptible of restoration.

Prognosis.—Osteomalacia is generally a fatal disease. Hence Solly, Dalrymple, and some other authors are inclined to regard it as of a truly malignant character. Although this opinion requires confirmation, it serves to show how exceedingly unmanageable the disease has hitherto proved to be in the hands even of the best practitioners. The period at which death occurs is very variable, some patients dying in a few months, others not under several years.

Treatment.—The progress of osteomalacia can be arrested only by causing a change in the action of the secernent vessels, but as we know of no means that are capable of doing this, all that can be done, in the present state of the science, is to endeavor to improve the general health by a well-regulated diet and the employment of tonics, as iron and quinine, the shower-bath, and change of air. Mercury has occasionally been administered, and carried to the extent of ptyalism, but, instead of proving beneficial, it has generally been productive of injury by still further exhausting the powers of life. Phosphate of lime, as having a tendency to supply the deficiency of osseous matter, has also been tried, but apparently with no better effect. If we adopt the idea that the disease is of an inflammatory nature, antiphlogistics ought to be advantageous, but thus far their employment has yielded no good results, but rather the reverse. When the disease is fully established, confinement in bed upon a soft elastic mattress will be necessary; and every precaution should be taken to avoid the occurrence of curvature and fracture of the affected bones. Pain must be relieved by the liberal use of anodynes.

SECT. VIII.—RACHITIS.

Rachitis, or rickets, is a disease of the osseous tissue, consisting in a deficiency both of its earthy and organic elements, as is shown by the diminished quantity of phosphate and carbonate of lime, and the absence of chondrin and gelatin, which form such important constituents of normal bone. The consequence is that the different classes of bone—the long, short, and flat—become so excessively softened as, in time, to yield under the slightest pressure, bending and twisting in various directions, and thus occasioning serious and generally irremediable deformity, as observed in the drawing fig. 315, taken from a patient at the Philadelphia Hospital.

Rickets, emphatically a disease of early infancy, is most frequently witnessed from the eighteenth to the twentieth month, although many cases occur before the end of the first year. Now and then an instance is observed as late as the twelfth year; but this is extremely uncommon, and altogether contrary to the usual course of the affection. Occasionally rachitis shows itself as an intra-uterine malady. Both sexes are liable to it, and, apparently, nearly in an equal degree. Cases have occurred in which it seemed to be hereditary, or in which

it attacked several members of the same family. It would appear from the accurate and masterly account of this disease by Glisson, published upwards of two

Fig. 315.

Rickets.

centuries ago, that it first took its rise about the year 1620, in the western parts of England, from which it gradually spread over the rest of Europe. In this country it has always been extremely uncommon, even among the lower classes, whose children are its most frequent subjects.

Causes.—Much labor has been spent by writers in endeavoring to ascertain the exciting causes of rickets, but really to so little purpose that our knowledge regarding it can hardly be said, even at the present day, to be more accurate than it was in the time of Glisson and his immediate successors. From the circumstance of its appearing occasionally in several children of the same family, it has by many been considered as hereditary, nearly all the older, and not a few of the modern, authorities concurring in this view of its origin. It has also been supposed, and apparently with as little reason, to have an intimate connection with a syphilitic, strumous, or scorbutic state of the constitution. Others, again, have referred its origin to the influence of a vitiated atmosphere, such as results from living in damp, crowded, and ill-ventilated underground apartments; but it does not appear, so far as can be ascertained, that the children

of such residents either in this or any other country are particularly prone to the complaint. Finally, there are many practitioners who look upon it as being due to the use of unwholesome food or imperfect alimentation, causing an impoverished state of the blood, with lesion of innervation and nutrition; and this is, perhaps, as plausible a view as can at present be taken of the subject. With regard to its connection with scrofula, it may be observed that rickets rarely coexists with tubercle, and also that the former disease does not generally occur so early in life as the latter. If syphilis has any agency in the production of rachitis, the fact remains to be proved. Whatever the exciting cause may be, there is no question that the immediate one is a deficiency of phosphate and carbonate of lime, upon which the solidity of the osseous tissue essentially depends. How far the want of chondrin and gelatin, which are such important elements of healthy bone, may disqualify the osseous tissue in rachitis for the reception of earthy matter is a problem which has not been determined.

Morbid Anatomy.—The alterations of the osseous tissue consequent upon this disease may be conveniently arranged under three heads, each possessing marked peculiarities. In the first, the bones are saturated with a reddish, watery fluid, a considerable quantity of which is also interposed between their outer surface and the periosteum, on the one hand, and between the medullary membrane and their internal walls, on the other. At a more advanced period, this fluid is replaced by a sort of gelatiniform substance, which becomes gradually organized, and ultimately adheres with great firmness to the parts with which it lies in contact. The periosteum is thickened and injected, the nutrient vessels are remarkably enlarged, and the medullary membrane is very spongy and vascular. The lamellæ of the long bones, naturally so hard and compact, are a good deal softened, while the areolar structure is greatly rarefied, many of the cells being more than double the natural size. Similar alterations are observed in the short and flat bones.

In the second stage, a peculiar spongoid substance is formed between the periosteum and the outer surface of the bones, varying from two to three lines, or upwards, in thickness. When the quantity of this substance is unusually great, it may exert such a degree of pressure upon the lamellæ of the compact tissue as to push them inwards towards the medullary canal, in such a manner as to reduce it very materially in size, if not entirely obliterate it. Simultaneously with these changes the bones are rendered so soft that they may easily be bent, cut, and even indented with the finger.

In the third stage—that of resolution—the recently formed substance in the long bones, as well as in some of the flat and short, assumes a compact character, and is gradually identified with the pre-existing tissues, which at the same time regain their primitive solidity. Owing to the presence of this new matter, the bones are much larger than in the natural state, and their firmness, especially in the adult, resembles that of ivory. Hence the term *eburnation* is sometimes applied to this state.

When rachitis proves fatal, the body is usually found in a state of excessive emaciation; the muscles are thin, pale, and flabby; the adipose matter is almost entirely consumed; the cerebral substance is unnaturally soft; the liver and spleen are enlarged and flaccid; the intestines are attenuated and distended with gas; and there is not unfrequently marked tumefaction of the muciparous glands; the mesenteric ganglions are increased in volume and consistence; the heart is softened and smaller than common; the lungs, which are often congested, are more or less tuberculized in about one-sixth of the cases; and the bronchial ganglions are hypertrophied, loaded with serosity, and of a deep purplish hue. Occasionally there is partial ossification of the arteries, muscles, and other structures, as if they had become the recipients of the earthy matter which naturally appertains to the bones.

Symptoms.—The symptoms of rickets possess nothing of a definite character in the earlier stages of the disease. Its approaches are generally stealthy, and at times almost imperceptible. The child, gradually losing its health and spirits, becomes dull and listless, and labors under derangement of the digestive organs, especially flatulence and colicky pains. After a while, marked emaciation sets in; the muscles are soft and flabby; the abdomen is tympanitic; the skin is dry and sallow; the face looks pale and doughy; the urine is scanty, turbid, and lateritious; and the alvine evacuations are thin, watery, and fetid, there being nearly always considerable diarrhœa. Dentition advances slowly, and the teeth, having a black, fuliginous aspect, often begin to decay almost as soon as they pierce the gums. The fontanels and sutures are unnaturally open; and the whole process of ossification is peculiarly slow and imperfect; sometimes almost stationary, if not actually retrogressive. As the disease proceeds, the bones grow more and more soft, and, being unable to sustain the weight of the body or to resist the action of the muscles, are at length strangely and frightfully distorted. The head, although abnormally small, is disproportionately large to the size of the face, and is sunk down between the shoulders; the clavicles are bent and extremely salient; the spine is curved in various directions, especially laterally, and diminished in length, the pelvic bones are curved inwards, so as to lessen very materially the corresponding cavity; the ribs are flattened, and the chest, in consequence, is sensibly increased in its antero-posterior diameter, giving it a narrow, pigeon-shaped appearance. The bones of the extremities are shortened, bent, and twisted upon their axes, while their articular ends, or epiphyses, are softened, rarefied, and greatly expanded, thus appearing much larger and more prominent than naturally. If the child has begun to walk, he becomes daily more feeble on his legs; he waddles, trips, falls, and soon returns to his nurse's arms.

In rachitis, there is an actual arrest of development of the bones, and, although this want of growth pervades the entire skeleton, it is always most conspicuous in the lower extremities, the femur, tibia, and fibula being shorter than in the natural state, and also diminished in the epiphyses, which, as already seen, are always

especially if the child has been much on his feet. Under such circumstances, the head and neck of the femur are sometimes forced by the weight of the body into a horizontal position below the level of the great trochanter; the individual is bow-legged, and the joints of the knee and ankle suffer great distortion from the weakened and relaxed condition of their ligaments. The flat bones, during the reparative process, become solidified and hypertrophied in their areolar texture, while the long ones are increased in thickness and strength along the concavity of their curvatures that they may be the better able to support the superincumbent pressure, and resist the effects of muscular action.

Diagnosis.—The only disease of the bones with which rachitis is at all liable to be confounded is osteomalacia or softening. The signs of distinction, however, are commonly very evident. In the first place, rachitis is an affection of infancy and early childhood, whereas mollescence never occurs until after middle age. Secondly, in rickets the softened and flexible state of the skeleton is only temporary; after a time, a process of repair is set up, and, gradually continuing, the affected tissues become at length more firm and compact than they are in the natural state; in osteomalacia, on the contrary, the disease, once begun, generally progresses until the patient is worn out by his suffering, no attempt being usually made at restoration. Thirdly, in rachitis there is no material alteration in the urine, whereas in mollescence this fluid is always loaded with a large quantity of earthy salts, the kidneys taking on a vicarious action, and so carrying off the material destined for the supply of the bones. Lastly, in rickets there is an actual arrest of development, in consequence of which the bones remain disproportionately short, thin, and dwarfish; in softening, on the contrary, the affected pieces retain their normal shape, although they are so changed in their consistence that they may readily be cut and bent in almost any direction.

Prognosis.—The prognosis of rachitis is generally unfavorable; for, although many persons escape with their lives, few recover without permanent deformity. In regard to the danger to life, it is commonly in proportion to the number of bones affected, the rapid progress of the complaint, and the age of the subject. Experience has determined that very young children are more liable to die of it than those who are more advanced in years, and those who are born of scrofulous parents than those who come into the world under more happy auspices. The duration of the disease is extremely variable; very tardy at one time, very rapid at another. In general, even under the most favorable circumstances, several years elapse before complete recovery occurs. The progress of the cure is often fatally arrested by some intercurrent malady, as measles, scarlatina, smallpox, or cholera. The longer recovery is postponed, the greater will be the danger of serious deformity. The duration of life is not necessarily shortened in persons who get well of rickets, as cases have occurred in which they attained the age of sixty, seventy, or even seventy-five.

Treatment.—In the treatment of rachitis active measures are out of the question. Our chief reliance must be upon a properly regulated regimen and the use of tonics, with a view of invigorating the general system, and of improving the condition of the blood, which is always materially altered in its properties. Whatever, therefore, has a tendency to strengthen the patient, and to enrich the circulating mass, must prove indirectly beneficial in removing the disease, and should claim serious consideration in every case.

The diet should be mild and nutritious, comprising an adequate amount of nourishment in the smallest possible space, so as not to oppress the stomach and create flatulence and acidity. The best article is, of course, the mother's milk, or, when this is insufficient or unwholesome, fresh cow's milk, or, better still, the milk of the ass, which is now so much used in some of the larger cities of continental Europe, and which approaches nearer, in its composition, to human milk than that of any other animal. If the teeth are properly developed, a small amount of animal food will be useful, especially fat bacon, well boiled, and not too salt, with good stale bread, and a little mashed potato. The body should be washed at least twice a day with salt water, followed by dry friction, or rubbed with a moderately stiff salt towel; and, if the system is not too much reduced,

cool or cold bathing will be found highly invigorating. Frequent exposure of the little patient to the fresh air, and exercise suited to his age and strength, are to be rigidly enforced. The secretions are improved by alteratives, especially blue mass and mercury with chalk, while the bowels are kept soluble with rhubarb, magnesia, or oil. Acidity is allayed by the alkalies, as lime water, soda, or potassa.

Tonic medicines, particularly quinine and iron, given in small doses, and long continued, with an occasional intermission for a few days, are always imperatively indicated, and there are few cases which are not promptly benefited by their exhibition, especially in the early stages of the disease, although they are nearly equally useful throughout its entire progress. The mineral acids, and the tincture of the chloride of iron, have long been favorite medicines, both with the empiric and the regular practitioner, and are particularly advisable when there is a coexistent scorbutic condition. Alterative doses of mercury occasionally exercise a salutary influence, especially when the patient labors under the strumous diathesis, the best form being the bichloride, in combination with a small quantity of iodide of potassium, dissolved in water. The pain, which is often considerable, is controlled by opiates, either alone, or conjoined with diaphoretics.

Lately, the phosphates, which were formerly so much employed in the treatment of rachitis, on the ground that they would tend to supply the deficiency of earthy matter, have again come into vogue, but it remains to be seen whether they really possess any advantage over the more ordinary tonic remedies, already referred to, or whether, indeed, they are not inferior to them. Their best form of exhibition is the syrup.

Doubtless, however, the most valuable remedy of all in this complaint, so far as any individual article is concerned, is cod-liver oil, given several times a day, in doses suited to the age and other circumstances of the patient. Possessing highly nutritive and alterative properties, it is admirably adapted to support the system, to enrich the blood, and to improve the secernent powers, which are so much at fault in rachitis. It may be administered either alone or in union with some of the more important tonics above mentioned.

Finally, the bed on which the rickety child sleeps should be perfectly smooth and somewhat elastic, so as not to permit the affected bones to sink down into any depressions or hollows, and so become bent and distorted. No pillow should be used, but the head, body, and limbs should all rest on the same plane. The clothes should be loose, light, and sufficiently warm to afford the requisite protection to the surface. In the earlier stages of the complaint, mechanical contrivances are not only altogether ineffectual, but pernicious; by and by, however, as the bones become softened, they should be supported with appropriate apparatus, to prevent deformity. Walking must, of course, be avoided as long as the extremities are unable to bear the weight of the body.

SECT. IX.—FRAGILITY.

Fragility of the osseous tissue is one of those affections which are to be regarded rather as an effect of disease than as a disease itself. It consists, as the name implies, in a peculiar brittleness of the bones, in which, especially in its more advanced stages, their substance is so completely changed in its character as to give way under the most trivial circumstances. All the bones are liable to this morbid brittleness, and cases occur, although rarely, where it literally pervades the whole skeleton. In 1857, the body of a female, supposed to be upwards of seventy years old, was brought into the dissecting rooms of the Jefferson Medical College, with upwards of eighty fractures, received a few days before in a fall from a third story window upon the pavement below. Nearly all the ribs, several of the vertebræ, and a number of the long bones were broken, and signs of former fractures existed in the humerus, thigh, scapula, and other bones. Devergie examined the body of a woman who died under symptoms of rachitis, in whose skeleton there were not less than eighty-three fractures.

met with a young man, whom I also saw many years ago, the bones of whose extremities were repeatedly broken by the most trivial accidents. The clavicles had suffered still more frequently, having been fractured altogether eight times. This universal fragility of the osseous tissue occasionally occurs at a very early period; sometimes, indeed, even in the foetus in the womb. Chaussier met with a remarkable example of this kind, where the long bones had experienced not less than one hundred and thirteen fractures, some being perfectly consolidated, thus showing that they had taken place some time previously, while the rest were either recent or had partially united. The child survived its birth only twenty-four hours. General fragility, however, is a comparatively rare affection; usually the disease is limited to particular bones, or, still more commonly, to particular portions of a bone; and those which are most prone to suffer are the head and neck of the femur, the ribs, sternum, radius, ulna, clavicle, and superior extremity of the humerus.

When the affection exists in its highest degree, the slightest accident is frequently sufficient to produce fracture, as a severe fit of coughing, kneeling upon a hard floor, or turning round in bed. Sometimes, indeed, the fragility is so great that the individual cannot be touched rudely without the occurrence of the injury. Of this description was the memorable case of the woman, recorded by Saviard, who could not be moved about in bed without breaking some of her bones. After a confinement of six months she died, when it was found that she had had fractures in all the long bones of the extremities, as well as of the clavicles, ribs, vertebræ, and pelvis, many of the pieces being so brittle that they could not be handled without crumbling into fragments, similar to old, dry bark.

Causes.—Fragility of the bones commonly comes on without any assignable cause, and the general health not unfrequently continues good until a long time after it has made its appearance. In most cases, if not in all, it is merely symptomatic of some other disease, particularly of rheumatism, gout, syphilis, scrofula, and scurvy, attended with an altered and impoverished state of the blood, and impairment of the assimilative powers. The bones themselves are very much in the condition in which they are in osteomalacia, that is, they are more or less softened by the removal of their earthy matter, and often so completely saturated with fat as to render them unfit for preparations. On the other hand, however, they are sometimes remarkably dry and brittle. These facts show that their intimate structure undergoes some important anatomical change, the immediate result, apparently, of inflammation. What tends to support this view of the nature of the affection is the circumstance that, long before the bones manifest any disposition to break, the patient is harassed with severe pains, deep-seated, fixed, and referred to particular portions of the skeleton, and that, upon dissection, the diseased parts are generally found to be extremely vascular, their areolar tissue being profoundly injected and infiltrated with bloody matter, while the periosteum is very thick, spongy, and highly congested.

Fragility of the bones is one of the usual concomitants of old age. As life advances, their vascularity sensibly diminishes, many of the vessels shrinking down, and becoming finally entirely obliterated. It is owing to this circumstance that old persons, especially females after the fifty-fifth year, are so much more liable to fracture than to dislocation, the part most prone to yield being the neck of the femur within the capsular ligament, whose areolar tissue is often astonishingly rarefied, while the compact is hardly as thick as ordinary letter paper.

This affection is sometimes observed in several members of the same family. Dr. Pauli, of Landau, has related an instance where it was distinctly traceable through three generations on the father's side. All the grandchildren, five in number, had each had several fractures, one as many as five, in the bones of the extremities, mostly as the result of inconsiderable injury. They were all remarkably healthy, and there was no evidence in any of them of a scrofulous taint of the system.

Symptoms.—There are, unfortunately, no reliable signs in this affection. On this account it is usually overlooked until it has reached its highest degree of development, when it is always incurable. In general the person is laboring

under severe pain, which is usually regarded as of a gouty, rheumatic, or syphilitic character, and which is rarely, if ever, referred to its proper source, until after the occurrence of curvature, or fracture, from causes so slight as to awaken, for the first time, a suspicion of the real nature of the disease. As the disorder progresses, the appetite and strength become impaired, the suffering increases in violence, and the urine is surcharged with earthy constituents, especially phosphate and carbonate of lime. This alteration in the urine is observable at an early period, and, in general, fragility goes on gradually augmenting down to the time of death, which happens at from six to eighteen months, the patient meanwhile being perfectly bedridden.

There are then only two circumstances that can be at all relied upon as diagnostic of this complaint; one is the severe and intractable character of the pain, deep-seated, and usually referred to the bones; the other, the altered condition of the urine, as declared by the presence of an inordinate quantity of earthy matter, especially phosphatic. When these phenomena coexist, there will be strong reason to conclude that there is serious lesion going on in the skeleton, and this suspicion will be converted into certainty when, superadded to them, there occurs, without any considerable external violence, curvature, fracture, or displacement of some of the bones.

Fragility, like softening, may generally be looked upon as an incurable affection. The only exception, perhaps, to this rule is when it occurs as an effect of the syphilitic or rheumatic poison, and even then it seldom admits of complete relief unless it presents itself in a very circumscribed form. The fragility of old age is always incurable.

Treatment.—No rational treatment has yet been laid down for this disease, nor will it be possible to do so until we shall have more enlightened views of its etiology, pathology, and diagnosis. In all cases, strict inquiry should be instituted into its origin, when such remedies should be administered as the result may seem to indicate. As a general rule, it may be stated that bleeding, except in very robust habits, is quite inadmissible; even active purgation is usually injurious. A tonic and supporting course, consisting of the different preparations of iron and quinine, and of the syrup of the phosphates, along with cod-liver oil, and vegetable acids, especially the citric, and a well-regulated, nutritious diet will afford the best chance of relief. Iodide of potassium and bichloride of mercury may be given in the syphilitic variety of the disorder; while in the gouty and rheumatic forms, colchicum may probably prove beneficial. To relieve the excessive pain which is so prominent a symptom in the latter stages of the affection, especially when it involves a large portion of the skeleton, anodynes must be given in full and sustained doses. Curvatures and fractures must be treated upon general principles. In most cases union occurs very promptly; sometimes, however, it is very tedious, and now and then the parts refuse to heal, despite the best directed efforts of the surgeon.

SECT. X.—ATROPHY.

Atrophy of the osseous tissue is characterized by the partial absorption of its elementary constituents, as is evinced by its lightness and porosity. It may occur in any portion of the skeleton, but the long bones are oftener affected than the short or flat. Like hypertrophy, it may be partial or general; that is, it may involve an entire piece, or be limited to a particular part of it. Atrophy, moreover, may be concentric or eccentric. In the former variety the bone is diminished in its diameter; in the latter it retains its original size, but is reduced in weight, and rarefied in its tissue. The principal causes are, protracted pressure, chronic inflammation, deficient nervous influence, and insufficient supply of arterial blood.

a. The influence of steadily exerted *pressure*, in producing atrophy of the osseous tissue, is well exemplified in the cranial bones in tumors of the dura mater; in the sternum and dorsal vertebræ in aneurism of the aorta; and in the ribs in cancer of the mammary gland. the compact sub-

stance is reduced to a thin, translucent plate, while the spongy texture is either wholly destroyed, or worn down to a few slender shreds. The immediate cause of the wasting process here is absorption, acting simultaneously and equally upon the animal and earthy constituents.

b. Atrophy from *chronic inflammation* is probably infrequent. One of the best specimens of it that I have ever seen occurred in a colored woman, who died of pulmonary phthisis at the age of forty. The body was much emaciated, and all the long bones were remarkably reduced in weight, though they had experienced no change in their external configuration. The compact substance was wasted to a mere shell, scarcely thicker than common wrapping paper, while the cells of the spongy texture were increased many times beyond the natural size. The medullary canal was much enlarged, and filled with a greasy reddish substance, not unlike fresh adipocire. These appearances are well shown in fig. 316, and afford a beautiful illustration of the eccentric form of atrophy.

Fig. 316.

Atrophy of bone.

Atrophy is sometimes the result of local injury, as a blow, wound, or contusion. The wasting in this case may be limited to the site of the original mischief, or it may extend to the entire bone, which, however, is uncommon. In what manner such an injury operates, whether through the agency of inflammatory irritation, or otherwise, in giving rise to atrophy, is unknown.

c. Deficient *nervous* influence is a frequent cause of atrophy both of the osseous tissue and of the soft parts. In paralysis of the lower extremities, there is generally notable wasting, not only of the muscles, but also of the long bones, which are greatly reduced in weight, rarefied in their texture, and diminished in size.

d. The effect of a diminished supply of *blood* in inducing atrophy of bone is

Fig. 317.

Atrophy of cellular structure of thigh-bone.

Fig. 318.

Advanced stage of senile atrophy of the thigh-bone.

sometimes very conspicuous in old fractures. In such injuries there is often considerable wasting of the osseous tissue, simply from obliteration of the nutrient

and is not to be removed from the
library by any person or
instruct whatever.

artery by the pressure of the callus. The atrophy is always eccentric, and is usually limited to one-third, one-half, or two-thirds of the affected bone, according to the seat of the original injury, or, more properly speaking, the quantity of the new matter, and the extent of the vascular obliteration.

e. Finally, there is what is termed *senile atrophy*. In old age, the bones are rendered light, porous, and brittle; the compact substance is reduced to a mere parchment-like shell, while the areolar texture is remarkably rarefied or expanded; the muscular prominences are diminished in size; the animal matter is partially absorbed; and many of the vessels are obliterated. These changes are nowhere more conspicuous than in the neck of the femur, which, in consequence, often breaks from the most trifling causes, and which, after this occurrence, is seldom, if ever, repaired by osseous matter. Fig. 317 is a section of a well-marked specimen of this kind; the internal structure is very much rarefied; and the head of the bone, flattened and expanded, is approximated to the shaft, from the partial absorption of its neck. Fig. 318 exhibits the affection in a still more advanced stage with porcellanous deposits.

Atrophy of the osseous tissue does not admit of cure. All that the surgeon can do is to amend the general health, when that is at fault, and to remove any local causes of disease when they are found to exist.

SECT. XI.—HYPERTROPHY.

Hypertrophy of the osseous tissue may be partial or general; that is, the abnormal growth may affect either a portion or the whole of a bone. The latter, however, is very uncommon, except in some of the broad pieces of the skeleton, particularly those of the skull, which, now and then, present an extraordinary degree of development, being perhaps three or four times the natural thickness, and so hard as to render it very difficult to saw them. The diploë is totally obliterated by dense earthy matter. Similar appearances are sometimes witnessed in the cylindrical bones of the extremities. In an old femur in my private collection, the medullary canal is scarcely large enough to admit a common-sized quill; the whole shaft consists almost entirely of compact substance, in many

Fig. 319.

General hypertrophy—internal structure.

Fig. 320.

General hypertrophy—external characters.

places more than six lines in thickness. The bones of the male are always larger and more distinctly developed than those of the female, and the bones of persons who take much exercise than those who are indolent, or inactive. By labor, their weight and dimensions increase; their spongy structure diminishes,

whilst the compact becomes harder and more dense, and acquires an almost rock-like solidity; the muscular prominences are rendered more conspicuous; in short, everything indicates that they are in a state of general hypertrophy. The osseous tissue usually contains a due proportion of animal matter, and on this account does not readily yield under external injury.

Fig. 321.

Hypertrophy involving both the thickness and length of the bone.

The adjoining cuts are excellent representations of general hypertrophy of the femur of a man affected with tertiary syphilis. Fig. 319 is a section of the bone exhibiting its interior structure, which is very much condensed throughout, except at the superior extremity, where there are still some remains of the areolar tissue; the medullary canal is entirely obliterated, and the weight of the bone is nearly twice as great as in health. Fig. 320 shows the external appearance of the bone. The drawings are from a specimen in my cabinet.

The adjoining sketch, fig. 321, is a specimen of hypertrophy of the bones of the leg and foot, both in thickness and length. It is from a drawing of a preparation in the collection of Professor Buchanan, of Nashville. All the bones are much enlarged, increased in weight, and ankylosed, at the ankle, tarsal, and metatarsal joints. The interosseous ligament was completely ossified. The foot and leg had been

the seat of extensive ulceration, followed by exfoliation from the hypertrophied bones.

General hypertrophy of the bones is usually incurable. It is only, or chiefly, when it depends upon a syphilitic taint of the system that it admits of relief; but as this subject has already been fully discussed elsewhere, it is not necessary to revert to it here.

SECT. XII.—OSTEOPHYTES.

An osteophyte is a kind of osseous vegetation, differing from an exostosis in not forming a well-defined tumor; it grows upon rather than from bone. It occurs chiefly in middle-aged and elderly subjects, upon the more vascular portions of bone, as its articular extremities, its rough lines, and its sutural cartilages, and is more frequent in the femur, fibula, and vertebræ than in any other pieces of the skeleton. Rokitsky has described what he calls the puerperal osteophyte, inasmuch as it is found in females dying a short time after parturition. It generally occupies the frontal and parietal bones, forming a layer which varies in thickness from a very thin film to half a line or more; sometimes it is spread over the whole inner surface of the cranium, either in scattered patches, or as a continuous incrustation.

The ordinary osteophyte presents itself in a great variety of forms; sometimes as a pointed stalactite, or sharp, thorn-like spicule, sometimes as a warty excrescence, sometimes as a lamella several lines in length and thickness, and sometimes, again, as a body bearing a close resemblance to a coral. In the vertebræ, an osteophyte occasionally extends like a bridge, from one piece to another, tying them firmly together; and a similar arrangement now and then occurs between the articular extremities of some of the long bones, as between the femur and tibia. The annexed cut, fig. 322, affords a good illustration of this disease as it sometimes occurs in the lower extremity of the femur. The whole surface of the bone is roughened by the new growths.

The exciting causes of these osseous growths are not always appreciable. In general, they are developed under the influence of a gouty, rheumatic, syphilitic, or scorbutic state of the system; occasionally they are directly traceable to the effects of external injury, and cases occur in which they succeed to caries or necrosis. Immense numbers of osteophytes are sometimes seen in osseous tumors, especially the encephaloid and fibro-plastic. The immediate cause of the disease is inflammation, attended with a deposit of lymph, which is gradually converted into osseous tissue, similar to the callus of a broken bone.

There are no symptoms by which this disease can be recognized during life, unless the osteophytes are of great size or unusually prominent, when they may occasionally be distinguished by a careful digital examination. Its progress is generally very tardy, and there is seldom any danger so long as these bodies do not exert any severe pressure upon important structures.

In the treatment of osteophytes, the first object should be to ascertain, if possible, the nature of the exciting cause, for upon this the whole management of the case will necessarily hinge. A gouty, rheumatic, or syphilitic state of the system should be met in the usual manner. The inflammatory character of the affection must not be overlooked. The most suitable local remedies are tincture of iodine, and iodide of lead ointment, leeches, and blisters, the latter being particularly applicable in the earlier stages of the disease.

Fig. 322.

Osteophytes of the inferior extremity of the femur

SECT. XIII.—TUMORS.

The bones, like the soft structures, are liable to two classes of tumors, the innocent and the malignant. The former includes exostosis, fibro-cartilaginous growths, aneurism, hematoid formations, serous cysts, hydatids, and myeloid tumors; the latter, encephaloid, colloid, scirrhous, and melanosis.

INNOCENT FORMATIONS.

1. EXOSTOSES OR BONY TUMORS.

An exostosis, of which fig. 323 affords a good idea, is an osseous outgrowth, the word, which is a Greek compound, signifying a bone growing from a bone.

Fig. 323.

Exostosis of the thigh-bone.

It is in fact a local hypertrophy, a circumscribed tumor, possessing essentially the same structure as the bone from which it springs, and with whose substance it is usually intimately identified. There is perhaps no term in surgical nomenclature which has been more abused than this, or which has been applied to so many different and almost diametrically opposite diseases. Among those who have especially contributed to bring about this confusion may be cited the name

of Sir Astley Cooper, who, under the appellation of exostosis, has described almost every variety of tumor, whether benign or malignant, whether fleshy, fibrous, cartilaginous, or osseous, connected with or growing from a bone. This classification, which was for a long time blindly followed by most writers, has recently given way to a more correct appreciation of the subject, and I know no pathologist whose opinion is worth much who does not consider an exostosis as essentially a local hypertrophy, free from malignancy, formed in the same manner as the primitive osseous tissue, and composed essentially of the same anatomical elements; in short, as a bone growing from a bone, and not upon a bone.

Exostosis is observed chiefly in young and middle-aged subjects, being very infrequent before puberty, and after the fiftieth year. It is more common in males than in females, and is generally confined to particular bones, as those of the cranium and of the extremities, especially the femur, and the phalanx of the great toe.

The superior maxillary sinus is occasionally the seat of this disease. In a specimen in my collection, the inner surface of the left antrum is literally studded with these growths, none of which exceed a small grain of wheat, which they also much resemble in shape. The tumor sometimes acquires an enormous bulk, and cases occur in which both cavities are affected simultaneously, though not in the same degree.

In the flat bones, as those of the head and pelvis, the outgrowth may occur upon either surface; in general, however, it evinces a preference for the external one, probably because it has a more perfect periosteum. When the tumor is attached to the inner surface, its tendency is to encroach more or less seriously upon the contents of the cavity which the bone assists in forming. These internal exostoses, as they may be termed, are most common in the cranial bones of syphilitic subjects.

A tendency to exostosis is sometimes observed in several members of the same family. A few years ago, I had under my charge, on account of a tumor of this kind on the shaft of the left radius, a lady whose sister and brother had each a similar enlargement, the former on the occipital bone, the latter on the clavicle. Boyer gives the particulars of a case where the disease was hereditary, the patient's father, brothers, sisters, nephews, and children having all suffered in a similar manner.

The number of these outgrowths varies from one to a considerable number. In general, they are solitary; but cases occur where there are a great many, as if there existed a sort of exostotic diathesis, as in fact there does under such circumstances. In the Mütter collection is the skeleton of a female in which a large number of bones are thus affected.

Exostoses sometimes observe a symmetrical arrangement, tumors of the same size and shape occurring at the same points of the corresponding pieces of the two sides. Such a disposition is occasionally witnessed on the frontal bone and lower jaw, but is most common on the humerus and femur, especially at their inferior extremities.

The volume of these growths is subject to no little diversity, some being very small, while others are extremely large, equal, perhaps, to the size of an adult head. The most bulky are usually found upon the bones of the extremities, particularly the lower part of the femur, though they are also occasionally seen upon the cranial, facial, and pelvic bones, where their presence is a source of the most hideous deformity.

Their shape is also very variable; sometimes they have a distinct, well-defined outline, being of a globular, ovoidal, or hemispherical figure; occasionally they jut out like long, slender spines or stalactites; in another series of cases, they have a knobby, nodulated, tubercular, or mammillated appearance; and, lastly, instances occur, although they are rare, in which they present themselves in the form of plates or lamellæ. These varieties of shape are doubtless entirely due to accidental circumstances; but they, nevertheless, deserve attention, on account of their practical relations. In regard to their surface, this may be either perfectly smooth, scabrous, or spiculated; most generally the latter.

The adjoining sketch, fig. 324, represents a remarkable form of exostosis, from a drawing of a specimen kindly presented to me by Dr. Lewis, of Alexandria. It grew upon the right femur of a lady, fifty-one years old, having commenced when she was only nine years of age. The tumor, before removal, was about the volume of a coconut, oval, smooth, and very hard. The integuments over its summit had latterly become inflamed and ulcerated, followed by a discharge of sanious matter, and the protrusion of a portion of bone. The general health becoming somewhat impaired, amputation was performed at the lower third of the thigh, the woman making an excellent recovery. This case is additionally interesting from the circumstance that several of the relatives of the patient had been affected with similar tumors.

FIG. 324.

EXOSTOSIS OF THE FEMUR.

Causes.—The origin of exostoses is involved in doubt. There is no question that, in the great majority of instances, they arise without any assignable cause. On the other hand, they may often be traced directly to the effects of external violence, such as a blow or kick. In the distal phalanx of the great toe, which is not an uncommon seat of the disease, it is not unlikely that the pressure of a tight boot is able to produce it. Exostosis in the stump after amputation of the thigh and leg is probably caused by the jarring which the femur and tibia experience during the operation of sawing, aggravated, perhaps, by a partial laceration of the periosteum. A syphilitic taint of the system has generally been considered as an excitant of the complaint, and that it is capable of exerting such an influence hardly admits of doubt. Nevertheless, it is extremely probable that its agency has been greatly overrated; for I can recall but few cases that have come under my observation where it was possible to trace the relationship in a satisfactory manner. Rheumatism and gout are also often accused of causing exostosis, and, although it is impossible, in the existing state of the science, to determine the character and degree of their agency in this respect, sufficient is known to justify the belief that it is very considerable. However this may be, it is extremely probable that these diseases play a most important part in the production of general exostoses, the history of most of the cases of the kind clearly proving such a connection.

The immediate cause of exostosis is inflammation leading to a deposit, in the first instance, of plastic matter, and, afterwards, of osseous, the process of development being precisely similar to that which presides over the formation of the original bone. The concomitant inflammation is not always seated exclusively in the bone, but partly in the bone and partly in the periosteum; and cases occur where there is reason to believe that the latter is mainly involved in the production of the tumor.

Structure.—In regard to its structure, an exostosis differs in no wise from healthy bone. It is essentially composed of two parts, a compact and an areolar, the former inclosing the latter like a dense, firm layer, varying in thickness from the sixth of a line to a quarter of an inch, according to the volume of the tumor. The compact substance sometimes constitutes the greater bulk of the morbid mass, and there are cases, especially when it involves the cranium, where it is of the consistence of ivory, being so close and hard as to render it extremely difficult to saw it. Such a structure is represented in fig. 325, from a specimen in my collection. The areolar texture is sometimes directly continuous with that of the bone from which the exostosis grows; at other times, however, it is independent of it, as in fig. 326, being either in immediate contact with the compact structure, or separated from it by a stratum of fibro-cartilage, cartilage, or fibrous

tissue. Its cells are of variable size and form, and are generally loaded with fatty matter, just as in a short bone of the skeleton, or in the articular extremity of the long.

Fig. 325.

An ivory-like exostosis, showing its internal structure.

The identity of the structure of exostosis with that of natural bone is proved, moreover, by chemical analysis. Even when the new substance is of unusual firmness, as in the eburnized variety of exostosis, the difference is much less than might, at first

Fig. 326

Spongy exostosis of the femur with a broad base, and pointed processes.

sight, be imagined. The following comparative analysis of healthy bone and of an ivory exostosis, by Berzelius, places the subject in a strong light. The principal difference, it will be observed, consists in the presence, in the latter, of an unusual quantity of phosphate of lime, and in a marked diminution of carbonate of lime and salts.

	Healthy Bone.	Eburnized Exostosis.
Animal matter	33.30	22.57
Phosphate of lime and magnesia	54.20	66.68
Carbonate of lime and salts	12.50	2.00
Loss	00.00	00.55
	<hr/> 100.00	<hr/> 100.00

When an exostosis is seated in a part of the body which is habitually the subject of considerable motion, as, for example, the inferior portion of the femur, it is usually surrounded by a distinct capsule, a sort of synovial burse, the object of which evidently is to ward off friction and facilitate gliding. The inner surface of the capsule, which is of a fibro-cellular nature, and of variable thickness, is perfectly smooth, unadherent, and lubricated by a sero-oleaginous fluid, so as to qualify it the better for the performance of its functions. Where no motion is required, the growth lies in immediate contact with the natural structures, the union between them being commonly so intimate as to demand a careful use of the knife to effect their separation. Occasionally, indeed, the soft parts are partially imprisoned in the osseous tumor, thereby rendering the dissection peculiarly tedious and difficult.

Progress.—The progress of this disease is generally tardy; it is only now and then that a case occurs which pursues a different course, or where the symptoms partake of an acute character. A syphilitic exostosis occasionally attains a considerable bulk in a short time, and the same thing has been observed, though less frequently, in the rheumatic form of the complaint. Under such circumstances, the formation of the tumor is generally attended with severe pain, liable to nocturnal exacerbations, tenderness and swelling of the part, and more or less constitutional disturbance. Ordinarily, however, there is nothing of the kind: the disease comes on slowly and almost imperceptibly, the first thing that arrests attention being a small tumor, which is altogether insensible, and exceedingly tardy in its progress, years elapsing before it acquires the size, perhaps, of a pullet's egg. If it is superficial, so as to admit of examination, it will be found to be hard and immovable from the first, and so it generally continues ever afterwards, whatever may be its bulk. Meanwhile, although it may itself be entirely indolent, it may be productive of pain in the surrounding structures, by the com-

pression which it exerts upon the nerves, and in this way the suffering is sometimes rendered exceedingly severe, being often of a neuralgic character, darting about in different directions, and extending far beyond the seat of the bony growth. When the tumor is situated among parts that are much exposed to motion, it is very liable to fret and irritate them in such a manner as greatly to aggravate the local distress. As the morbid mass enlarges it must necessarily act obstructingly, interfering with the functions of the affected structures, and ultimately, perhaps, entirely abolishing them. Thus an exostosis of the orbit may continue to increase until it pushes the eye completely out of its socket, not only filling the whole cavity, but encroaching more or less extensively upon the cheek and cranium. In a similar manner a bony tumor may project into the pelvis, and impede the delivery of the child. An exostosis of a rib may compress the lungs; of a vertebra, the spinal cord; of the cranium, the brain. Another effect is that it stretches, flattens, and displaces the muscles, tendons, nerves, and vessels, thereby partially disqualifying them for the exercise of their functions.

Sometimes the coverings of the tumor are invaded by ulceration and even gangrene, thereby more or less freely exposing its surface, which occasionally, in turn, takes on the same kind of action. At other times the morbid mass perishes, apparently from a want of nourishment, and is detached very much in the same manner as a slough of the soft parts. Exostoses of immense volume occasionally experience such a fate. The occurrence will be most likely to happen when the tumor has a narrow, cartilaginous base.

Diagnosis.—The diagnosis of exostosis cannot always be easily determined unless the tumor is situated superficially, when its great firmness and immobility will generally serve to point out its true character without any difficulty. When the tumor occupies some internal cavity, its nature may be suspected, but no surgeon, however skilled in the art of discrimination, can positively say to what class of growths it really belongs. Besides, an exostosis may sometimes seriously interfere with the diagnosis of other affections. Thus, a tumor of this kind, occupying the pelvic cavity, may impinge against the bladder, or even project into it, in such a manner as that the sound, coming in contact with its surface, shall impart a noise and sensation similar to those communicated by the presence of a calculus.

Prognosis.—The prognosis varies. So long as the tumor is small and indolent, it may commonly be considered as of little moment; but when it increases rapidly, or is so situated as to interfere with the functions of a joint, or to encroach upon an important organ, it becomes a matter of serious import; the more so, because it is then not always possible to get rid of it by an operation, and there is generally nothing else that can reach it. When an exostosis projects into a joint, an operation is a hazardous undertaking, liable to be followed by the worst results; and when it occupies an internal cavity it is generally utterly inaccessible. An exostosis of the inner surface of the cranium usually proves dangerous by determining epilepsy, paralysis, and other bad symptoms; in the pelvis it may, as already stated, interfere with parturition, and in almost any part of the body it may induce neuralgia.

Treatment.—The treatment of exostosis must be guided, in great degree, at least in its earlier stages, by the nature of the exciting cause. When the affection has been occasioned by a deranged state of the system, or by the rheumatic, gouty, or syphilitic poison, colchicum, aconite, and iodide of potassium, either alone, or in union with bichloride of mercury, will be indicated, and can hardly fail, if judiciously administered, to prove highly beneficial. Under the influence of these remedies the growth of the tumor is often promptly arrested, and eventually entirely dispersed. The use of mercury is particularly serviceable in these cases, but to produce its full effects it is generally necessary to carry it to the extent of gentle ptyalism, maintained for some time, especially in obstinate cases. When the complaint gives rise to much pain, opium, conjoined with diaphoretics, will be required.

Topical applications are particularly useful when the tumor is of rapid growth, exquisitely sensitive, and the result of external injury, or of a syphilitic taint of

the system. In the earlier stages of the disease, the remedies most to be relied upon are leeches, blisters, saturnine lotions, and tincture of iodine employed in the ordinary way. If blisters, which are the most valuable of all topical means, are used, the skin over the tumor should be raised very thoroughly, and a free discharge should afterwards be maintained by some stimulating unguent, with a view to a permanent pyrogenic effect. In the syphilitic form of exostosis, mercurial fumigations sometimes answer a good purpose, succeeding when all other remedies fail.

When the tumor has attained considerable bulk, and, above all, when it is of long standing, and of great firmness, or productive of excessive suffering, the only chance of relief is ablation, or, if this is impracticable on account of the nature and extent of the exostosis, amputation of the affected limb. The incisions through the integuments are made as in ordinary growths, the most eligible shape being the crucial, elliptical, or T-like. Free exposure is effected, and in doing this care is taken not to interfere with any important structures, the division of which might afterwards impair the usefulness of the parts. If the skin is diseased, or much attenuated, the affected portion is, of course, removed. The exostosis is then attacked with the knife and a common metacarpal saw, the former alone, if stout, being commonly sufficient to effect ablation when the tumor has a cartilaginous base, or an unusually soft structure. In general, however, the saw will be necessary, and there are many cases where the gouge, chisel, and trephine may advantageously be employed. If the tumor has a very large base, and is insensibly confounded with the substance of the bone from which it grows, it should be divided into several sections, by perforating it at different points, and then detaching them separately, or piecemeal. Various kinds of saws have been invented for removing exostoses, but they are all more or less complicated and unwieldy, and may well be replaced by the more simple instruments in common use. In whatever manner the ablation is effected, the bony portion of the wound should be rendered as smooth as possible by means of the raspator, otherwise it will seriously interfere with cicatrization. As it is, there will, in any event, be more or less suppuration, retarding the progress of the cure, and the patient may congratulate himself if he escape erysipelas and other bad consequences. The hemorrhage attending the operation is usually very slight. The edges of the wound should be lightly approximated, and the parts kept constantly wet with water-dressing, either cold, cool, or tepid, according to the exigencies of the case.

2. FIBRO-CARTILAGINOUS TUMORS.

The fibro-cartilaginous tumor, the enchondroma of recent writers, depicted in fig. 327, may be developed in the cancellated structure, or upon the outer surface

Fig. 327.

Fibro-cartilaginous tumor of the hand.

of the bones, beneath the periosteum. Its figure is globular; its surface rough, or nodulated; its consistence firm, dense, and elastic; its color white, or grayish. When boiled, it yields a peculiar form of gelatin, termed chondrin. The tumor is essentially composed of a fibrous and of a cartilaginous substance. The former constitutes the nidus in which the latter is deposited, and consists of a vast number of oblong or rounded cells, from the size of a clover-seed to that of a pea. These cavities cannot generally be distinguished until the cartilaginous element has been scraped away, or removed by maceration. The morbid mass is strikingly conglomerate, and often attains a large bulk. When it originates, as it commonly does, in the central part of the bone, it gradually encroaches upon the compact tissue, which it expands into a thin, porous shell, either entirely osseous, or partly osseous and partly cartilaginous. Finally, the attenuated lamella gives way at

one or more points, and thus allows the morbid growth to protrude beneath the periosteum, which is itself often very much altered in its character.

This tumor ordinarily affects only one bone, is not malignant, and is productive of little inconvenience, except from its size. It is peculiar to early life, is often directly chargeable to external violence, manifests no tendency to degeneration, not even when of long standing, is generally slow in its progress, and occasionally appears simultaneously in several parts of the skeleton. Every portion of the osseous system is liable to it; but the pieces most frequently affected are the metacarpal bones, the phalanges of the fingers, the humerus, and the lower jaw. To the tumor now described, especially when it is hard, fibrous, and interspersed with osseous matter, or red and dense, like half-boiled beef, or fresh pork, the unmeaning title of *osteosarcoma* was formerly applied by surgical writers. When the disease is of long standing, the growth sometimes undergoes partial ossification, as in the specimen represented in fig. 328. Fig. 329 exhibits a fibro-cartilaginous tumor of the ribs, from a drawing of a preparation in my collection.

Fig. 328.

Enchondromatous tumor undergoing ossification.

Fig. 329.

Enchondromatous tumor of the ribs. a. External appearance b. Internal structure.

A tumor of this kind occasionally attains an enormous bulk, as in an enchondroma of the scapula and humerus in a young man of twenty-six, whom I saw last winter, where it weighed upwards of thirty pounds.

The only remedy for this affection is free excision. All local and general means, even in its earlier stages, are unavailing.

3. ANEURISMAL TUMORS.

Aneurism of the osseous tissue consists in an extraordinary development of the minute vessels, and presents precisely the same anatomical features as aneurism by anastomosis of the soft parts. Confined usually to one bone, it may occur in several, or even in a considerable number. In one case it was discovered in the cranium, sternum, ribs, vertebrae, and innominate bone of the same subject. Its favorite seat is the upper extremity of the tibia, just below the knee. It may arise at different periods of life, but is most common in young adults. The tumor varies in volume from a pullet's egg to a cocoa-nut.

The disease always begins in the cancellated structure, which is converted into

chambers of various sizes, filled with coagulated blood, disposed in concentric layers, as in old aneurismal tumors. Some of the cells occasionally contain fluid blood, or blood partly fluid and partly clotted; but this is rare. The outer table of the bone is expanded, attenuated, and perforated, or so soft, flexible, and elastic that it may be bent like cartilage. In some instances, on the other hand, it is remarkably brittle, and may be crushed like the shell of an egg. The periosteum is thickened and indurated; but the joints in the immediate vicinity of the disease are commonly healthy, even when they are separated from it merely by a thin layer of cartilage. The vessels which ramify through the substance of the bone are tortuous, brittle, increased in size, and open by numerous little orifices into the aneurismal sac at various points of its extent.

There is a form of this affection in which the vessels, as was first clearly shown by Mr. Stanley, consist principally of enlarged capillaries, exhibiting the same general characters as an anastomotic aneurism or an erectile tumor of the soft

Fig. 330.

Anastomotic aneurism of bone.

parts. The disease, represented in fig. 330, has hitherto been chiefly noticed in the broad bones, especially those of the cranium of young children.

The causes of this lesion are involved in obscurity. In some instances it has been traced to the effects of a blow; in others to a fall, or jump from a considerable height. Either of these occurrences, by disturbing the vascular action of the bone, might produce the disease.

The enlargement, even in its early stage, is tense, painful, and attended with distension of the superficial veins, swelling of the surrounding structures, and slight discoloration of the skin. In a short time a deep-seated pulsation, or throbbing synchronous with that of the left ventricle, and similar to what is witnessed in some erectile tumors, may be perceived in the affected part. In the advanced stage of the malady the beating is accompanied by a sort of undulating movement, and is easily interrupted by compressing the main artery of the limb between the tumor and the heart. The enlargement varies in size. In a case mentioned by Mr. Bell, it was more than nineteen inches in circumference, by upwards of six in length. In some instances, pressure applied to the tumor with the finger imparts a peculiar crackling sensation, not unlike that of dry parchment or an egg-shell. The soft parts around the disease are generally cedematous, the whole limb is apt to be swollen, and the motion of the contiguous joints is constrained and painful. Towards the last the general health always seriously suffers.

The only effectual remedy for this disease, provided its location is favorable, is amputation. In the early stage relief may possibly be afforded by securing the main artery of the limb. Lallemand relates a case in which ligation of the femoral artery completely arrested an aneurismal affection of the head of the tibia; but this must be regarded as an exceptional example.

I have myself secured this vessel in two instances for this disease, with the effect only of very transient benefit. In both the pulsation soon returned, and the growth of the tumor went on as before the operation. In a remarkable case, in a young man of twenty, who consulted me in 1860, a spontaneous cure occurred. The disease, seated in the head of the tibia, had existed for several years, when, the pulsation ceasing, the tumor gradually diminished in volume, and eventually lost all its characteristic features.

The anastomotic form of this disease admits of removal only when it is of limited extent. When it is situated in the cranial bones, it gradually destroys the osseous tissue, and ultimately involves the brain and its envelops, rendering interference out of the question. Several cases have been reported in which the carotid arteries were tied for this disease, but in none with any permanent benefit.

4. HEMATOID TUMORS.

There is a variety of tumor, closely allied to that just described, which, for the sake of uniformity in surgical nomenclature, I shall term hematoid. It is produced by a deposit of blood in the cancellated structure, forming a firm, oval, and elastic tumor, filled with dark, solid coagula. The best specimen of this disease that I have ever met with occurred in a man, aged thirty-five, a portion of whose lower jaw I amputated on account of what was, at the time, supposed to be a bony tumor. The growth, about the size of a common orange, extended from the canine tooth on the right side to the middle grinder of the left, and consisted of a mere osseous shell, without any vestige of the cancellated structure; it was occupied by three red, solid coagula, the largest of which did not exceed the volume of a pigeon's egg. The cavity was only partly filled by the clotted blood, which adhered to the inner surface of the bony wall, and was evidently organized. The tumor had appeared three years before without any assignable cause. Whence was this blood derived? Did it proceed from a rupture of some of the vessels of the bone? If so, the fact could not be ascertained by the most careful examination.

5. SERO-CYSTIC TUMORS.

Serous cysts, similar to those which occur in the soft parts, especially the ovary, kidney, and liver, are occasionally met with in various pieces of the skeleton, particularly in the lower jaw, the tibia, and femur. They are always developed in the areolar tissue, and show themselves in two distinct forms, the unilocular and multilocular, of which the first is by far the more frequent, the other being, in fact, extremely uncommon. Pathologists failed, until recently, to seize the distinctive features of this disease, and to assign to it a proper place in their nosological tables. Mention, it is true, was made of it by some of the authors of the last century, especially by Bordenave, but it was only in an incidental manner, and it remained for Dupuytren to furnish the first clear account of it. It is more than probable that what the older surgeons were in the habit of calling osteosarcoma and spina ventosa were frequently, if not generally, growths of this description, with cavities filled with liquid or solid matter. I have certainly commonly found them so, and it may, therefore, be concluded that the same thing has happened to others.

Morbid Anatomy.—The unilocular cyst varies in size from that of a hempseed to that of a pullet's egg, its shape being generally irregularly rounded, or somewhat globular. It consists essentially of a thin, delicate, polished membrane, having, apparently, all the characteristics of the serous tissue. This membrane is closely adherent to the bony wall of the cyst, and undergoes important changes in consequence of age, and repeated attacks of inflammation, becoming dense, thick, opaque, and tough. The contents of the cyst are variable: sometimes clear and limpid, like well-water; sometimes cloudy, ropy, or glutinous; sometimes sero-purulent; and finally, again, though this is uncommon, thin and discolored, from the
older cavities occasionally

contain solid matter, of an albuminous, curdy, or fibrous nature; and I have seen specimens in which they were occupied by a peculiar, micaceous-looking substance, not unlike cholesterine.

The multilocular cyst, represented in fig. 331, is less frequent than the uni-

Fig. 331.

Cystic disease of the femur.

locular. As the name imports, it is composed of a greater or less number of cells, divided by bony septa, and lined by a serous membrane, similar to that in the unilocular cyst, of which the multilocular appears to be merely an exaggerated variety. Its contents are generally of a sero-sanguinolent character, although sometimes they are clear and purely serous, like those of a hydrocele. In one case, I found it thick and red, like the dregs of claret wine. In a group of multilocular cysts, a few will occasionally be seen to be filled with solid matter, or matter partly solid and partly fluid. When this is the case, it may generally be assumed that the cysts are old, and that their vessels have undergone important changes in their secretory action, in consequence of which they pour out concrete instead of liquid substance. I have witnessed instances, however, in which the material was of such a nature as to induce the belief that it was originally deposited in a solid form. However this may be, the substance is generally of a fibrous or fibro-cartilaginous character, and so firmly adherent to the walls of the cysts which contain it as to be with difficulty enucleated. Interspersed through this substance are occasionally little nodules, fragments or spicules of bone, and earthy concretions, or a combination of calcareous with osseous matter.

Age and Sex.—Serous cysts of the bones are most common in young adults and middle-aged subjects; they are seldom met with before puberty, or after fifty. Both sexes are liable to them, but in what proportion has not been determined. Their causes are involved in obscurity. In general the disease arises spontaneously. In the lower jaw, which, as has already been stated, is its most frequent seat, its origin is often ascribed to the irritation of a decayed fang, or to violence done in the extraction of a tooth; but before we can admit the influence of either as a cause of serous cysts, it must be remembered that thousands of persons constantly suffer in this way, without any such occurrence, and hence the development of these bodies may, after all, under such circumstances, be a mere coincidence. So, also, with respect to blows, fractures, contusions, and other mechanical injury, so often invoked as sources of this and other organic maladies of the bones. If they are really capable of producing such an effect in one case, why should they not in another? We must, therefore, look beyond these causes, and conclude that some other agent is concerned in their origin, although of the nature of that agent we are entirely ignorant.

Progress.—The progress of this disease is always slow. In the jaw we often meet with cases of serous cysts of six, twelve, and even fifteen years' standing, without any serious disturbance of the general health, or any particular local disorder, save what results from the pressure of the tumor upon the surrounding structures. Neither the cysts, their fibrous contents, nor the parts adjacent manifest any tendency to malignancy, and I am inclined to believe that whenever such an occurrence is observed it is to be received as a strong evidence that the growth was originally of a bad character, and not that it became so in consequence of any new epigenesis. When the tumor is large, whether it is multilocular or not, fluid or solid, it generally exhibits a marked tendency to destroy the bone in which it is located, pressing aside the compact lamella, and gradually involving its entire circumference. In the lower jaw the parts most commonly affected are the body and ramus, extending often beyond the middle line in front, and backwards as far as the condyloid process.

Symptoms.—The symptoms of cystic disease of the osseous tissue are obscure. The first thing that usually attracts attention is a dull, aching pain in some particular bone, as, for example, the jaw, which is often mistaken for toothache, or rheumatism; this gradually increases in severity and frequency, and is at length found to be dependent upon the presence of a hard tumor, or the expansion of a portion of the bone, more or less tender on pressure and motion, but unattended by any discoloration or intumescence of the overlying textures. The progress of the disease is always tardy, and it often happens that, after having attained considerable development, it remains, to all outward appearance, for some time perfectly stationary. Then, taking a new start, it again increases, and thus it continues, now advancing and now stopping, until it has perhaps acquired the volume of a large orange, or even of a fist. Still, the general health continues good, there is no emaciation, and the countenance is perfectly free from that distressed, anxious, and sallow state which characterizes it in malignant disease. Even the pain is generally comparatively trivial, and if it were not for the mechanical obstruction occasioned by the encroachment of the tumor upon the adjacent parts, the patient would hardly be conscious of being unwell. If the parts be now carefully examined, they will be found to be of unequal consistence, the firmer parts being incompressible, while the softer ones readily yield under the finger, emitting a peculiar crackling noise not unlike that of dry parchment. In the absence of signs of malignancy, pulsation, lividity, and varicose enlargement of the overlying vessels, these circumstances afford the best evidence of the true nature of the disease, but if there is any doubt respecting it, this may generally be promptly dispelled by a resort to the exploring needle, the escape of serous, or sero-sanguinolent fluid determining the diagnosis. The tardy growth of the tumor and the absence of constitutional disorder are, indeed, commonly of themselves sufficient to mark the character of the malady. Between cystic and hydatid diseases of the bones no signs of distinction exist, nor is this a matter of importance, as the treatment is essentially similar.

Treatment.—The only available treatment in cystic disease is removal of the morbid mass, and some of the most brilliant exploits in modern surgery have been performed upon tumors of this kind. When it involves the jaw, the greater portion of that bone sometimes requires excision, the affected part being cut away along with a portion of the sound tissue, the same principle guiding the surgeon as in the extirpation of morbid growths of the soft structures. When the cysts are small and not numerous, they may sometimes be effectually scooped out, the cavity being afterwards stuffed with lint, and made to heal by the granulating process. On the other hand, cases occur, as when the disease involves the entire circumference of one of the bones of the extremities, where, neither of these procedures being available, nothing short of amputation will answer.

I am aware that various plans of treatment have been suggested for arresting this disease in its earlier stages, or curing it without the knife when it has attained a considerable magnitude. So far, however, as I am informed, there are none which are entitled to any confidence. The most plausible of these are iodine injections and the introduction of the seton; the former of which experience has proved to be ineffectual, while the latter is so unscientific as not to be thought of, much less practised, in any case.

6. HYDATID TUMORS.

One of the most remarkable diseases of the bones is the development of hydatids in their spongy structure, an occurrence which, although uncommon, has now been so repeatedly observed as to entitle it to distinct notice in a systematic treatise on surgery. The first account of these bodies was given by two Dutch pathologists, Van Wy and Vander Haar. Since then attention has been directed to them by other observers, who, minutely detailing the facts which have come under their notice, have thus laid the foundation of our knowledge of this interesting subject.

Although it is extremely probable that all the different classes of bones are

liable to these formations, they have hitherto been observed almost exclusively in the long and flat bones, particularly in the tibia, for which, judging from the frequency of their occurrence here, they appear to have a decided preference. They have been found three times in the frontal bone, twice in the iliac bone, twice in the humerus, once in the femur, and once in a vertebra. What was formerly known under the vague name of *spina ventosa* was an osseous tumor which probably occasionally contained bodies of this kind.

Hydatids of the bones are always developed in the spongy texture, as this alone affords them an opportunity of growing and expanding, the compact tissue being too dense and firm to admit of their increase. The only exception to this occurs when they form in the frontal sinus, but even here there is no new law in operation, since the cavity in question is, in fact, only a large cell, exceedingly well adapted as a residence for such bodies. In the tibia, the disease is always situated in the spongy structure which exists in such abundance in the head of this bone, just below the knee.

How these bodies are developed is still a mystery. That the germs are conveyed to the spongy tissue of the bones in the blood which is sent to them for their nutrition and growth is evident enough, but why they should be deposited here in preference to other parts of the body is a question which the most refined pathology is unable to unravel. Nor is anything certainly known in regard to the nature of the exciting causes of these bodies; for if, as has occasionally happened, they have shown themselves in a particular portion of the skeleton after the occurrence of a blow, contusion, or other injury, it does not prove that their development was the consequence of such mischief.

Sex does not appear to exercise any particular influence upon the formation of hydatids of the bones, as they have been observed with nearly equal frequency in men and women. Most of the patients in which they have hitherto been found were adults, but in one instance they occurred in a child three years of age. Borchard has narrated a case where they existed in several situations in the same individual.

Morbid Anatomy.—Examination has proved that these bodies are really acephalocysts, similar to those which are occasionally met with in the liver, ovaries, lungs, and other internal viscera. Of a spherical or rounded shape, they are sometimes irregularly flattened, or compressed, and vary in size from that of a pea to that of a marble, their dimensions being evidently influenced by their age, and the extent of the cavity in which they are developed. Their number, which is seldom large, is usually in an inverse ratio to their volume. They are inclosed in a sort of parent-cyst, soft in structure, thin, and of a whitish appearance, and they float about in the midst of a serous fluid, of a saline taste, and partially coagulable by heat, alcohol, and acids; circumstances clearly betraying its albuminous character.

The cavity in which these bodies are situated is deserving of special attention. It is evidently, in the first instance, simply one of the cells of the areolar tissue, in which the germ of the animal is deposited, and where it is destined afterwards to attain its full development. As its growth proceeds, it presses upon the osseous matter, pushing its fibres farther and farther apart, at the same time causing a partial removal of it by the action of the absorbents, until what remains is at length converted into a mere bony sheet, hardly as thick as a piece of parchment, elastic, and crackling under the finger. The shell is lined, as already stated, by a thin, closely adherent membrane, which evidently plays an important part in the development and protection of the new being. Cases occur in which it consists of several compartments, cells, or lodges, although in general it is unilocular. The bone immediately adjacent to the disease is usually thickened and roughened by irregular deposits.

Symptoms.—The symptoms attending the formation of these bodies are extremely obscure, and cannot, for a long time, be separated from those which accompany other diseases in and about the skeleton. Their growth is always very tardy, and a number of months generally elapse before there is any pain and discoloration of the integuments. The patient is merely aware that there is some

tumor, steadily augmenting in bulk, and slowly encroaching upon the surrounding parts; hard and firm at first, afterwards more soft, and ultimately becoming quite elastic, and emitting a peculiar crackling sound on pressure very similar to that of dry parchment. If it be deep-seated, it will cause a gradual wasting of the superimposed tissues, the muscles and tendons being spread out like thin ribbons, while portions of the fibrous membranes are actually absorbed. Meanwhile, the tumor mechanically impedes the functions of the surrounding parts, pain and tenderness set in, and the integuments show signs of irritation and discomfort. At this stage of the complaint the affected bone sometimes gives way under the most trivial accident, refusing afterwards to unite, or undergoing consolidation only after a long while and after much trouble. Occasionally, the most prominent portion of the tumor ulcerates, and discharges a part of its contents; such an event, however, is extremely rare. The general health remains good for years, but in the end it is always much impaired in consequence of the local distress.

Diagnosis.—The most important diagnostic signs are, the tardy progress of the tumor, the want of pain and swelling, the change from a hard, incompressible substance to one of comparative softness and even elasticity, and the complete absence of all appearance, both local and constitutional, of malignancy. After all, however, these symptoms are merely of a negative character; for at last the only reliable source of information is the exploring needle, though this also, unfortunately, is not available until the morbid growth has acquired a great bulk, and is almost on the verge of bursting. Even the elastic feel and crackling noise which, in the latter stages of the complaint, form such prominent features, are of no diagnostic avail, as they are common to several other varieties of bony tumors.

Prognosis.—Hydatic disease of the osseous tissue is always a grave occurrence, not so much on account of the damage to the general health as of the injury it inflicts upon the affected bone, weakening its structure and thus impairing its usefulness, generally to an irremediable extent. In several of the recorded cases the acephalocysts burst into the knee-joint, causing violent suppuration, and destruction of the functions of the articulation. In a few others, the animals perished, and shrunk up into dirty, reddish-looking masses, which afterwards became a source of irritation, followed by high constitutional disturbance, excessive pain, and hectic fever.

Treatment.—The only remedy that can at all reach this disease is extirpation, performed early, before there is any serious structural lesion of the bone. As soon, therefore, as the diagnosis is fully established, the tumor should be freely exposed by an incision, either crucial or elliptical, and attacked with the saw, pliers, trephine, or chisel and mallet, as may seem advisable. Its contents being turned out, the living membrane of the osseous shell is carefully peeled off, or, when this is impracticable, painted with a strong solution of iodine, to destroy its secreting surface, lest there should be a speedy reproduction, if not of hydatids, at all events of serous fluid. The cavity is then filled with lint, smeared with cerate, and the flaps being approximated are lightly held in place with a few strips of adhesive plaster. The cavity gradually shrinks, and a cure is ultimately effected by the granulating process.

When the case is one of an aggravated nature, involving the entire circumference of the affected bone, or when the hydatids open into a joint, the only question will be whether the treatment shall be by resection or amputation. The former procedure can be suitable only when the disease is of limited extent. Amputation will be necessary when the case is desperate, as when the bone is irremediably destroyed, or broken and unwilling to unite, or when the tumor has discharged its contents into a neighboring articulation, and has induced so much disturbance, local and constitutional, as to threaten life.

7. MYELOID TUMORS.

The osseous tissue is more liable to the myeloid tumor than any other class of textures, and it is here that the new structure generally acquires its most perfect

development. Doubtless it may occur in all, or nearly all, the pieces of the skeleton, but its favorite sites are the tibia, femur, and inferior maxilla, especially the latter. Commencing generally, if not always, in the cancellated structure, its point of departure is probably the endosteum, extending from thence to the compact layers, which it gradually disparts, and converts into thin, cartilaginous plates, bending and crackling under the finger like dry parchment. Continuing its growth, it may, in time, attain the size of a fist, or even of a fetal head, encroaching seriously upon the surrounding parts, and interfering, more or less, with the exercise of their functions. The arteries leading to it are generally somewhat enlarged, and the tumor itself is commonly quite vascular. A section of it exhibits a smooth, compact appearance, of a reddish, pink, or lilac tint, inlaid with soft bony fibres, and pervaded by little cysts, either simple or compound, and occupied by different kinds of fluids, as serum, sanguinolent matter, or altered blood, or all these substances commingled.

There are no signs by which this growth can be distinguished from other tumors of the bones; its rapid development, its elastic feel, and its lobulated form assimilate it very much, in its external characters, to encephaloid, and the resemblance is still further shown by the fact that the disease is liable to recur after extirpation, and also that, in its advanced stages, the patient presents all the evidences of the cancerous cachexia. The only remedy is excision or amputation; excision when the tumor involves the jaws, amputation when it is seated in the bones of the extremities.

MALIGNANT FORMATIONS.

The various malignant affections of the bones may, as far as practical purposes are concerned, be all conveniently grouped under one head. Of these affections, encephaloid is much the most common; next in point of frequency is colloid, then comes scirrhus, and finally, as the most rare of all, melanosis. The origin, progress, and termination of these formations are the same here as in other organs and tissues.

1. *Encephaloid*, hematoid fungus, cerebriform cancer, or osteocephaloma, generally, if not invariably, originates in the spongy structure of the bones, from which it gradually extends to the compact lamella, and finally to the periosteum. It most commonly attacks the upper and lower jaw, and the long bones of the extremities, particularly the femur, humerus, and digital phalanges. No portion of the skeleton, however, is exempt from it. The most terrific feature of the disease is its tendency to recurrence after extirpation. It may show itself at any period of life, but young persons are most obnoxious to it.

Occurring, now and then, as an infiltration, encephaloid of the bones most commonly presents itself in the form of a tumor, arranged in rounded, lobulated masses, of the color and consistence of the medullary structure of the brain. Not unfrequently it contains small cavities, filled with clotted blood, dirty-looking serum, or soft, gelatinous, oily, sebaceous, or melliceroid matter. Occasionally one part of the tumor exhibits the brain-like character, while another is strictly hematoid, or composed of a mixture of blood and encephaloid. In the great majority of cases, however, the two substances are pretty intimately blended together. Vessels, sometimes of considerable volume, may be seen ramifying over the surface of the morbid growth, and dipping into its interior. The outer table of the bone is transformed into a thin, parchment-like lamella, perforated in various places, or entirely destroyed by absorption. A section of the tumor usually exhibits, in addition to the appearance just described, osseous fragments, or pieces of fibro-cartilage. The superincumbent integuments, traversed by large bluish veins, are at first soft and glossy; but at length, from the constant and increasing pressure exerted upon them, they ulcerate, and allow the fungous mass to protrude.

Some of the more extraordinary alterations which the osseous structure is capable of undergoing in this disease are well seen in fig. 332, from a specimen in the cabinet of Professor Buchanan. The patient was a mulatto girl, about

twelve years of age, who had labored for some time under a large, lobulated tumor, partly elastic and partly inelastic, situated in the lower part of the leg,

Fig. 332.

Encephaloid of the tibia.

and attended with great dilatation and distension of the subcutaneous veins. Amputation being performed, the stump healed kindly, and for several weeks the girl did well; but in a few months she began to complain of pain in her hip and side, and she died in less than a year, apparently from internal malignant disease. A section of the tumor displayed an immense number of osseous spicules, of extraordinary length and delicacy, whose intervals were occupied partly by cartilaginous and partly by gelatinous substance, with here and there a cyst containing bloody-looking matter. The external characters of encephaloid are well displayed in the adjoining cut, fig. 333, from a specimen in my collection.

2. Of *colloid* of the osseous tissue very little is known. It is most frequently met with in the diseased conditions of the bones denominated osteosarcoma and spina ventosa,

Fig. 333.

Encephaloid of the thigh-bone.

Fig. 334.

Colloid tumor.

which are often almost wholly composed of cells and cavities, filled with jelly-like matter. The question, however, respecting the identity of these affections can be determined only by future observation. A case in which a colloid tumor grew from the body of the sphenoid bone, outside the dura mater, came under my notice in 1844, in a patient who died at the age of thirty-nine years from epilepsy, produced by a fall twelve months previously. On examination, Dr. Collescott

and myself found, in the situation referred to, a lobulated tumor, of irregular form, and about the size of a pullet's egg, which had flattened the Varolian bridge, and evidently induced the disease in question. A section of the morbid mass, fig. 334, showed that it was composed of several compartments communicating with each other, and occupied by a white, semi-concrete substance, in all respects similar to that of colloid.

3. *Scirrhus* of the osseous tissue is extremely uncommon. It occurs exclusively in old subjects, and is usually concomitant of the same disease in the breast or some other organ. Generally limited to a single bone, it may affect several pieces simultaneously, and always begins in the cancellated structure. Its favorite seat is the femur, but it may appear in any part of the skeleton, in the short and flat bones, as well as in the long. In the case of a woman upwards of forty years of age, recently examined by Dr. J. E. Mears, scirrhus deposits existed in the skull, sternum, femur, lung, diaphragm, uterus, and ovaries. The left breast had been extirpated some time previously to her death on account of carcinoma.

The heteroclite matter is deposited under two varieties of form, the infiltrated, and the tuberoid. In the former it is diffused through the areolar tissue, and exhibits the color and consistence of fibro-cartilage, or the rind of fresh pork. In the tuberoid variety the morbid mass is either solitary, or it consists of several agglomerated nodules, from the volume of a hazel-nut to that of an almond. Occasionally three or four distinct tumors are developed simultaneously in the same bone. They are of an irregularly rounded or oval shape, dense and firm in their consistence, and of a greenish, whitish, or yellowish color. The bone is seldom much altered in its size or external configuration, but is liable to be absorbed, and fractured at the seat of the disease.

4. The occurrence of *melanosis* in bone is very unfrequent. It may appear in small, disseminated masses, nodules or clusters, or in the form of an infiltration. It has been observed in various parts of the skeleton, but is most common in the pieces of the extremities, particularly the femur and tibia. Coexisting generally with melanosis in other organs, it is situated either upon the surface of the bone, beneath the periosteum, in the medullary canal, or in the spongy structure, the latter of which it sometimes dyes of a deep black color. In its progress and mode of termination it closely resembles medullary sarcoma.

General Diagnosis, Prognosis, and Treatment.—Much has been said, especially of late years, respecting the diagnosis of cancerous diseases of the osseous tissue, and from reading the accounts of them in some of the books one would suppose that their recognition was a matter of the greatest facility. Nothing, however, is more untrue. With the exception of encephaloid, it is extremely difficult to detect the real nature of any of them during any portion of their progress, and even encephaloid cannot always be satisfactorily discriminated until it has acquired an unusual bulk. In the latter case, the most reliable guides are, the early period of life at which the tumor shows itself, the rapidity of its growth, the great bulk it attains, the depth of its situation at the commencement of its development, the lobulated condition of its surface, and the extraordinary enlargement of the subcutaneous veins. In general, too, it will be found that the disease is developed in one of the long bones, as the humerus, femur, or tibia, and in preference, as it were, in their articular extremities. The moment ulceration occurs the case speaks for itself, the diagnosis being no longer equivocal.

The progress of encephaloid is generally very rapid, especially when it occurs upon the periphery of the bones, a few months usually sufficing for the formation of an immense tumor, and the complete destruction of the osseous tissue, or its conversion into a soft, sarcomatous, or fibro-cartilaginous mass, with hardly any trace of the primitive structure. The growth is commonly of a lobulated character, and of varying degrees of consistence, being soft at one part, tolerably firm at another, and perhaps almost bony at a third, according to the nature of the portion examined. As it increases in size, it displaces the surrounding textures, flattening the muscles and nerves, and thus impairing their functions;

the integuments are stretched, and, in places, attenuated; and the subcutaneous veins are enlarged, varicose, and of a bluish color. The colloid tumor is also capable of attaining a great bulk, but its progress is usually much more tardy than that of encephaloid, and there is seldom any considerable augmentation of the subcutaneous veins. Scirrhus of bone usually coexists with scirrhus of the mammary gland, uterus, or liver, and the only symptom leading even to a suspicion of its presence is the peculiarity of the attendant pain, which is usually either sharp and lancinating, or else dull, heavy, or aching, and fixed, the affected part being, at the same time, exquisitely tender on pressure and motion. The patient often becomes bedridden during the progress of the case, and the diseased bone not unfrequently gives way under the most trivial accident, as a mere twist of the limb in stepping out of the bed upon the floor. Melanosis of the osseous tissue is seldom discovered during life, unless it happens to be seated in a superficial bone, as the sternum, or one of the ribs; in nearly every instance that has yet been observed, it was present at the same time in other parts of the body.

Cancer of bone follows the same course as cancer of the soft parts. If left to itself, the malady inevitably proves fatal, and hardly any one makes a permanent recovery after an operation, however early and thoroughly executed. In all the cases excepting one, of encephaloid of the extremities that I have either operated upon myself, or seen operated upon by others, there has been a speedy recurrence of disease, often indeed in less than three months, either at the cicatrice, the neighboring lymphatic ganglions, or in some internal organ, carrying off the patient a short time afterwards. In the instance here referred to, the patient, who was upwards of thirty years of age, had an encephaloid tumor of the forearm, which I amputated in consequence. He survived the operation six years, finally dying, as was supposed, of cancer of the lungs, in a state of complete exhaustion. There is no doubt that many cases of cure have been reported of operations upon encephaloid tumors that were in reality altogether benign in their character. Errors of diagnosis must, indeed, be sufficiently common in the hands of young and inexperienced practitioners. Judging from personal observation, I am inclined to believe that malignant growths of the maxillary bones are less liable to relapse after excision than those of any other pieces of the skeleton, and in this view of the subject, if I mistake not, the opinion of surgeons generally coincides. Nevertheless, even here the ultimate issue of the case is nearly always unfavorable. The circumstances justifying interference in this class of maladies have already been so fully pointed out in the chapter on carcinomatous diseases in general, as to render any further discussion of them unnecessary in this place. In regard to the choice of the operation, as to whether this should be amputation or excision, the decision must always be given in favor of the former whenever the morbid growth occupies an extremity, the removal being effected as high up, or as near to the trunk, as possible, as conferring greater safety. Thus, when the hand is involved, the forearm should be cut off near the elbow, and in encephaloma of the radius and ulna, the limb should be amputated pretty close to the shoulder. If the tumor is seated in the upper jaw, the whole of that structure should be excised together, perhaps, with portions of the palate, spongy, and malar bones. Thorough work must be made, or interference will be productive of infinite harm instead of good. After recovery from the operation, the patient must be put upon a properly regulated diet, with an alterative and tonic course of treatment, and exercise in the open air.

SECT. XIV.—TUBERCULAR DISEASE.

Tubercles of the bones are much more common than is generally imagined. The bones usually affected are the vertebræ, the short bones of the hand and foot, and the articulating extremities of the long bones. The particular seat of tubercles is the spongy texture, though occasionally they are formed upon the outer surface of the bones, beneath the periosteum.

There are two varieties of form in which this matter is deposited. In one,

perhaps the more common, the tubercles are *encysted*, the inclosing membrane, which varies in thickness from the fifth of a line to half a line, being composed of plastic matter, very soft at first, but gradually becoming harder and harder, until finally, in some cases, it acquires the character of fibro-cartilage. It is of a dull grayish color, is made up of delicate, inelastic fibres, and is frequently furnished with small vessels, passing into it from the surrounding structures. The number of tubercles is generally small; their size ranges from that of a pea to that of a cherry; and they are of a yellowish, opaque appearance. When they become softened, as they commonly do in a few months, the pus either works its way out, or it escapes, by a sort of fistulous route, into a neighboring joint, establishing thereby an analogy with pulmonary tubercles opening into the bronchial tubes. Sometimes a spontaneous cure takes place, the heterogeneous substance being absorbed, and the cavity occupied by the cyst being obliterated by osseous matter.

In the second variety, the tubercular matter is deposited directly into the cells of the osseous tissue, forming grayish, semi-transparent, opaline patches, from the

Fig. 335.

Bone infiltrated with tubercular matter.

one-sixth of an inch to an inch in diameter. This infiltration, exhibited in fig. 335, is noticed chiefly in the bodies of the vertebrae and in the bones of the tarsus, where it is frequently pervaded by numerous vessels, too delicate to be discerned with the naked eye. The bony tissue immediately around is sometimes deeply injected, but seldom otherwise diseased. In this, as in the preceding variety, the tubercular deposit, after having existed for some time, gradually softens, its vascularity disappears, and the cells in which it was contained are filled with earthy matter. This, however, is not always the case; for now and then the ulcerative process continues until the bone is totally destroyed.

The progress of tubercular disease of the bones is always chronic, though not equally so in both forms, the infiltrated proceeding more tardily than the encysted, and causing generally also a greater amount of havoc in the osseous tissue. There is nothing definite, however, in regard either to the commence-

ment of the softening process, or to the ultimate elimination of the resulting matter from the affected structures. Much will doubtless depend, in every case, upon the condition of the system, the age of the patient, and the presence or absence of complications. As a general rule, from six to twelve months will elapse from the moment of the deposition of the tubercular substance to the completion of the softening process. The pus left by the disintegration of the heterogeneous matter is similar to that which occurs in the lungs in the advanced stage of phthisis, being of a pale yellowish color, bordering slightly upon greenish, and of a thin fluid consistence, with small whitish flakes not unlike soft-boiled grains of rice. After an opening has been effected into the abscess, the discharge generally becomes very watery and bloody, as well as irritating, and comes away in large quantities, a number of sinuses often existing in the diseased parts, as if they were necessary to carry off the superabundant secretions. In many cases, broken-down osseous tissue is intermingled with the pus, passing off either as little granules or as minute fragments, which not unfrequently choke up the abnormal track, and thus excite new irritation.

The adjoining cut, fig. 336, from a specimen in my cabinet, exhibits the effects which a tubercular abscess may exert upon the osseous tissue, in causing a well-marked excavation, similar to what occurs in the lungs.

The abscess that arises from the disintegration of tubercular matter is the form

which is usually met with in bone, the phlegmonous, as stated elsewhere, being of extremely rare occurrence. The symptoms attending it are generally obscure, but its existence may be suspected when, along with the ordinary signs of osteitis, the affected part is the seat of circumscribed, deep-seated, gnawing pain, with

Fig. 336.

Tubercular excavation of the cuneiform bone.

excessive tenderness at one particular spot, and a glossy, shining, oedematous condition of the integuments. The breaking of the abscess is always preceded by considerable swelling of the soft structures, and by more or less disturbance of the system, the constitution frequently sympathizing severely with the local trouble. In addition to these circumstances, the history of the case, as the age of the patient, the site of the morbid action, and the absence or coexistence of strumous disease in other structures, will generally furnish useful light, and thus materially aid in the establishment of a correct diagnosis.

The *treatment* of tuberculosis of bone does not materially differ from that of tuberculosis generally. As the local deposit is usually merely a reflection of the state of the system, the great object should be to employ such remedies as are necessary to modify this condition of the constitution and to provide for the supply of a better and richer blood. The principal means included under this head are, a well-regulated and adequately nutritious diet, cod-liver oil, and the various chalybeate preparations, either alone, or in union with quinine, mild purgatives, and gentle exercise in the open air.

The local remedies are, of course, of the ordinary antiphlogistic character, consisting of leeches, blisters, and the dilute tincture of iodine, with early and free incisions of the soft structures to relieve pain and tension. If the existence of an abscess is suspected, prompt recourse is had to the trephine, the operation and after-treatment being conducted in the same manner as in acute abscess of bone.

SECT. XV.—NEURALGIA.

Neuralgia of the osseous tissue is infrequent. I have seen a large number—perhaps it would be more correct to say an immense number—of cases of neuralgia of the soft structure in almost every part of the body, but only a few of neuralgia of the bones. In nearly every instance that has fallen under my observation the disease was associated with some organic lesion of the affected texture, such as abscess, caries, exostosis, or interstitial deposits into the Haversian canals and cancellated tissue, thereby compressing the vessels and the nerves distributed throughout their tunics. A lady, aged fifty, had long been afflicted with neuralgia of the cranium, caused by the falling of a window-sash upon the upper and posterior angle of the left parietal bone. The pain, without observing any regularity in its accession, gradually increased in severity, and became at length so intense as to require from one to two drachms of morphia a week, besides enormous quantities of sulphuric ether, even for temporary relief. The seat of pain was a small spot, not larger than the end of a finger, and exquisitely tender to the touch. A disk of bone, embracing the affected portion, being removed with the trephine, an exostosis, not more than the eighth of an inch in thickness,

was discovered upon its inner surface, which thus at once explained the nature of the case. Complete recovery followed the operation.

A married woman, aged twenty-eight, had suffered, at times, most acute and distressing pain from a small bony tumor at the anterior and outer part of the lower extremity of the left radius. The tumor had come on about twelve years previously, and had all along been exquisitely sensitive on pressure and even on the slightest touch. It projected but little beyond the natural level, and was unaccompanied by any visible change in the soft parts. The pain had been liable to periodical exacerbations, and was often so severe as to deprive the woman of appetite and sleep. The general health had always been good; the complexion denoted a robust state of the system, and the menstrual function was usually performed with great regularity. Upon removing the tumor, I found that its substance was almost as hard and dense as ivory. The pain at once disappeared, and has never returned.

I have met with a number of cases similar to the last, which may be regarded as, in some degree, typical of this affection as it usually appears in the skeleton. Most of them occurred in young females, between the ages of fifteen and thirty, without, seemingly, any direct connection with the catamenial function, which was usually well executed, and without any marked hysterical predisposition. In all the cases that I have met with, the pain was liable to periodical exacerbations, not, however, by any means always coincident with menstruation, and the parts were exquisitely sensitive under motion and pressure. The pieces that I have found most frequently affected are the radius, ulna, tibia, fibula, clavicle, skull, and innominate bones. The coccyx is also not unfrequently affected, especially in married women who have borne children.

Neuralgia of bone may arise spontaneously, or it may be a result of direct injury, as a blow, wound, or contusion, causing inflammation in the affected part. It may also be produced by a syphilitic taint of the system, as is witnessed in the tertiary form of this disease, in which the pains are not unfrequently of a darting, shooting, lancinating nature, or else dull, heavy, and aching, as in neuralgia of the soft structures. In abscess of bone the suffering is frequently of the same character; hence the difficulty which the practitioner so often experiences in discriminating between the two affections. The disease is frequently associated with neuralgia in other parts of the body.

What the precise nature of the change is which the osseous tissue undergoes in this affection has not been determined. The probability is that it is sometimes altogether functional, while at other times it depends upon interstitial deposits, either as a simple hypertrophy or as a small exostosis, compressing the vessels and nerves at the seat of the disease, and thus causing the excessive pain which so often attends it.

The *treatment* of neuralgia of bone is too often conducted upon empirical principles; a circumstance which is doubtless due to the fact that it is generally difficult, if not impossible, to ascertain the true nature of the disease. In recent cases, especially in such as are directly chargeable to the effects of external injury, a free incision down to the seat of the disease, dividing the periosteum and even the superficial layer of the bones, will occasionally effect a prompt cure, especially if the wound is kept open for some time with stimulating dressings to promote discharge. Now and then a small issue, made with the actual cautery, will answer an excellent purpose. When the cause is of a syphilitic nature, iodide of potassium and mercury are the best means of relief. Quinine, arsenic, and strychnia are indicated when the disease is of miasmatic origin. In obstinate cases, the only reliable plan is removal of the affected bone with the trephine or other suitable instrument, as the object is to get rid of the compressing agent, whether this is merely simple hypertrophy of the part or an exostosis properly so termed. Dr. Nott, of Mobile, has on two occasions excised the greater portion of the coccyx for the cure of this disease, and a similar operation has been performed by others, though not always with a satisfactory result.

SECT. XVI.—FRACTURES.

1. GENERAL CONSIDERATIONS.

There is no class of injuries which a practitioner approaches with more doubt and misgiving than fractures, or one which demands a greater amount of ready knowledge, self-reliance, and consummate skill. Constant in their occurrence, and often extremely difficult of diagnosis and management, they frequently involve consequences hardly less serious and disastrous to the surgeon than to the patient himself. If I were called upon to testify what branch of surgery I regarded as the most trying and difficult to practise successfully and creditably, I should unhesitatingly assert that it was that which relates to the present subject, and I am quite sure that every enlightened practitioner would concur with me in the justice of this opinion. I certainly know none which requires a more thorough knowledge of topographical anatomy, a nicer sense of discrimination, a calmer judgment, a more enlarged experience, or a greater share of vigilance and attention; in a word, none which requires a higher combination of surgical tact and power. As for myself, I never treat a case of fracture, however simple, without a feeling of the deepest anxiety in regard to its ultimate issue; without a sense of discomfort, so long as I am conscious that, despite the most assiduous attention and the best directed efforts, my patient is likely to be lame and deformed for life. A crooked limb, whether rendered so by injudicious treatment or not, is an unpleasant sight to a sensitive surgeon, inasmuch as it continually reminds him of his bad luck or want of success. I do not wish by these remarks to be understood to say that it is always in his power to cure these accidents without deformity or impairment of function. To utter such a sentiment would be contrary to experience and common sense. There are many cases of fracture which do not admit of any other result, no matter how attentively or skilfully they may be managed; and there are not a few which turn out badly, disgracefully badly, simply because of the want of proper co-operation of the patient. In such cases no surgeon is responsible.

A fracture may be defined to be a solution of continuity of the osseous tissue, or, in other words, a division of the bony fibres, occasioned either by external violence or muscular contraction. The lesion presents itself in various forms, of which the principal are the simple, compound, comminuted, impacted, and complicated. To these may be added the incomplete fracture, in which a bone, instead of being entirely broken, is divided only in a portion of its diameter.

A fracture is said to be simple when it is unaccompanied by any wound of the soft parts directly over the end of the fragments, thus exposing them to view, or, at all events, permitting them to be felt. The case is a simple one, as far as the bone is concerned, even if there is a wound in the immediate vicinity of the fracture, provided it has no direct communication with it. A compound fracture is one where the opening in the skin and muscles extends down to the bone, the ends of which often protrude through the wound, girted, perhaps, by its edges. When a bone is broken into a number of pieces, the term comminuted is applied to it. The word impacted is employed to signify that the extremity of one fragment is forced into that of the other. Finally, a fracture is complicated when it is associated with dislocation, wound, hemorrhage, laceration, or other mischief. It will greatly facilitate the discussion of the subject if we discard all these terms, excepting the first and last. Hence, after some general observations, we shall treat first of simple fractures, and afterwards of fractures complicated with other lesions.

All the bones of the body are liable to be broken, though not by any means with equal frequency. Those which are most prone to suffer in this manner are the long bones of the extremities, particularly those of the leg and forearm. The clavicle is also often fractured. The scapula, the two jaw-bones, the sternum, ribs, innominatum, vertebræ, sacrum, and coccyx, together with the bones of the hand and foot, are rarely broken, owing either to their protected situation, to their mobility, or to the manner in which they are united to each

other and to the surrounding parts. It may be stated also, as a general law, that the long bones are more liable to give way at or near their middle than at their extremities; a circumstance of some importance in a diagnostic and practical point of view.

The relative frequency of fractures of the bones of the superior and inferior extremities has not been satisfactorily determined. It doubtless varies in different institutions and in different localities, according to the nature of the occupations of those who are the subjects of them. The following table, composed of the statistics of four different hospitals, shows the preponderance to be very slightly in favor of the lower limbs:—

	Cases.	Upper extremity.	Lower extremity.
Pennsylvania Hospital	1473	572	901
Hôtel Dieu, Paris	1856	850	1006
Middlesex Hospital, London	1280	764	516
Native Hospital, Calcutta	1346	665	681
	<hr/> 5955	<hr/> 2851	<hr/> 3104

Respecting their *direction*, fractures may be oblique, transverse, or longitudinal. Of these varieties, the first is by far the most common, though it is impossible, from the want of statistics, to estimate its relative frequency. My experience is that transverse fractures are extremely rare. In the extensive osseous collection of Dr. Mütter, there is not a solitary specimen of the kind; and my own is equally barren. I am speaking now, of course, only of fractures of the long bones, and especially of fractures of their shafts; for in the short and flat bones such an occurrence is not without a certain degree of frequency. There is reason to believe that many of the so-called cases of transverse fractures of the shafts of the long bones are in reality oblique fractures, approaching more or less closely to the horizontal line, and yet not strictly falling within it. There are few practitioners, I imagine, who will not coincide with me in this view, and who, like myself, have not had frequent occasion, upon further and more thorough exploration, to correct their diagnosis in cases of this description. If the question were one solely of a speculative nature, it would be of little consequence; but when we consider its practical bearing, it is impossible to lay too much stress upon it. As it will, however, be again adverted to in speaking of the treatment of fractures, nothing further need be said respecting it here. The annexed cut, fig. 337, conveys a good idea of an oblique fracture.

Fig. 337.

Oblique fracture of the bones of the forearm.

Longitudinal fractures are so extremely rare that great doubt was at one time entertained respecting the possibility of their occurrence. That they do, however, occasionally take place, is sufficiently established by the cases that have been published from time to time in our medical journals, and by the specimens that are to be seen in different museums and private collections. They are nearly always produced by gunshot violence, and have hitherto been met with chiefly in the humerus, femur, and tibia. In a very few cases the fracture has passed nearly through the entire length of the shaft of a bone; but, in general, it is not more than a few inches in extent. Occasionally a fissure of this kind, after having passed a certain distance, runs off in an angular direction towards the surface of the bone, where it terminates, as in fig. 338. A longitudinal fracture is sometimes

seen at the inferior extremity of the humerus, and also, but more rarely, at the lower end of the femur, separating one of the condyles of these bones, or even both of these protuberances, as happens when there is at the same time a horizontal or oblique fracture a short distance above the corresponding joint. A longitudinal fracture is occasionally met with in the patella.

The extremities of the fragments of a broken bone exhibit much diversity in regard to their form and size; in general, one is much larger than the other, as well as more sharp, rough, and irregular, as in fig. 339. In the majority of cases, they have a ragged, serrated, or denticulated appearance, the projecting pieces of one end corresponding with the depressions in that of the other. This arrangement, which is produced by the irregular division of the osseous fibres, bears no little analogy to that which occurs in the edges of a lacerated wound. The truth is, to carry out the analogy still further, an oblique fracture is nothing but a lacerated wound of the osseous tissue, which presents the same difficulty in regard to its perfect coaptation and speedy reunion as a similar lesion in the skin and muscles. The irregularities upon the extremities of the fragments are often sadly in our way, offering a great obstacle to the successful reduction and subsequent maintenance of the parts. Sometimes, indeed, the projecting pieces are so long and sharp as to pierce the integuments, or to require to be sawed off before the bone can be properly set. Such an occurrence is not uncommon in fractures of the tibia, and it is also witnessed, though less frequently, in the femur, radius, and clavicle.

Fig. 339.

Longitudinal and oblique fracture.

Fig. 339.

Appearances of the ends of the fragments.

Sometimes the fracture is *impacted*, that is, the end of one fragment is forcibly driven into the other, so as to be, as it were, interlocked. Such an occurrence, of which fig. 340 affords an excellent illustration, can only arise, as a general rule, in those bones which contain an extraordinary amount of areolar substance.

As a bone may give way at any part of its extent, at its middle, or at either end, it follows that the two fragments are rarely of the same length; instead of this, there is often a most marked disparity, as is exemplified in fractures of the extremities of the long bones, as the femur, in which, especially in fractures of its neck within the capsular ligament, the superior fragment is sometimes hardly an inch and a half in length, while the other is perhaps upwards of a foot and a quarter. Fracture of the olecranon affords a similar illustration. Such an occurrence is not without its influence in regard to the treatment and final issue of the lesion; for the nearer, as a general rule, the length of the fragments corresponds, the easier, other things being equal, will it be to maintain their apposition, and secure prompt and perfect union.

A fracture may be single or multiple; that is, a bone may break at one or more places, sometimes as many as three, four, or even five; in other words, it

Fig. 340.

Impacted fracture of the neck of the femur.

may literally be crushed and comminuted. Such lesions are generally the result of inordinate violence, and are, therefore, very liable to be followed by serious consequences; often, indeed, by loss of limb and life.

In fractures of the leg and forearm, affecting both bones, it is extremely rare to find the injury situated on the same level; on the contrary, there is generally a considerable distance between the two fractures, amounting, according to my observation of numerous cases, ordinarily to from one to two, three, and even four inches. The interval is usually considerably greater in the leg than in the forearm, probably because of the greater inequality in the size of its two bones. What the cause of this occurrence is it is not easy to determine; but it may be supposed that it is due mainly, if not entirely, to the manner in which these pieces are respectively articulated to the wrist and ankle-joints, in consequence of which the violence occasioning the lesion is transmitted more forcibly along one bone than the other, thereby compelling the former to yield before the latter. Thus, as the tibia is more intimately connected with the foot than the fibula, it follows, if this explanation be correct, that it ought to break lower down than the fibula, and this, I believe, is what usually happens, although there are many exceptions.

Fractures occur at all *periods of life*. During delivery, the bones of the arm and leg are occasionally broken in rude attempts at extraction. In 1856, an infant, four weeks old, was brought to me on account of a fracture of the shaft of the right femur, caused two days previously by a child rolling over it in bed. The thigh was much swollen, and at least an inch and a half shorter than the sound one; all the extension and counter-extension that I could make with my hands failed to restore it to its normal length. Fractures occasionally occur in the fœtus in the womb. Chaussier met with a remarkable example of this description, in which each of the long bones had suffered more or less from these lesions, some of which were recent, others beginning to unite, while others were consolidated. The child survived its birth only twenty-four hours. Cases of a somewhat similar character have been reported by other observers. In childhood, the bones being remarkably flexible, on account of the large amount of animal substance which they contain, are particularly prone to give way at their epiphyses; in old age, on the contrary, they are very light and brittle, from the rarefaction and fatty degeneration of their substance, and are, therefore, extremely liable to break from the slightest causes. Thus, a fracture of the neck of the femur within the capsular ligament is often produced by a mere twist of the thigh in bed, by catching the big toe in a fold of the carpet, or by stepping off the curbstone.

Causes.—The causes of fractures are generally divided into predisposing and exciting; the first having reference to the part and system, or to local and constitutional circumstances, the second to external violence and muscular action.

The conformation, situation, and office of certain bones are so many *predisposing causes* of fracture. Thus, as was before stated, the long bones, which are the great levers of locomotion, and which, in consequence, are constantly under the influence of large and numerous muscles, are much more subject to this accident than the short or flat bones, which are more passive in their character, as well as more closely articulated together, so that any force that may be communicated to them is more easily broken. The body of the scapula is seldom broken, because it is not only thickly covered by muscles, but, having no fixed point below, it is incapable of being injured by any shock transmitted by the hand, elbow, or shoulder. The acromion process, however, owing to its exposed situation, is not unfrequently fractured; while the coracoid process, protected by the deltoid, clavicle, and head of the humerus, rarely suffers from this cause. The radius, being articulated with the hand, is more liable to break than the ulna; the fibula, owing to its slender form and brittle texture, is oftener broken than the thick and heavy tibia; and every surgeon knows how very prone the collar-bone is to fracture, its exposed situation, the peculiarity of its conformation, and its connection with the sternum and scapula rendering it particularly obnoxious to this occurrence.

Of the influence of age, in promoting the occurrence of fracture, mention was

made in a previous paragraph, and it need not, therefore, detain us here. It may be stated, however, that, as we advance in life, there is superadded to the preternatural brittleness of the osseous tissue, another cause of fracture, namely, abnormal rigidity of the muscles, thus rendering us more liable to falls, and consequently, more prone to the accident in question.

Various *diseases* or states of the general system have usually been regarded as predisposing causes of fracture. Of these, the most common are syphilis, cancer, scurvy, and rickets.

That a *syphilitic* state of the system, involving the skeleton, may so affect some of the bones as to render them abnormally fragile is sufficiently established by modern observation. In 1847, I attended a man, aged thirty-one years, for a fracture of the body of the right humerus, caused, a short time previously, by throwing a small chip at a person. He was perfectly well at the time, with the exception of some nocturnal pains in the arm and forearm. He had had primary syphilis seven years previously, and had been treated with mercury. The bone united in five weeks.

It is well known that *cancer*, fig. 341, may so alter the osseous tissue as to render it preternaturally brittle, and thus predispose it to fracture. Such an occurrence, indeed, is probably not so uncommon as is generally supposed. I have myself, however, seen only one instance of it. The patient was a female, seventy-three years old, from whom I had removed, with the assistance of a former colleague, Professor Miller, nine months previously, the left mammary gland, on account of scirrhus, under which she had labored for nearly three years. The wound healed kindly, but, some time after, the disease reappeared at the cicatrice, and gradually carried her off, not, however, before she had become extremely emaciated and bedridden. During the last month of her life, she complained of almost constant pain in the right thigh, deep-seated, and particularly severe at night; and three days before she expired, in an attempt to turn in bed, the femur gave way just above its middle. The limb was free from swelling and discoloration. No cancerous matter could be detected in the affected bone, which was quite soft, humid, and brittle, for some distance above and below the seat of fracture.

Fig. 341.

Encephaloid of the thigh, followed by fracture.

Of the influence which *scurvy* exerts upon the osseous tissue, in predisposing it to fracture, the modern practitioner has little opportunity of judging, as the disease at the present day seldom appears in that violent form which characterized it in former times. As described by the older writers, it was often attended with the most horrible ravages, in which the skeleton not unfrequently participated, the synovial membranes, cartilages, and ligaments being ulcerated, and the epiphyses separated from the bones. In 1855-6, scurvy prevailed extensively in certain regions of the United States, especially in the Southwest, but I am not aware that it predisposed any of its subjects to the occurrence of fracture, or that it retarded the process of reunion in those who suffered from it at the time.

There are certain states of the skeleton, including *rickets*, in which the bones become so remarkably brittle as to break under the most trivial injury. Cases are recorded where, from these and other causes, nearly every one of the long bones was broken not only once, but a number of times. What is remarkable in these cases is that they usually recover quite as soon as ordinary fractures. I have in my collection a part of the skeleton of an old woman, who, in falling from a second-story window down upon the pavement below, received not less

than fifty-three fractures, involving the vertebræ, the scapula, the bones of the pelvis, and most of the bones of the extremities.

Gout and *rheumatism* are sometimes enumerated as predisposing causes of fracture. The following case, which I saw with Dr. Metcalf, would seem to countenance the possibility of such an occurrence.

Henry Welker, a common laborer, aged thirty-two, had always enjoyed good health until two years and a half ago, when he was attacked with articular rheumatism, affecting the principal joints, first of the superior, and then the inferior extremities, where it had continued for the last twelve months. The only cause which he could assign for his suffering was exposure to cold and fatigue in a pork-house, where he had worked for fourteen successive winters. In December, 1855, he broke his thigh-bone, at the junction of the lower with the middle third, while pulling off his boot with his hands, the foot being at the time bent at a right angle with the leg. No pain or swelling followed the accident. The most remarkable feature in the case, when Dr. Metcalf first saw it, was the imperfect aeration of the blood, as indicated by the livid state of the face; the bowels were torpid, the tongue was coated, and there was considerable emaciation, but no disease of the heart and lungs. No chalky deposit existed in the joints. At the end of a month and a half, the parts being united, the dressings were removed, and the man was permitted to walk about on crutches. A week after this, he struck the affected thigh slightly against the rail of the bed, fracturing the bone at its upper third. Union took place in about the same time as before, the quantity of callus in each instance being uncommonly large.

The *exciting causes* of fracture are two, external violence and muscular contraction. The former, which is by far the more common, may act upon a bone either directly, or indirectly through some other bone. In the first case, the force is applied to the bone itself, as in fracture of the jaw from the kick of a horse, or in fracture of the leg from the passage of the wheel of a carriage. Most fractures are of this description, and they are therefore generally complicated with more or less injury of the soft structures. In the other case, the force, instead of being applied immediately to the bone, is transmitted to it through another bone, or perhaps a chain of bones. It is in this way that the radius is so frequently broken just above the wrist by falls upon the hand, the force being concentrated upon its inferior extremity, in consequence of the manner in which it is articulated with the carpus, while the ulna, which is but slightly connected with it, generally escapes. Fracture of the clavicle affords an instance of a bone being broken by indirect mechanical violence operating at two opposite points. Thus, in falls upon the shoulder, the sternal end being impelled by the weight of the body, and the acromial end by the object which it strikes against, the bone, acted upon by the two forces, gives way at its weakest part, which is usually about its middle. When a bone is very brittle, the slightest external violence may be sufficient to break it. In old people the neck of the femur is frequently fractured by the merest twist of the limb in bed, or by stepping carelessly out of bed upon the floor.

It is not often that a bone is broken by muscular action, and yet such an accident is not, perhaps, as uncommon as is generally imagined. I have myself met with several instances of it. In three, the subjects were remarkable for their health and muscular development, and the fracture in each was produced while they were engaged in feats of strength, in which the elbows were planted firmly upon a counter, and the hands interlocked with each other. While the muscles of the arm and forearm were in a state of the utmost tension, the humerus snapped off suddenly, with a loud noise; in two cases at its middle, and in the other at its inferior extremity. In another case, the fracture, also seated in the humerus, was caused by throwing a small chip. In this instance, alluded to in a previous paragraph, the bone had suffered for a considerable time under nocturnal pains, and had, no doubt, been rendered brittle by the effects of the syphilitic virus. The patient, aged thirty-one, was otherwise in good health, but the muscles of his arm were rather soft and flabby.

Mere muscular contraction is sometimes sufficient to break the femur. A

case of this kind occurred some years ago, in an eminent physician of Buffalo, while he was engaged in throwing a tenpin ball. A similar accident, precisely, happened in this city, in 1858, in a gentleman, aged fifty-two, apparently in the most perfect health at the time. The bone gave way a short distance below the great trochanter, at a moment when the limb was strongly rotated upon its axis. The patella and olecranon are frequently fractured by the action of the extensor muscles of the thigh and arm.

From the above cases it is evident that a diseased state of the bone is not at all necessary to the production of this accident by muscular contraction, although such a change is perhaps generally present at the time of the fracture, and therefore deserves to be considered as a predisposing cause of it.

When the osseous tissue is preternaturally brittle, mere muscular spasm is capable of producing fracture, as in the interesting case related by Dr. Lente of a boy, twelve years of age, who broke both his thigh-bones during a severe epileptic convulsion.

2. SIMPLE FRACTURES.

The symptoms of fracture may be considered, first, in relation to the broken bone itself; secondly, in relation to the soft parts; and thirdly, in relation to the constitution.

So far as the affected bone is concerned, there are only three symptoms which are at all reliable as evidences of the existence of fracture. These are crepitation, deformity, and preternatural mobility.

Crepitation is the peculiar noise which is produced by rubbing the two ends of the broken bone against each other, and is always, when well marked, characteristic of the nature of the injury. In general, it can be both heard and felt. In order to produce it, it is necessary that the ends of the fragments should be at least partially in contact, and hence, to effect this object, the surgeon is often obliged, as a preliminary step, to extend and counter-extend the affected limb. For this reason it is always absent in impacted fractures, while in fractures of the leg and forearm, involving only one of the bones, it is usually very faint and indistinct from the difficulty of moving the broken pieces upon each other. Much swelling or great depth of muscle will also obscure the crepitation.

Deformity, although not invariably present, is, in general, one of the most prominent symptoms of fracture. It exhibits itself in different forms, as in shortening, or in angular displacement, and usually occurs at the time of the accident, the cause which produces the fracture being also the cause of the distortion. Occasionally, however, it does not come on until several hours, or perhaps even several days after; as, for example, in a partially impacted fracture of the neck of the thigh-bone, in which the patient may be able to walk some distance, and yet the limb retain its normal shape. The degree and character of the deformity are greatly influenced by the nature and situation of the fracture. Thus, the more oblique the fracture is, the greater, as a general rule, will be the displacement of the ends of the fragments, and, consequently, also, the distortion of the limb. Sometimes, as in fracture of the patella, the olecranon and calcaneum, the deformity manifests itself by a vacuity or hollow at the natural situation of the bone, and by an unusual protuberance upon the lower part of the thigh, arm, and leg, caused by the separation of the upper fragment by the action of the extensor muscles. Finally, the deformity may be much increased by extravasation of blood, or by the effusion of serum and lymph consequent upon the resulting inflammation.

Preternatural *mobility* is, next to crepitation, the most important and reliable symptom of fracture. There are few instances in which it is wholly absent, while in the great majority it exists in a well-marked, if not in a high, degree. It usually appears immediately after the occurrence of the accident, and continues to a greater or less extent until the completion of the consolidation of the fracture. In the impacted fracture it may be entirely wanting, or remain absent until the ends of the fragments are unlocked. In fracture of the leg and forearm, involving

only one bone, the degree of mobility is sometimes very slight, the sound bone impeding, or altogether preventing, the motion of the affected one.

In every fracture produced by external violence, whether applied directly or indirectly to the part, there must, of necessity, be a certain degree of *contusion* of the soft structures at the seat of the injury. It may be limited to the skin and subjacent cellular tissue, or it may extend deeper, and involve the muscles, aponeuroses, vessels, nerves, periosteum, and even the bone itself. In consequence of this occurrence, there is not unfrequently a considerable effusion of blood beneath the skin, and in the connective tissue of the muscles, causing distension and sometimes discoloration. For the same reason, there is generally a good deal of pain, often of a sharp, spasmodic character, which is aggravated by the slightest motion of the parts, and by every attempt at exploration. It has its seat rather in the soft structures than in the affected bone, although the latter generally participates in it, and by the sharpness of its extremities frequently increases its severity. A short time after the accident, swelling usually sets in, and often proceeds to a considerable height, its degree being greatly influenced by the amount of injury sustained by the soft parts, by the motion to which the fractured bone is subjected, and by the state of the system at the time of the accident. As a general rule, it may be affirmed that the pain and swelling are less in fractures produced by muscular contraction than in such as are caused by mechanical violence, whether directly or indirectly applied.

Inability of motion in the affected bone, and in the portion of the limb articulated with it, is generally a prominent symptom. Cases, however, occur in which it is either very slight or entirely absent. In an impacted fracture of the thigh, for instance, a patient will sometimes walk a considerable distance without the slightest assistance even from a cane, and in fracture of the clavicle I have repeatedly seen him carry his hand to his head, and even circumduct the arm.

Another symptom, consequent upon fracture, is *spasm* of the muscles at the seat of the injury; it is most common in nervous, irritable persons, and generally comes on within a short time after the accident. When severe, as it frequently is, it constitutes a source of real suffering. It is aggravated by motion and inflammation, and may continue, with more or less interruption, for several hours, if not days.

Finally, the patient often experiences a sense of *numbness* in the affected part, reaching frequently to the distal extremity of the limb. This may be caused either by the injury sustained by a nervous trunk at the time of the accident, or by the compression of the soft parts by extravasated blood or by the ends of the broken bone. Sometimes it does not arise until inflammation has supervened, and then it is generally owing to the presence of an unusual quantity of serum and lymph.

The amount of *constitutional disturbance* in fracture varies, in different cases, from the slightest exaltation of the normal action to the most intense excitement, depending mainly upon the nature of the fracture, the degree of injury sustained by the soft parts, and the state of the system at the time of the accident. In very many cases, there is an entire absence of traumatic fever, while in others it is present in a very high degree, the pulse being strong and frequent, the countenance flushed, the skin hot and dry, the thirst intense, and the appetite and sleep much impaired, if not totally suspended. In the more violent forms of fracture, the patient often experiences severe shock, from which he may not fully recover for many days, or which may even terminate in death. Whenever there is much constitutional disturbance, the affected limb will be apt to be in a high state of inflammation, the parts being hot, swollen, and painful, and, at times, even covered with small vesicles, such as a heedless observer might easily mistake for the phlyctenulæ which so often announce the occurrence of gangrene.

Displacement of the Ends of the Fragments — The displacement of the fragments shows itself, as already stated, in two principal directions, the longitudinal and horizontal. Of these, the former is by far the more common, as it is present, to a greater or less extent, in nearly all cases of oblique fracture in whatever portion of a bone occurring. It is produced by the overlapping of the extremi-

ties of the broken bone, the lower being drawn above the upper, or the one riding over the other, as it is sometimes expressed. The extent of this form of displacement varies from the slightest possible change in the length of the affected bone to two, three, and even four inches, which may be regarded as its maximum. It is generally most conspicuous in fracture of the femur and humerus, while in fracture of the forearm and leg, affecting only one bone, it is either very slight or totally wanting. Finally, the displacement may be lateral, anterior, or posterior, according to the nature of the exciting cause.

In the horizontal displacement, the lower fragment may form an angle, more or less acute, with the superior, thereby giving the bone an arched appearance; or, the two pieces remaining in contact with each other, the inferior one may perform a rotary movement, while the other continues perfectly stationary. In some cases, as in fracture of the lower end of the radius, there is often considerable lateral displacement, and similar phenomena are apt to occur in fracture of the tibia and fibula at or near the ankle-joint.

The causes of displacement are muscular action, mechanical violence, and the weight of the limb connected with the broken bone. Of these the first is the most common, and it need hardly be added that a knowledge of the fact is of the greatest practical importance in regard to the proper management of the injury. In some instances the displacement is entirely produced by the vulnerating body. Thus in fracture of the nose, the blow which inflicts the injury also displaces the fragments. The wheel of a carriage passing over the leg may not only break its two bones, but likewise cause great deformity by forcing asunder their extremities. Finally, the displacement may be occasioned by the weight of the limb connected with the injured bone, as in fracture of the clavicle, in which the outer fragment is drawn downwards and inwards by the weight of the shoulder and arm.

Diagnosis.—The most valuable symptoms of fracture, diagnostically considered, are, crepitation, deformity, and preternatural mobility. The coexistence of these symptoms is unmistakably denotive of the nature of the accident, but, unfortunately, they are not always associated; one or even two may be absent, and therefore a case that ought to be treated in the most prompt and decisive manner, may for the want of a correct appreciation of its character, be either entirely neglected, or, at all events, grossly mismanaged. Besides, the symptoms here enumerated may be simulated by other accidents, especially dislocation, and certain affections of the joints.

The crepitation of fracture is sometimes imitated by the grating produced by an effusion of plastic matter into a joint, the sheath of a tendon, or a synovial bursæ; and the difficulty may be still further increased, if, under such circumstances, the suspected fracture is situated near a large articulation. In general, however, it will be sufficiently easy to distinguish between them by a consideration of their respective characters. In fracture, the crepitation can be both felt and heard; it is dry, coarse, or rough, resembling the sensation and noise produced by rubbing two unequal surfaces against each other. The crepitation from plastic matter, on the contrary, is of a finer quality, or more faintly marked, and may be likened to the feel and noise caused by gently rubbing over each other two pieces of sole leather; in a word, it lacks the roughness and distinctness of the other. Moreover, it must be remembered that it is never present until after the occurrence of inflammation, whereas the other always exists from the very beginning of the accident. Crepitation, it is true, might be produced as a consequence of previous disease, and the possibility of such an occurrence should not be lost sight of in our examinations. Finally, when the case is obscure, the crepitation may sometimes be detected by the aid of the stethoscope, especially when the bone is thickly covered by muscles, as in fracture of the neck of the femur within the capsular ligament, or in fracture of the ribs in corpulent subjects. This mode of examination was originally suggested by Lisfranc, but as the expectations held out by him have not been realized, few practitioners of the present day resort to it.

The deformity in fracture manifests itself either in shortening, in lateral dis-

placement, or, as not unfrequently happens, in the two united. Elongation is never present, in which respect fracture differs from certain forms of dislocation, in which lengthening is a prominent symptom. The degree of shortening varies from a few lines to several inches, and is, therefore, an event of much diagnostic value. It may exist from the commencement of the accident, or it may not show itself until some time after its occurrence, being materially influenced by the action of the muscles, and the nature of the treatment. Whatever the degree of the deformity may be from these causes, it may always be effectually removed by extension and counter-extension, either alone or aided by pressure; but as soon as these forces cease to operate, it is usually immediately reproduced, which is not the case in dislocation. Here, the reduction having been effected, the parts generally retain their relations until some new cause produces a new displacement.

Too much stress cannot be placed upon preternatural mobility as a sign of fracture. Next to crepitation, it is unquestionably the most important diagnostic symptom. There may be unnatural latitude of motion in a dislocation, but this can happen only when the accident is attended with extensive laceration of the ligaments of the joint; in ordinary cases there is either an absence of motion, the displaced bone being firmly fixed in its new position, or the motion is so slight as to bear only a faint resemblance to that observable in fracture.

The general expression of the affected parts, fig. 342, often affords valuable diagnostic signs. The deformity, for example, of the hand and wrist, in fracture of the lower extremity of the radius; the eversion of the toes in intra-capsular fracture of the femur, and the shortened and retracted appearance of the arm in fracture of the humerus, are generally unmistakable evidences of the nature of the accident. The manner in which the patient inclines his head and supports the

Fig. 342.

Fracture of the lower end of the radius.

elbow and forearm in fracture of the clavicle, is too significant to be overlooked by any one that has ever witnessed it. The peculiar aspect and attitude of a broken thigh, conjoined with the utter helplessness of its muscles, or the absence of all voluntary power, are signs which seldom admit of misinterpretation.

In fracture without displacement there is sometimes a persistent soreness or tenderness on pressure with the finger at the site of the injury, which, with proper care in the examination, may lead to useful diagnostic information. I have seen this repeatedly in fracture of the clavicle in children, and also in fracture of the bones of the forearm in fat, elderly subjects, and therefore look upon it as a most valuable symptom in all cases where the ordinary means of recognition fail.

The pain, swelling, and loss of function, present in suspected fracture, are of no practical value, as similar phenomena are produced by other injuries, as contusions, wounds, sprains, and dislocations. Their occurrence being wholly accidental, must, therefore, not influence the surgeon in his attempt to form a correct estimate of the real nature of the case, or the relative value of the symptoms of this and other analogous affections.

Mode and Time of Examination.—Although the symptoms which have now been described will generally be sufficient, along with a careful consideration of the history of the case, to enable the surgeon to determine the diagnosis of this lesion, especially if he will take the trouble of comparing them with the symptoms of other accidents, it will, nevertheless, be proper, in concluding these remarks, to say a few words respecting the manner of conducting the examination of the affected parts, as the ultimate issue of the case will greatly hinge upon this circumstance.

Experience satisfies me that few practitioners know how to examine a broken limb. They take hold of it as if they were afraid of causing suffering, and the

result, therefore, is often most disastrous. I am far from wishing to be understood as being an advocate of rough surgery; on the contrary, no one abhors it more than I do, and yet there are times and circumstances when the best interests of the patient demand that he should be most thoroughly examined, no matter what amount of pain he may be compelled to undergo. But there is no longer any need of such infliction now that we can prevent suffering by anæsthesia. The patient being rendered insensible, perquisition is performed at the surgeon's leisure, slowly and deliberately, and with an eye to the ultimate result, not forgetting self. The sooner such manipulation is instituted the better, for there will then be less likelihood of inflammatory swelling and other obstacles calculated to embarrass our progress or to obscure the diagnosis. Fractures of the shafts of the bones will rarely offer any difficulty, inasmuch as their symptoms are generally so well marked that the most casual inspection will be sufficient for their detection. But it is different when the lesion involves their extremities. Here the most laborious and painstaking examination sometimes hardly enables the practitioner to form an accurate judgment respecting the real nature of the injury. Under such circumstances, therefore, he must not content himself with one or two trifling explorations; he must handle the parts again and again, until he has thoroughly established the diagnosis.

For the reason already assigned, the parts should always be examined as early as possible after the infliction of the injury, but I would make no exception where some time has elapsed, and a good deal of swelling has supervened; for it is impossible that a broken bone, or the parts by which it is covered, should do well as long as its extremities are displaced, and thus permitted to fret, irritate, and perhaps prick the muscles and other structures in contact with it. The sooner, indeed, the parts are placed in their natural relations, the more likely will they be to do well, and to escape the ill effects of inflammation. There are instances, however, where, as may be supposed, immediate interference might prove highly prejudicial, using the term immediate here with reference to the surgeon's first visit. The patient may have been neglected, or his attendant may have mistaken the nature of the case, and in this manner several days may have passed uselessly away. The limb is now found to be in a very swollen and painful condition, intolerant of the slightest manipulation, nay, perhaps in an erysipelatous condition. To make an elaborate examination under such circumstances would be highly improper; for it could not fail to aggravate the morbid action, and perhaps urge on gangrene. The hand is withheld; the limb is placed in an easy position, and antiphlogistics, both local and constitutional, are freely plied; when action has sufficiently abated, but not until then, the proper examination is effected, and the diagnosis, if possible, established.

The mode of conducting the examination varies. In the upper extremity the surgeon will usually be able to get on without any assistance, but in fracture of the thigh and leg it is often necessary to make extension and counter-extension while the parts are subjected to methodical manipulation. When there is marked displacement, the merest touch of the hand will generally suffice to detect the nature of the lesion; but, under opposite circumstances, the nicest digital exploration may be required before a satisfactory result can be obtained. In general, it will be necessary to make pressure and counter-pressure at the seat of the injury, and to rotate the portion of the limb below the fracture upon its axis. In this manner, especially if proper extension has been made, the ends of the fragments, brought into close contact, may be made to yield the friction-sound, previously described, and at the same time display the full extent of their mobility. Another procedure is to grasp the two extremities of the suspected bone, and then, while the superior one is firmly held with the thumb and fingers, to roll the inferior upon its axis. If, while this is being done, both parts move together, the probability is that there is no fracture, but if the lower should move, and the upper remain stationary, there can be no doubt of the fact.

Mode of Repair.—The mode of repair in fracture is precisely similar to that of the soft parts, the only difference being the superaddition of the carbonate and phosphate of lime, or the earthy constituents of bone. In order, however, to be

thoroughly understood, it is necessary to study it with reference to the situation and disposition of the ends of the fragments of the broken bone, as the rapidity and perfection of the cure are greatly influenced by the manner in which they are arranged and held together during the treatment. The more perfect this is, the more complete, generally, all other things being equal, will be the reunion. For practical purposes, the whole subject of repair may be considered as consisting of four stages.

The first stage, which, on an average, extends from the first to the eighth day, is one altogether of preparation, in which nature clears away the rubbish, and places the ends of the fragments in a suitable condition for the process of repair, properly so called. The blood which was extravasated at the moment of the accident, at and around the seat of the fracture, is in great degree, if not entirely, absorbed; the inflammatory products, especially the intermuscular, are also disposed of; the swelling subsides, the pain disappears, and there is no longer any tendency to spasmodic action, the muscles having become calm and quiet under their new relations. Any traumatic fever that may have been present will also be found to have vanished. Thus the part and system have happily passed through the preliminary stage of the reparative process.

If the parts be examined at the commencement of the second stage, it will be seen that the ends of the broken bone, as well as the periosteum, and the other soft parts in their immediate vicinity, are abnormally red and injected, and covered by plastic matter, resembling very much in its color and consistence pale currant jelly, or a thick solution of isinglass. It is usually most abundant upon the surface of the bone, and is often sufficient to lift up the periosteum; a considerable quantity is also generally seen between the periosteum and the muscles, and even among the muscles themselves, all these structures being more or less actively engaged in the process of repair. A similar substance, but usually less abundant, is poured out within the medullary canal, the lining membrane of which is also in a state of inflammation, as is evinced by its discolored and injected condition. In the latter part of this stage, which lasts from the eighth to the twentieth day, the newly-effused matter, which differs in none of its properties from that which serves to unite a recent wound, becomes gradually more and more solid, until at length it assumes the consistence of a concrete substance.

The third stage is characterized by still further changes in the consistence of the effused matter, and by its gradual conversion, first into fibro-cartilage, then into cartilage, and finally into bone; or, more correctly speaking, cells are developed in the new substance, into which the osseous granules are deposited, the whole process bearing the closest possible resemblance to that which takes place in the formation of the original bone. The period at which the bony matter begins to be developed in the adult varies from the eighteenth to the twenty-fifth day, its appearance and progress being influenced by numerous local and constitutional causes, to be described under another head.

The ossific process proceeding in the way now described, two layers of bony matter are formed, one lying upon the outer surface of the fragments, the other within the medullary canal, each extending some distance beyond the seat of fracture, as is seen in fig. 343. To these two strata is confided the office of

Fig. 343.

Fractured tibia, with new bone beneath the periosteum, and within the medullary canal.

temporarily supporting the fragments, or of holding them together until their ends are permanently united by osseous substance; a circumstance which does not take place, as a general rule, until several months later. To this new matter the older pathologists applied the term *callus*, in consideration of its hardness, which, when the process of repair is completed, is fully equal to that of the

original bone, which it also closely resembles in its structure. From its office, the outer and inner callus, or that which invests the broken bone and lies in its medullary canal, is now universally known as the temporary or provisional callus, while that which is placed between the two ends of the bone, and thus serves to cement them together, is designated as the definitive or permanent callus. The temporary callus is, figuratively speaking, nature's splint, or the means which she employs to support the fractured bone until the continuity of the fragments is re-established by the deposit and organization of osseous matter between their extremities.

As the first stage in the reparative process is one of preparation, so the last is one of completion; reunion having been effected, nature now busies herself in removing whatever is redundant or superfluous, thereby fitting both bone and muscle for the resumption of their respective functions. The provisional callus, having ceased to perform its office as a splint, is gradually brought under the influence of the absorbents, its more superficial portions being taken away first, and afterwards the more deep, until the broken bone regains not only its original form and volume, but also its pristine smoothness, all evidence of fracture disappearing, excepting, perhaps, a little seam or ridge corresponding with the line of junction of the two fragments. While these changes are going forward upon the exterior of the bone, nature is busy at work in its interior, disposing of the provisional callus in that situation, and thus restoring the medullary cavity to its normal condition. This can occur, however, only when there has been perfect apposition of the ends of the fragments; for when the reverse is the case, the new bone remains permanently in the canal, as is shown in fig. 344, from a specimen in my collection.

Fig. 344.

United fracture, showing the condition of the medullary canal.

Any cartilaginous or osseous matter that may have been formed between the periosteum and muscles, or among the muscles themselves, is likewise removed as a substance foreign to the part, and, therefore, useless, if not positively prejudicial.

It will thus be seen that the fate of the provisional callus is precisely similar to that of the plasma which is effused between the edges of a wound, both gradually disappearing as soon as their service can be dispensed with, or as soon as the parts have acquired sufficient firmness to enable them to maintain their connection. The period required for effecting these changes in a broken bone varies from a few weeks to several months, according to the circumstances of the case.

Such is a brief account of the several changes which attend the repair of bone in the more simple forms of fracture, when the ends of the fragments are thoroughly maintained in their natural relations. Under such circumstances there is but little need of provisional callus; the ends of the fragments soon inflame, and unite almost by the first intention. But it is seldom that a patient is so fortunate; on the contrary, the fracture being generally oblique, is subject to more or less displacement, thus compelling nature to provide a temporary splint by the formation of provisional callus. I do not believe, however, as has recently been so much insisted upon, that there ever is an entire absence of this kind of callus, however intimately the ends of the bones may be in apposition with each other. To prove the truth of this remark, it is only necessary to examine the numerous specimens of fracture of the skull and other portions of the skeleton in our museums; they will conclusively demonstrate that even the most simple fracture, unaccompanied by the slightest displacement, is never repaired without the development of a

certain quantity of osseous matter upon its surface. At the same time it must be admitted that the provisional callus, in such cases, is very small, and that it bears no proportion to the enormous amount of substance that is so often formed when the ends of the bone are separated from each other. Under the latter circumstances, nature labors under great disadvantage, and is, therefore, obliged to make extraordinary efforts to effect reunion, which she can do only by the development of a large provisional callus. From these facts, then, we may deduce the general law that the quantity of new bone is always, other things being equal, in proportion to the contact of the ends of the fragments, being small when this is very accurate, and more or less large when it is imperfect.

When the ends of the bone are not closely approximated, the first thing that nature does is to round off their edges, and to close the medullary cavity by a shell of new matter, as in fig 345; the next, is the formation of a large provisional callus for the more secure consolidation of the fracture. The whole process is

Fig. 345.

Appearances of the ends of the fragments in an old ununited fracture.

one of time and labor, not of speed and ease, as in the former case. When the ends are completely separated but opposite, or nearly opposite, to each other, they are generally united by a bridge of new bone, extending from one to the other, and ultimately affording sufficient strength for the support of the weight of the body upon the affected limb, as in fig 346, from a specimen in my cabinet. Or, instead of this, especially in elderly subjects, the junction is effected by fibrous, fibro-ligamentous, or cartilaginous matter. Finally, osseous union is not impossible when the extremities of the fragments overlap each other to an extent even of several inches, provided they are in contact; for in this case inflammation is established in the contiguous surfaces, followed, after a long time, by a large permanent callus. We see many curious specimens illustrative of this fact, though, in general, the union is ligamentous.

There are certain pieces of the skeleton in which in fracture no provisional callus ever forms. Such are the olecranon, acromion, patella, and neck of the femur. Instead of uniting by osseous matter, as the other bones do, the cure is generally effected through the medium of fibrous, ligamentous, or cartilaginous substance, and the consequence is that the part commonly remains weak ever afterwards. Various causes conspire to produce this result, as the difficulty of maintaining the contact of the broken surfaces, and the inordinate secretion of synovial fluid, which, mingling with the effused plasma, thus impairs its vitality, and renders it unfit to become the nidus of bony deposit; but the most efficient one of all is the want of nourishment of the smaller fragment produced by the laceration of its nutrient vessels. Thus, in intra-capsular fracture of the femur, the only connection between the upper fragment and the pelvis is by the round ligament, the arteries of which are altogether unequal to its proper support.

Treatment—The leading indications in the treatment of fracture are to procure reunion and to prevent deformity. Before the manner of fulfilling these indications is discussed, it is proper to lay down certain rules for the transportation of the patient, and the mode of preparing his bed.

Fig. 346.

Fracture of the arm-bone of a chicken.

Fractures are often received by persons at a considerable distance from their homes, either on the road, in the field, or at some secluded building. This renders it necessary to carry them to their own houses or to some hospital, in order that they may undergo the proper treatment. In fractures of the superior extremity, clavicle, scapula, or ribs, the requisite dressings may be applied at once; or, if this is not convenient, the patient may either walk or ride, the suffering limb being supported in a sling, or, in the case of a broken rib, the body may be swathed with a long napkin. It is only, as a general rule, in fractures of the inferior extremity, spine, or pelvis, that the patient will require to be carried, and the best way of effecting this, if the distance is not too great, is to place him upon a narrow door, a long shutter, or two pieces of board, supported by two cross-pieces, the ends of which are intrusted to four assistants, a pillow and comfort having previously been put under the patient's head and body. Or, instead of this, the transportation may be conducted by means of an easy furniture-car, provided with a good mattress, and drawn slowly along in order to avoid jolting. Whatever mode be adopted, the limb should be temporarily splinted, and placed in as comfortable a position as possible, an intelligent person sitting by the patient's side, and rendering such aid as may be required on the way. In carrying him to his chamber, four assistants will generally be necessary, two to support the body, which they do by crossing their arms behind the trunk and interlocking their hands, and two for the lower extremities, the surgeon himself taking charge of the broken one.

A comfortable *bed* is to a man with a broken thigh or leg an indispensable article, and the practitioner who fails to give the proper instructions respecting it, is guilty of a gross dereliction of duty. Indeed, for his own sake hardly less than for that of his patient, he should give prompt attention to this subject, inasmuch as it is impossible to effect a good cure without it. When we reflect upon the fact that in fractures of the lower limbs, the patient is often compelled to remain in the recumbent posture for weeks together, and how difficult it is, in most cases, to maintain the requisite extension and counter-extension, the force of this injunction cannot fail to be perceived in its true light. The essentials of a good fracture-bed are, first, firm and stout slats, instead of a cord or sacking bottom; secondly, a well constructed mattress of hair, moss, or cotton; and thirdly, a hole in the mattress, opposite the buttock, for the evacuation of the bowels, the opening being closed by a door of similar manufacture, and furnished with hinges and other appliances. If long confinement in one posture is necessary, or if the patient has been worn out by previous disease, an air-mattress may be required, in order to prevent bed-sores. If a sheet is used, its edges should be carefully secured to the sides of the mattress, otherwise it will soon be rumpled, and so become a source of annoyance.

It has been a much mooted question whether a fracture should, as a general principle, be set as soon as possible after its occurrence, or whether time should be allowed for the subsidence of the resulting inflammation. It appears singular that upon a subject so clear as this there should be any difference of opinion. It certainly requires no great knowledge of the nature of accidents to discover why such cases should receive the earliest possible attention; as long as the ends of the fragments are permitted to remain apart, their tendency inevitably must be to excite spasm and inflammation, thereby increasing the suffering of the patient and retarding his cure. Of this fact there can be no doubt, and therefore my plan is to treat every case of the kind as early as possible with the bandage and splint; applied, of course, not firmly, but gently and cautiously, simply with a view of giving support to the parts, and thus preventing further mischief from the sharp and projecting ends of the broken bone. I can hardly imagine an instance to which such treatment would not be adapted. We might as well expect that a man's limb would do well if it had a thorn imbedded in its muscles, as that it would be comfortable with two pieces of bone sticking in them. It is an absurdity to think it could be otherwise.

Apparatus.—Before an attempt be made to set the fracture, it is necessary to

provide the requisite apparatus for effecting its maintenance. The means which are employed for this purpose are splints, cushions, bandages, and adhesive strips.

Splints are made of various materials, as wood, trunk-board, leather, felt, gutta percha, tin, and iron, according to the nature of the fracture or the fancy, whim, or caprice of the practitioner. In fracture of the thigh and leg, especially in that form which requires permanent extension and counter-extension, the best article is *wood*, adapted to the size and shape of the limb, at the same time that it combines lightness with strength. In fracture of the superior extremity, particularly of the humerus and of both bones of the forearm, splints made of *trunk-board* generally answer best, as by a little manipulation, after immersion in hot water, they may easily be moulded to the form of the limb. A piece of paste-board affords a capital support to a broken jaw or finger. Unoiled sole *leather* and *felt*, the latter being rendered stiff by gum shellac, make excellent splints, which I have often used with much satisfaction in fractures both of the upper and lower extremities. Previously to applying them, they must be softened in hot water, the sharp angles and edges having been pared off with a knife. The *tin case* I have employed a great deal, especially in fracture of the humerus at the elbow, and of the tibia at the ankle, ever since I entered the profession. *Iron* splints, in the form of the double inclined plane, are much in vogue in England; but are seldom used in this country. Many years ago, I was induced to make trial in a few cases of fracture of the condyles of the humerus and of both bones of the forearm, of a splint composed of light *wire*, adapted to the size and shape of the limb; but not answering my expectations, on account of its not being as manageable as I had been induced to anticipate, I soon abandoned it. For fracture of the bones of the hand and fingers, *carved* splints are sometimes employed. During the last twenty-five years an immense number of patented apparatuses have been presented to the notice of the profession; but I am not aware that any of them have come into general use, or that they possess any particular advantage over the more common contrivances.

Splints made of *gutta percha* are much used, not, perhaps, without reason on account of their neatness and easy adaptation. Cut into proper shape and size, they may, after having been dipped in hot water, be readily moulded to the form of the part, which, upon cooling, they always retain. Previously to applying them, they are lined with wadding, or old linen, to prevent irritation of the skin.

Maisonneuve employs splints made by saturating a piece of cloth, linen, or muslin, with a thick solution of plaster of Paris in water, and then doubling the cloth upon itself as many times as may be requisite to obtain the proper strength, when it is immediately secured to the limb with a roller. The advantages of this apparatus are that it dries in a few minutes, and that it thus forms almost instantaneously a firm, stiff shell for the broken limb, perfectly adapted to its inequalities, exceedingly light, indisposed to absorb discharges, and admitting of easy application and removal.

Sets of felt splints, adapted to all regions of the body, and put up in portable cases, have lately been introduced to the notice of the profession by Dr Ahl, and are likely, from their convenience and cheapness, to come into general use. They are very light and flexible, are not affected by cold or warm water dressings, and are easily moulded to every inequality of the surface of the parts to which they are applied.

Fracture *cushions* are generally made in the form of small bags, stuffed with bran, fine chaff, cotton, wool, hair, moss, or any other soft material. They are designed to fill up the inequalities between the splints and the limb, and must necessarily vary in shape, length, breadth, and thickness, according to the exigencies of each particular case. Instead of cushions, simple pads or compresses are often used, especially in fractures of the superior extremities. For enveloping short splints, calico or muslin is employed; or, what I always prefer, wadding. The same article answers admirably for filling up the inequalities between the short splints and the affected limb. Bags filled with sand are sometimes very convenient and useful, especially in fractures of the leg. Stretched along each

side of the limb, they keep up steady, equable pressure, well calculated to prevent displacement of the fragments.

The fracture *bandage* should consist of coarse linen, calico, or muslin, and should possess sufficient strength to answer the purpose for which it is intended. Nothing is worse, or more likely to cause annoyance, than a thin, flimsy bandage. If the material is new it should be washed before it is used, to rid it of its starch, and the selvage should be torn off to prevent it from exciting irritation, or producing welts in the skin. The bandage most commonly used is the ordinary single-headed roller, of a length and breadth suitable to the affected limb or part of the body to which it is to be applied. In fractures of the leg and thigh, especially such as are of a complicated character, the bandage of Scultetus may often be advantageously employed, as it can be easily undone and reapplied without the slightest disturbance of the limb. It consists of numerous strips of the ordinary roller, of equal or unequal length, according to the size and shape of the part which they are intended to surround. In applying them, they are arranged in such a manner that one overlaps another nearly one-half.

Too much caution cannot be observed in the use of the bandage in the treatment of fractures. It is an agent for good or for evil; for good, if applied properly; for evil, if applied improperly. Its object is twofold: first, to afford uniform compression of the limb, thereby preventing swelling and spasm; and, secondly, to retain the necessary apparatus. Its application is governed by the general principles laid down in a former part of the work, the rule being always to begin at the remote part of the limb, and to proceed thence upwards some distance beyond the seat of the fracture, care being taken to put it on with sufficient tightness to fulfil the object for which it is designed, without incurring the risk of interrupting the circulation, or of doing other mischief. If it be too slack to support the parts in a proper and uniform manner, it will be useless; if too tense, it will give rise to severe inflammation, swelling, and even gangrene. For the want of this precaution, many limbs have been lost, and a still greater number rendered permanently useless.

Adhesive strips are at present much employed in the treatment of fractures, either as retentive means, or for the purpose of maintaining extension and counter-extension. In the latter capacity, I was, I believe, the first to call attention to the subject, in my *Treatise on the Diseases of the Bones and Joints*, published in 1830. I had witnessed their excellent effects in the practice of my early preceptor, Dr. Joseph K. Swift, of Easton, in a case of very oblique fracture of the leg, complicated with so much injury of the soft parts as to interfere effectually with the employment of the gaiter and other counter-extending bands. The man had suffered a great deal of pain, until his patience was almost exhausted, when trial was made with adhesive strips, carried along the sides of the limb towards the knee, their free extremities being tied below the foot, to the transverse block connecting the two splints. Great comfort was at once experienced, and the case progressed favorably from that time forward. Soon after I had occasion to use adhesive strips in a case of my own, with results equally gratifying. Since then I have employed this substance with great advantage in the treatment of fracture of the clavicle, ribs, olecranon, and patella, as well as of the thigh and leg. Valuable papers have been published on this mode of management by Wallace, Gilbert, Neill, Crosby, and others. In a short article in the *Philadelphia Medical Examiner* for 1852, I also called attention to the subject, giving very briefly the results of my experience up to that period. Dr John Swinburne, of Albany, is in the habit of treating fractures of the long bones almost exclusively with the aid of adhesive plaster, generally dispensing with the roller and often even with splints. The importance of this agent, for the purposes here referred to, will be fully pointed out under the head of special fractures.

Coaptation and Dressing.—Everything having thus been provided, and the requisite number of assistants obtained, the surgeon proceeds to restore the broken pieces to their original situation, or, to use a common expression, to set the fracture. This may be done either by simple manipulation, or by pressure and counter-pressure, or by this means aided by extension and counter-extension.

The former will usually suffice in fracture of the upper extremity, the jaw, and nose, while the latter will generally be required in fracture of the thigh and leg; in either case, the affected limb should be held as quietly as possible, not only during the adjustment of the fragments, but also during the application of the dressings. It need hardly be observed that these manipulations should be conducted in the most gentle manner, with an eye both to present comfort and future consequences. There is no department of surgery where the humane practitioner may exhibit his skill and sympathy to greater advantage than in this, or where his conduct will be more closely watched and commented upon than upon such an occasion.

Extension and counter-extension are always necessary in oblique fractures of the thigh and leg, attended with displacement. By the term extension is understood the force which is required to draw the upper end of the lower fragment to a level with the lower end of the upper fragment, in order to place them in their natural relations; by counter-extension, on the contrary, is implied the resistance which is employed to prevent the limb, or even the body, from being dragged along by the extending power. The extension is generally made upon that part of the limb which is articulated with the lower piece, and the counter-extension upon that which is articulated with the upper. Thus, for example, in fracture of the shafts of the bones of the forearm, the extending power acts upon the hand, and the counter-extending power upon the arm, while in fracture of the body of the humerus the two forces are respectively exerted upon the forearm and the chest; and so in regard to fracture of the inferior extremity. When but little muscular resistance is anticipated, as in a child or feeble person, the extension and counter-extension may be applied directly to the two fragments, but at as great a distance from the seat of the injury as practicable. On the whole, however, I give the former method a decided preference, as it is much less likely to irritate and worry the muscles.

In reducing a fracture, the injured parts should be put in the most favorable position for relaxing the muscles, and the extending forces should be applied in as slow and gradual a manner as possible. If the limb is suddenly pulled, or stretched by fits and starts, the muscles which are concerned in effecting and maintaining the displacement will inevitably be thrown into violent spasmodic contraction, thus not only causing pain, but perhaps severe injury to the soft structures, if not actually frustrating our intention. The degree of force which should be used in making extension must vary according to the amount and character of the displacement, and the number and power of the muscles concerned in producing it; in all cases it should be sufficient to remove the shortening of the limb, or, what is the same thing, to restore it to its normal length, and to surmount every obstacle that opposes the reduction. The extension is always begun in the direction of the lower fragment, and is afterwards continued in that of the injured bone, until the object of its application has been attained. The ends of the fragments being now pressed into their natural situation, the fractured limb is enveloped in a suitable bandage, and immovably fixed by splints, every hollow between them and the skin being filled with cotton, to ward off pressure. A sling, to suspend the hand and forearm, completes the dressing if the fracture occupy the superior extremity.

In fracture of the thigh and leg, the patient lies in bed until the ends of the broken pieces have become completely consolidated, or, at all events, until he has made such progress towards recovery as to admit of the use of the starch bandage, and of exercise in the open air upon crutches. During his confinement, the limb is placed in the most favorable manner for relaxing and resting the muscles which pass over the fracture; for this purpose it should be put in the extended position, and be well secured with apparatus designed to maintain permanent extension and counter-extension. In some cases the limb is placed in the semi-flexed position, over a double inclined plane, but such a course will seldom be necessary or proper, except, perhaps, in fracture of the upper part of the body of the thigh-bone, attended with great and obstinate displacement of the superior fragment, in consequence of the joint action of the psoas and iliac muscles. In

transverse fracture of the patella, the thigh and leg are sometimes placed over a single inclined plane, the foot being considerably elevated above the level of the trunk.

After-treatment.—The fracture having been reduced and dressed, the patient is carefully watched, in order that he may be safely conducted through his long and arduous confinement. His diet for the first few days should be light and cooling, and the bowels should be opened, if necessary, by some mild aperient, as a dose of castor oil, Epsom salts, or citrate of magnesia. If fever supervene, the antimonial and saline mixture is freely used, aided, if the symptoms are urgent, and the patient is plethoric, by venesection, although such a procedure will rarely be called for. Action having subsided, the patient gradually resumes his accustomed diet, being still careful, however, to err rather upon the side of abstinence than on that of excess. Pain is relieved by anodynes; the bladder, if necessary, by the catheter.

During all this time the fractured limb is carefully watched, the patient being visited for a while at least once a day, or, if the case is at all troublesome, even twice a day, until all danger of mischief is over. If there are considerable pain and swelling, it will be well to remove the dressings at the expiration of the first twenty-four hours, otherwise they may be retained for some time longer. While I am an advocate for the careful watching of the dressings, I am opposed to frequent change, as it is calculated to injure the ends of the broken bone, and to impede the reparative process. If the first dressings have been applied lightly, as they always should be, and the parts are well seen to afterwards, it is hardly possible for the patient to do badly. The great danger, in nearly all cases, as far as the safety of the limb is concerned, is during the first week; that passed, there is seldom any risk.

In most fractures of the long bones there is more or less spasm, jerking or twitching of the limb, coming on within the first ten or twelve hours after the accident, much to the discomfort both of the part and system. This is owing partly to the pressure and irritation produced by the ends of the fragments, partly to the inflammation of the muscles, and is in general easily remedied by the rectification of the displacement, aided by warm applications and a full anodyne, either alone or in union with camphor and tartar emetic. The worst forms of this complaint are met with in nervous, irritable persons, in whom it occasionally persists with great obstinacy, despite our remedies, for a number of days, much to the annoyance of all concerned.

In fractures of the thigh and leg, especially the latter, the limb must be carefully protected from the pressure of the bedclothes, by means of a contrivance, such as that exhibited in fig. 347. It consists of two pieces of wood connected by several semicircles of hoop, or wire, attached by a longitudinal piece.

Fig. 347.

Wire rack for fracture of the leg.

In fracture of the superior extremity, the patient is often able to walk about immediately after the accident, taking out-door exercise, and, perhaps, even attending to business. But it is very different when he has a broken leg or thigh. Here, as a general rule, he is obliged to remain recumbent, often for a most unreasonable time, until, it may be, he is bedridden, and worn out with suffering. This is wrong. Such a case demands an immediate change of treatment. The starched bandage is substituted for the previous dressings, and the patient is sent out into the open air upon crutches. Prompt amendment follows; the general health rapidly improves, and the process of repair, having received a new impulse, steadily advances to completion.

As fractures are constantly liable to be followed by weakness and stiffness of the limb, the rule is to move the joint nearest the injury as soon as the union is sufficiently advanced to preclude the possibility of displacing the fragments or interrupting the consolidating process. This constitutes what is called *passive motion*, a most important element in the management of this class of lesions. It should not be commenced, as a general rule, before the end of the second week,

and should be repeated once a day, or every other day, according to circumstances; it should be very gentle at first, and be gradually increased until the limb has completely regained its normal functions. During its performance the parts are properly supported by assistants, and the dressings are reapplied the moment it is over. The restoration of lost function will be greatly promoted by frequent washing with warm water and soap, followed by frictions with some sorbefacient lotion, as spirits of camphor, soap liniment, or weak solutions of iodine.

As soon as the callus has acquired sufficient firmness to sustain the ends of the broken bone, the splints and bandages are either discontinued, or applied more loosely, the object now being merely to keep the parts at rest until the union is perfectly consolidated. In fractures of the inferior extremity, some days should usually elapse before the patient is allowed to rise, or bear any weight upon the affected limb; the new bone is still weak, no definitive callus has yet formed, and the individual, awkward from long disuse of his joints, is liable to fall from the slightest accident. These precautions are so extremely important that they should always receive the most scrupulous attention.

Immovable Apparatus.—The treatment of fractures of the extremities may often be advantageously conducted with the immovable apparatus, concerning which so much has been said and written of late years as a comfortable and time-saving expedient. When this method of treatment was first announced, in 1834, by Dr. Seutin, of Brussels, it was almost universally regarded with suspicion, and even now, after the numerous trials that have been made with it in different parts of the world, it is questionable whether it is receiving the attention it merits. In this country it has been but little employed at any time, either in private or hospital practice. It is difficult to determine to what this neglect is attributable, whether to fear, to indolence, or to apathy. Many practitioners are afraid that the apparatus may do mischief; others feel themselves incompetent to apply it properly; while a third, and perhaps the most numerous class of all, reject it on account of the supposed trouble attending its use. Such objections are altogether frivolous. The accumulated experience of the profession during the last twenty years is sufficient to convince any one, even the most sceptical, of the safety and utility of this mode of dressing fractured limbs. It is not, of course, applicable to all cases; but if proper judgment is exercised in their selection there are few in which, in some stage or other of their progress, it will not be beneficial. I am myself averse to the early use of the immovable apparatus, convinced that the safest plan is always to wait until there is complete subsidence of the resulting inflammation and swelling. From ten days to a fortnight is a good average period for the commencement of its application; employed earlier, it may induce undue compression, and thus compel removal. I would, then, have an eye to time and circumstances; avoiding premature interference, on the one hand, and too long delay, on the other.

The immovable apparatus may be prepared with various substances, all of them possessing more or less, though not equal, merit. Cowper, an old English surgeon, employed compresses and bandages, saturated with a mixture of the albuminous part of eggs and wheat flour, which was replaced by Lawrence by powdered chalk. Seutin was the first to recommend starch; Velpeau uses dextrine; Smee prefers gum Arabic and whiting. Gum shellac and glue have also been highly lauded, and of late much has been said in commendation of the plaster of Paris bandage. Of these various articles starch is perhaps the best; it certainly possesses the advantage of cheapness, and of being easily prepared, applied, and removed, as well as being always easily procurable.

The apparatus of Smee, called the *moulding tablet*, is also an excellent contrivance, nowise inferior to the starch bandage, and but little more expensive. It consists of two layers of coarse, old sheeting, cemented together by means of a thick paste made by rubbing very finely powdered whiting with mucilage of gum Arabic. The sheeting soon dries, without shrinking, into a hard, firm substance, which, with the aid of a sponge and hot water, may afterwards be accurately moulded to the fractured limb, and worn with great comfort and efficiency.

Dextrine is a yellowish-white, pulverulent substance, obtained from amylaceous vegetables and plants; it exists in union with fecula, amidine, diastase, and gum, and possesses remarkably glutinous and adhesive properties, well adapted to the object for which it is employed. Besides, it is very cheap, and generally dries in one-sixth of the time that starch does. The only objection to it is the greater difficulty of removing it. It is converted into a paste of the consistence of thin molasses, with equal parts of water and camphorated spirits, the latter being allowed to soak in well before adding the former.

Plaster of Paris, originally employed by the Moors of Spain, was first tried in Europe, as a scientific dressing in the treatment of fractures, by Professor Kluge, of Berlin, in 1829. The bandage is prepared by rubbing the dry plaster thoroughly into the meshes of a thick muslin roller, the ends of which are freely sprinkled with water previously to the application made with as few reverses as possible. The great advantages of this dressing are the rapidity with which it dries and adapts itself to the parts, and the fact that it forms an unusually firm, hard casing, which permits the limb to be handled and moved with great ease during any transportation that may be necessary to place the patient in more comfortable quarters.

The *chalk and gum bandage* forms an excellent substitute for the plaster and starch bandage. It is prepared in the same manner as the latter, over which it possesses the advantage of more rapid desiccation and of greater strength, so as to render a resort to strips of pasteboard rarely necessary. The adhesive mixture consists of equal parts of precipitated chalk and gum Arabic, made into a suitable consistence with boiling water.

The *starch bandage* which I prefer, on account of its simplicity and the facility of procuring it, is thus applied: Supposing the leg to be the part injured, the first thing to be done is to procure a pint of starch, without any lumps, a bundle of wadding, several long rollers, two light binder's board splints, and an apparatus for maintaining extension and counter-extension until the dressing is perfectly dry. The fragments being accurately adjusted, the limb is surrounded, in its entire length, from the toes to within an inch and a half of the knee, with two layers of wadding, in order to protect its bony prominences from the pressure of the bandage. Special pains, moreover, are taken to fill up the hollows on each side between the ankle and the tendo Achillis. A wet roller is now applied from below up in the usual manner, care being taken not to make the reverses over the edge of the tibia, lest they should occasion unpleasant, if not injurious, compression. A layer of starch is next put on, either with the bare hands or with a paint brush, the substance being well rubbed into the meshes of the cloth. Resuming the roller, it is now carried down the limb as far as its extremity, when the starch is again applied, and so on until three layers have been formed. Two splints, made of binder's board, not too thick or heavy, and accurately shaped to the foot and leg, are steeped in hot water, and, being carefully moulded to the parts, are secured with another roller, also thoroughly saturated and covered with starch. Finally, the dressing is completed by the application of a dry bandage. If the fracture is a very simple one, unattended with any disposition to displacement, as often happens when the tibia alone is broken, the limb is simply placed in an easy position upon a pillow arranged in the form of an inclined plane, or in an ordinary fracture-box; otherwise it will be necessary to use the apparatus of Desault, as modified by Physick, or some similar contrivance, in order to keep up extension and counter-extension until the bandage is completely dried; an event which seldom happens before the expiration of thirty, thirty-six, or forty hours, even in very hot weather, as the evaporation always proceeds with difficulty. The desiccation, however, may often be materially expedited by artificial means, especially by warm sand-bags stretched along the sides of the limb.

When the apparatus is perfectly dry it forms an immovable case for the limb, making equable and uniform pressure throughout, and maintaining the fragments of the broken bone accurately in position with each other. If the parts feel entirely comfortable, the patient may now sit up in bed or on a chair, or he may even walk about on crutches, the leg being properly supported in a sling. Gen

rally, however, it will be found that there is for a day or two a sense of soreness, with, perhaps, some degree of throbbing, inviting recumbency rather than the erect posture. If the apparatus causes marked discomfort, by bearing unequally upon any portion of the limb, or if throbbing and swelling arise, immediate measures must be adopted for its removal. For this purpose it should be slit up

Scutin's scissors.

along the outer side of the limb, about an inch or an inch and a half external to the crest of the tibia, by means of Scutin's scissors, represented in fig 348, one of the blades of which is probe-pointed, and, therefore, well adapted to the object. The limb being properly supported by an assistant, the hardened shell is gently peeled off from its surface, which is next carefully sponged

with alcohol and laudanum, or spirits of camphor, when the apparatus is immediately reapplied with the aid of a roller. Thus, by simply removing the bandage from time to time, an opportunity is afforded of inspecting the limb, and ascertaining its precise condition, not only at the seat of fracture, but everywhere else.

When the patient is able to move about on crutches, the limb should be carefully supported in a sling, arranged in the manner represented in fig 349.

If the fracture is seated high up in the leg, the apparatus should extend a short distance above the knee, as it then becomes a matter of great moment to keep the joint in as passive a condition as possible. In compound fracture,

Fig. 349.

Fracture of the thigh, done up in starch bandage.

Fig. 350.

Dressing in compound fracture of the leg.

attended with discharge, a hole should be cut in the apparatus opposite the wound, so as to admit of the necessary drainage, as shown in fig 350.

Great care should be taken that the edges of the splints do not produce any injurious compression; to obviate this, it is usually recommended that they

should be torn instead of being cut, it being alleged that, when thus treated, they will be much less likely to create mischief. My experience, however, is that this is not the fact, and I, therefore, invariably bevel the inner edges with a stout knife, thereby effectually preventing all risk of this kind.

It is impossible, also, to bestow too much attention upon the bandage; the care or negligence with which this is applied will make all the difference in the result, both as it respects the patient's comfort and the character of the cure.

The plaster of Paris bandage, prepared in the manner already mentioned, is applied in the same way as the starch, the limb being previously enveloped in cotton wadding and a dry bandage. Great care is taken with the reverses and the various depressions of the limb. The bandage, moreover, must not be drawn with quite the ordinary firmness, allowance being made for shrinkage. Splints may usually be entirely dispensed with, especially if folded cloths, saturated with plaster, are applied whenever more than usual support is required, but extension must be kept up by assistants until the bandage is perfectly dry, as it always will be in a few minutes.

3. COMPLICATED FRACTURES.

The only class of fractures, besides the simple, which deserves to be considered under a distinct head is the complicated, as it is easy to comprise under this denomination every form of accident that can possibly arise either at the moment of the injury, or during the progress of the treatment. The propriety of this arrangement will become more obvious as we proceed with the discussion of the subject. In adopting this plan, I shall treat successively, and as concisely as possible, of fractures complicated with wounds, hemorrhage, dislocation, comminution of the bone, excessive laceration of the soft parts, erysipelas, pyemia, and, lastly, tetanus.

Complicated fractures may be oblique, transverse, or longitudinal, the frequency of their occurrence being in the order here enumerated. They are always caused by mechanical violence, as gunshot, falls from a great height, severe blows, or the passage of the wheel of a carriage, wagon, or railway car. Complicated fractures from the latter cause have, of late, become very common, and are a frequent source of loss of limb and life.

The *symptoms* of this variety of fracture are, like those of simple fracture, sometimes extremely obscure, requiring great care and skill on the part of the surgeon to determine their character. In general, however, they are sufficiently well marked to enable him to distinguish them from such as attend other accidents, especially if an opportunity is afforded him of examining the parts before the supervention of much swelling. There are usually greater pain and shock than in an ordinary fracture, the resulting inflammation is more severe, and there is greater risk of violent secondary effects, as erysipelas, gangrene, copious suppuration, necrosis, caries, prostration, hectic irritation, and tetanus. In fact, complicated fractures are among the most serious occurrences that are met with in practice, being alike perplexing to the surgeon and dangerous to the patient; demanding the nicest judgment and skill for their successful management, and entailing, not unfrequently, the greatest possible suffering, horrible deformity, and loss of limb, if not also of life. It may be stated, as a general rule, that complicated fractures of the lower extremity are more dangerous and difficult of management, as well as more liable to be followed by distortion and permanent lameness, than those of the superior.

The process of repair in complicated fracture proceeds on the same principle as in the simple form of the lesion, only that it is usually more tedious, and that it is attended with a larger quantity of callus. When there is a wound in the soft parts, the union is generally effected through the medium of granulations, which, arising from the ends of the fragments, ultimately assume the ossific disposition, and thus form the connecting link between them.

The *treatment* of this form of fracture varies according to the circumstances

of the case, or the nature and severity of the complication ; a fact which imposes the necessity of considering the subject somewhat in detail.

When the case is complicated with a *wound* in the soft parts, constituting what is usually called a *compound fracture*, fig. 351, and the limb is deemed capable of preservation, the first and most important consideration is the reduction of the fracture. This may generally be done by putting the limb in the most favorable position for relaxing its muscles, and by well-directed and gentle efforts at extension and counter-extension, along with proper manipulation, especially if the fracture is transverse, and the opening large ; but if it is oblique, and there is a projection of one or both ends of the fragments, they occasionally fail, and compel us to resort to other measures. Under such circumstances, the soft parts which seem to gird or bind the bone, and prevent it from yielding, should be carefully divided, when a renewed attempt at reduction will probably be successful. Should every reasonable effort of the kind, however, prove fruitless, then, instead of leaving the bone in its exposed situation, where

Fig. 351.

Fracture of the leg, complicated with wound and comminution of the bone.

it would be sure to die, the proper plan will be to cut away a portion of it, especially if it terminate in a very long and narrow point.

Whatever may be the character of the wound, its edges should be carefully approximated by suture and plaster, aided by collodion to exclude the air ; or, instead of this, the wound may be covered with a light compress wet with blood, and supported by a bandage. In this way, a compound fracture may occasionally be speedily converted into a simple one, union sometimes occurring in a few days.

The *hemorrhage* in complicated fracture may be open or concealed, according as there is a wound or no wound ; arterial or venous ; insignificant or copious. In the first case, the bleeding will manifest itself in the usual manner, and is to be arrested by ligature or compression ; in the second, it will be indicated, if it is at all considerable, by unusual swelling, attended with a sense of fluctuation or unusual softness, and by more or less discoloration of the integuments. If the principal artery of a limb has been severed, there will be an absence of pulsation in the parts below, with coldness of the surface. When no doubt remains concerning the diagnosis in such a case, the main trunk of the vessel is exposed some distance above the seat of fracture, and ligated ; or, if this is deemed improper, an incision is made through the bloody tumor, and, its contents being turned out, the divided artery is sought and secured above and below the seat of injury. This, in fact, is usually the preferable procedure, especially as there must frequently be considerable uncertainty whether the effusion is arterial or venous ; a circumstance which, perhaps, thus leads to the performance of a most serious operation in a case where one of a most simple character might suffice.

When the fracture is attended with a *dislocation*, the case necessarily assumes a very serious character, as it may give rise, especially if the joint involved is a large one, or the bone greatly shattered, to the question of primary amputation. In such an event the most experienced surgeon will often find it difficult

to come to a prompt and correct decision. The principal circumstances which should induce him to make an attempt to save the limb are, the integrity of the patient's health at the time of the injury, together with a knowledge of his previous habits, and the simplicity of the dislocation, or the almost total absence of complication, as it respects the affected joint. If, on the other hand, the dislocation is compound, and the bone is badly broken, at the same time perhaps that it protrudes at the articulation; if all these injuries exist, or if, along with them, serious mischief has been inflicted upon the soft parts, as a violent contusion of the skin and muscles, or the laceration of important vessels or nerves, no doubt should be entertained respecting the propriety of the operation, and the sooner it is performed after the occurrence of reaction the better it will be for all parties concerned. I believe that a compound fracture, extending into a large joint, as the knee or ankle, and attended with extensive rupture of the ligaments, muscles, and other structures, should always, as a general rule, be treated in this way. It is true a case apparently of the most desperate character occasionally recovers, but such a consideration should not have too much weight, or induce us to neglect a measure which is sanctioned not less by reason than by experience.

When the case is not such as to demand amputation, the dislocation should always be reduced before an attempt is made to adjust the fracture. Great difficulty will sometimes attend such an operation, but this may usually be overcome by patience and perseverance, aided by the means furnished by modern improvement. It is sheer folly to postpone the reduction of the dislocation until the bone has become sufficiently consolidated to enable it to bear the requisite manipulation; one of two things would be almost sure to happen in such a case, either a reproduction of the fracture, or an utter failure to replace the luxated bone.

The most common causes of *comminuted* fracture are, gunshot violence, railroad accidents, falls from a great height, and the passage of the wheel of a carriage. If the bone is broken into several pieces, and any of them are completely detached, or so loose as to render their reunion improbable, all such pieces ought to be carefully removed; after which the edges of the wound should be gently approximated, and kept in position by sutures and adhesive strips, covered with collodion. The limb, surrounded by the bandage of Scultetus, and supported by appropriate apparatus, is placed in an easy position, and care is taken to moderate inflammation by the usual antiphlogistic means. If the wound suppurates, it must be covered with an emollient poultice or the warm water-dressing, with as little disturbance as possible to the injured bone.

When the fracture is complicated with violent *contusion* of the soft structures, the retentive apparatus should be applied rather slackly, and the parts kept constantly wet with cold water, or, what is better, a strong solution of acetate of lead and opium. If the inflammation run high, recourse may be had to bleeding, purgatives, and antimonials. The limb is carefully watched, in order that prompt advantage may be taken of any change as soon as it arises.

In consequence of injury sustained by the skin, either at the time of the accident, or from the pressure of the bandage, the cuticle is sometimes raised into little *vesicles*, filled with a thin, limpid, reddish, or yellow fluid. Such an occurrence always awakens anxiety both in the patient and practitioner, especially if he is young and inexperienced, as it is apt to be associated with the idea of gangrene. From this, however, it may always be easily distinguished by the absence of lividity, severe pain, and other symptoms of excessive action. The proper treatment consists in puncturing the vesicles with a fine needle, and using the warm or cold water-dressing.

If the principal artery, vein, or nerve of a limb has been destroyed, at the same time that there is extensive laceration of the soft parts around, the case will probably require amputation, especially if there has been severe shock or extensive hemorrhage, with previous derangement of health. Such a case is, at all events, a bad one, liable to be fatal, if not also of life. If, on the other hand, the prin

the midst of the torn and broken structures, and the patient is young and vigorous, although he may have bled severely, we should by all means make an attempt to save the limb, having previously explained to the patient and his friends the risk which such an undertaking involves. Some of the most gratifying results that reward the care and skill of the practitioner are cases of fracture complicated with extensive laceration of the soft structures and comminution of the bones. I have several times succeeded in effecting excellent cures when, the main artery being intact, the limb hung merely by a comparatively small quantity of skin and muscle, and when I was compelled to remove a number of pieces of bone, or even saw off the ends of the fragments.

Accidents after Complicated Fractures.—The most common and important accidents after complicated fractures are erysipelas, œdema, abscess, gangrene, spasm, tetanus, pyemia, delirium, and congestion of the brain and lungs.

Erysipelas usually comes on within the first forty-eight hours after the occurrence of the injury. The disease is most liable to appear in persons of intemperate habits, and in such as are dyspeptic, or enfeebled by previous suffering, and generally adds very much to the danger of the case, perhaps already sufficiently grave before. Its extent and continuance will depend upon various circumstances, which will readily suggest themselves to the mind of the reader. The treatment is conducted upon general principles, our main reliance being upon the correction of the secretions, and the support of the system, by fresh air, quinine, iron, milk-punch, nutritious food, and anodynes, with the topical application of dilute tincture of iodine.

The occurrence of *œdema* is sufficiently common in complicated fractures of old, dilapidated subjects, and is best remedied by the bandage, aided by spirituous lotions, tonics, and a nutritious diet. Punctures will seldom be necessary, and should always be used with the greatest caution.

Abscesses, diffuse, painful, and troublesome, may form at the seat of the fracture, or in its immediate vicinity. In either case, the matter should be speedily evacuated; otherwise it may not only cause extensive havoc among the soft parts, but caries and necrosis of the ends of the broken bone, with risk of pyemia and phlebitis.

Gangrene may be produced by injudicious bandaging obstructing the circulation, excessive inflammation, or injury of the main artery, vein, or nerve of the affected limb. The occurrence is most common in unhealthy subjects and in young persons after railway and other severe accidents, and often makes fatal progress before its presence is suspected by the patient or his attendant. Great pain in the part, of a smarting, pungent, or burning character, accompanied with discoloration and tumefaction in the distal portion of the limb, should always excite alarm and lead to a thorough examination. Tight bandaging in particular should be avoided in complicated fractures, especially in the early stages of the treatment.

Severe *spasm* frequently attends this class of injuries, but as this subject has already been discussed in connection with simple fractures, nothing further need be said respecting it here.

Pyemia, as an effect of complicated fracture, is uncommon, at least in private practice, except when the accident has been caused by railway injury, the bursting of a gun, the passage of the wheel of a wagon, or some similar violence. It is distinguished by its usual insidious character, and generally sets in from the fifth to the tenth day, its approach being announced by violent rigors, alternating with flushes of heat, great depression of the system, delirium, and excessive restlessness. The structures which are most apt to suffer are the lungs, liver, spleen, joints, and connective tissues. The treatment is supportant and alterant; by quinine, brandy, and nourishing broths, for the former; by mercury, in moderately large and properly sustained doses, for the latter. In general, such cases fare badly, death occurring within a week from the commencement of the attack, despite our best directed efforts.

Tetanus, in complicated fractures, is most liable to supervene in nervous, irritable subjects, during hot weather, although it may take place at any season of

the year, as well as in every description of individuals. It is an extremely formidable symptom, which should be promptly met by the removal of the affected parts, and by large quantities of anodyne and antispasmodic remedies. If occasionally a case is cured without amputation, it forms the exception, not the rule. In such an event, there is no time for delay; whatever is done must be done quickly and effectively, at the very inception of the disease, before there is any decided evidence of stiffness in the muscles of the jaw.

Traumatic delirium is sufficiently frequent after these accidents, especially in old intemperate persons, and should be treated upon the principles laid down in a previous chapter.

Congestion of the lungs and other internal organs, as a consequence of these injuries, is most liable to occur in elderly persons, as a result of a determination of blood either from actual irritation or a sluggish condition of the vessels from protracted confinement. As such attacks are very apt to prove disastrous, everything should be done to prevent them, by getting the patient as speedily as possible out upon crutches into the open air.

Amputation.—The circumstances which are likely to call for primary amputation have already been casually alluded to, and it may now be added that the operation should always be performed, as a general rule, whenever, along with a shattered or comminuted condition of the fractured bone, there is extensive laceration of the soft parts, with almost total disorganization of their substance. It is true, as was before intimated, that apparently desperate cases are sometimes cured, and that limbs, so mashed and wounded as to render amputation the only probable chance of success, are now and then saved. But it is equally true that such instances are extremely rare, and if we take into account the protracted sufferings of the patient, and the likelihood that he will ultimately perish, the reasons for performing immediate amputation are, to use the language of Mr. Percivall Pott, “vindicable upon every principle of humanity or chirurgic knowledge.”

It is not uncommon for cases to occur in which the fracture is *multiple*, or in which the bone is broken at several points, but where the upper fracture is perfectly simple, and perhaps situated in a portion of the limb which it is desirable to preserve. Hence it becomes an important question how the surgeon should act in such an event. To my mind, the subject is a very plain one. If it is really important to save the broken bone beyond the part that must necessarily come off, in order to make a longer and better stump, there can certainly be no objection to such a course, provided, however, that the proximal fracture is perfectly simple in itself, and that there is no serious lesion of the soft structures, endangering limb and life by gangrene or other bad consequences. I have more than once adopted this plan, and have not, so far as I recollect, had any cause to regret it. No sensible surgeon would, of course, allow a bone to remain, under such circumstances, if it were comminuted, or if, the fracture being simple, there were serious injury of the muscles, integuments, or other important textures; to do so would only be to trifle with the safety of the case.

Secondary amputation may be required when, after an attempt to save a limb, and the employment of suitable antiphlogistic remedies, the parts become gangrenous; or when the consolidation of the fracture is prevented by profuse suppuration, and the patient is gradually worn out by diarrhoea and colliquative sweats. In the first case, the operation is performed as soon as the mortification is arrested, and there is a distinct line of demarcation between the dead and living parts; in the second, as soon as it is perceived that the suppuration cannot be arrested, and that the patient has still sufficient strength to bear the pain and shock which must necessarily attend its performance.

4. INCOMPLETE FRACTURES OR BENDING OF THE BONES.

The bones are liable not only to break, but also to bend, as seen in figs. 1 and 353. Such an accident can only happen in young sub infants and children, in whom the osseous tissue, contain

animal matter, is comparatively soft, flexible, and elastic. Bending of the bones of the skull, especially the frontal and parietal, is occasionally witnessed at an

Fig. 352.

Fig. 353.

Incomplete fracture of the bones of the forearm.

early age, as an effect of external violence, as that, for instance, produced when a child falls, head foremost, down a flight of stairs, or out of a second story window upon the pavement below. Under such circumstances, the cranial bones, at the part struck, are depressed beyond their natural level, and yet there is not, so far as can be ascertained, any fracture, strictly so called; they are merely bent or indented, and if no untoward occurrence take place, they will, generally in the course of a few

days, resume their proper position by their own resiliency, aided doubtless by the locomotive action of the brain, propelling them outwards away from its surface. In an adult, an accident, capable of producing such a result, would almost certainly lead to fracture of the skull, and that probably of a very grave character; for the reason that the cranial bones, after a certain time, are always loaded with a large quantity of earthy matter, in the form of carbonate and phosphate of lime, the presence of which renders them more or less brittle, and thus predisposes them to fracture. This tendency to fracture increases in proportion as we advance in years, and is, consequently, most distinctly marked in old age and decrepitude, in which the osseous tissue, almost destitute of animal substance, generally yields under the slightest force, the accident frequently eventuating in incurable injury.

Bending of the bones was incidentally observed by a considerable number of practitioners in the last century, and, indeed, even prior to that period; but the first systematic account of it was published in 1810, by Professor Jurine, of Geneva. In 1821, it was described by Dr. John Rhea Barton, and since then it has been carefully investigated by Professor Hamilton, of New York.

I have myself met with this accident in ten cases, in children whose ages varied from three to eleven years, three being girls, and the remainder boys. Although it is most common in the ulna, radius, and clavicle, it also sometimes occurs in other pieces of the skeleton, as the humerus, femur, tibia, fibula, and ribs. External violence alone is capable of producing this lesion. I am not acquainted with any cases in which it was occasioned by muscular contraction. In fact, considering that bending of the bones is exclusively confined to children, it is hardly possible that the accident could arise from such a cause; certainly not, unless there existed extraordinary muscular development with remarkable flexibility of the osseous tissue, a condition of things hardly compatible with a healthy state of the system. In the bones of the forearm, which suffer more frequently than any other, the injury usually originates from force applied indirectly, as, for example, when a child, in the act of falling, instinctively throws out the arm to protect the body, and so receives the shock upon the hand, the concussion concentrating and exploding upon the radius, or the radius and ulna. In one of my cases, the bend was produced by the body of the child being suddenly propelled against the forearm at a moment when the elbow was planted upon the floor, and the wrist lying upon a stool. Flexion of the clavicle is the result either of direct violence, or of force applied to the top of the shoulder, especially if the body is at the same time propelled in the opposite direction, as in the case of a fall.

The *seat* of this lesion is variable; in the long bones, as those, for instance, of the forearm, it usually occurs a short distance below their middle, but it may

also take place higher up, or further down. The radius and ulna may both suffer synchronously, but very frequently one alone is affected, or, if both are implicated, they do not suffer in an equal degree.

Judging from the cases of this accident that have fallen under my observation, I am inclined to believe that it generally happens without any particular predisposition, either constitutional or local. In every instance of the kind, the subject of the injury was in good health at the time of its occurrence.

What is the precise *nature* of this lesion? Is it really, as the name implies, a mere bending of the bones, or is it a flexion combined with partial fracture? These questions are easily answered. In very young subjects, as in children not more than a few years of age, and in the milder forms of the lesion, the osseous fibres are merely extended or stretched, so as to permit themselves to be drawn out of their natural course; in cases of an opposite character, on the other hand, there is no doubt that, while some of the fibres are bent, others are both bent and broken. These conclusions are beautifully borne out by the experiments of Dr. Hamilton upon the bones of young chickens, which, from the fourth to the sixth week, and consequently before the completion of the ossific process, could be readily bent without fracture to an angle varying from twenty-five to thirty-five degrees; whereas, the bones of older chickens, thus treated, always partially broke, their fibres being incapable of withstanding the force used in flexing them.

These partial fractures, sometimes called *interperiosteal*, from the fact that the fibrous envelop of the bones remains intact, bear a close resemblance, in the mode of their production, and the nature of the resulting injury, to the appearances presented by a green hickory stick, forcibly bent over the knee, but not to such an extent as to occasion any external sign of fracture, although it will be found, upon making a section of the wood, that many of its fibres have actually been broken, while others, and perhaps the greater number, have merely been bent.

The *symptoms* attendant upon this accident are pain and deformity at the seat of the injury, loss of power in the limb, and absence of crepitation. The pain varies in degree, being sometimes slight, at other times severe; swelling soon supervenes, and the part feels numb and heavy. A marked curvature, generally very gentle, but sometimes quite abrupt, always exists at the affected part, and can seldom be completely effaced without the application of very considerable force; indeed, often not without breaking the bone entirely across, especially if it was partially fractured previously. In the latter case, there is usually at the convexity of the curvature a slight depression, capable of receiving the point of the finger, its boundaries being formed by rough, sharp, bony fibres. Further than this there is no displacement, and under no circumstances is there any crepitation. The use of the limb is always greatly impaired, but not completely destroyed, as it commonly is in ordinary fracture. Finally, I may mention, as another highly important and diagnostic sign, the great difficulty which is so frequently experienced in restoring the parts to their proper position.

The *treatment* must be conducted upon the same general principles as that of ordinary fractures. When the bones are merely bent, slight pressure and extension will usually suffice to accomplish restoration, the affected parts being compelled, as it were, to retrace their former steps. If flexion be conjoined with partial solution of continuity, the reduction will necessarily be more difficult, and may, in fact, altogether fail, owing to the manner in which the osseous fibres are interlocked with each other, and the inability which is experienced in disengaging them, so as to induce them to slip back into their proper position. However this may be, the attempts to remove the curvature by external pressure should neither be too violent nor too long continued, lest they be injurious. The object should be to restore as much as we can by gentle means; what cannot be effected in this manner, may well be left to the power of nature. In time, the absorption of the broken and resisting osseous fragments, and the action of the muscles, which seldom fail to reinstate the parts, in eight weeks may elapse before the final completion of the cure.

found the use of leather splints, well padded, and accurately shaped to the limb, of great service in bringing the bones into their proper relations. When the accident is followed by undue inflammation, recourse must be had to the usual antiphlogistic remedies, especially leeching and cooling lotions.

There is a variety of partial fracture, known by the term *fissure*, which is peculiar to the bones of elderly subjects, no well-marked instance of it having ever been met with in infants and children. Such an occurrence, which is, in general, much more interesting in a pathological than in a practical point of view, is by no means uncommon in the skull, especially along its base, where it is always associated with severe, and frequently fatal, injury of the brain and its envelops. The fissures in many of these cases are most extensive, involving the sphenoid, occipital, temporal, frontal, and perhaps even the ethmoid and parietal bones. In the other pieces of the skeleton the occurrence is more rare; but examples are occasionally seen both in the long, short, and flat bones, as the result of external violence, generally directly applied, though sometimes indirectly. The accident is, now and then, produced by gunshot injury. The lesion, however induced, consists essentially in a forcible separation of the osseous fibres, and exhibits itself in a great variety of forms; the crack sometimes extending through the entire thickness of a bone, at other times merely through its outer table, and at other times, again, involving both the compact and areolar tissues, but not passing completely through them. The length of the fissure varies from a few lines to a number of inches, perhaps as many as six or eight, although this is exceedingly uncommon. The width of the crevice is generally very slight, perhaps barely sufficient to admit the blade of a penknife. In rare cases, as when it involves the extremity of a bone, it may gap somewhat, so as to give the part the appearance as if it consisted of two fragments, firmly adherent at one end. Finally, the fissure may be straight, curved, or angular.

Of the rarity of this lesion, as an uncomplicated occurrence, an idea may be formed when it is stated that there are probably not more than three or four well-marked specimens of it in all the osteological cabinets of this city. As a conjoint affection, it is occasionally met with in compound fractures, especially when caused by railway accidents. There are no signs by which the nature of the injury can be distinguished during life; a circumstance which is the less to be regretted, because the treatment does not differ from that of ordinary wounds, fractures, and contusions, with which it is so generally associated.

Fig. 354.

Diastasis of the femur: reunited.

5. DIASTASIS OR SEPARATION OF THE BONES AT THEIR EPIPHYSES.

The extremities of the bones of young subjects are, as is well known, united to their shafts, or bodies, by means of cartilaginous matter, which, in some of the pieces, and in some individuals, does not assume the osseous form until after the twenty-first year, and occasionally, indeed, not until even a later period. Up to this time, consequently, these junctions are liable to be severed, so as to allow the contiguous extremities to separate from each other, and it is this occurrence that constitutes what is technically called diastasis, as seen in fig. 354.

It is probable that this accident may occur in all parts of the skeleton united in this way, although there are doubtless some in which it is more common than in others. Its occasional existence has been recognized, by dissection, in the humerus, radius, femur, and tibia, and there are few systematic treatises which do not allude to it as being now and then met with in some of the other bones. The most common cause of diastasis is a wrench of the part, violent traction, or a severe fall. I am not aware that it has ever been produced by muscular contraction; and, on the other hand, it is rarely the result of direct

violence, as, for instance, the kick of a horse, or the passage of the wheel of a carriage, such an accident more generally eventuating in fracture of the bones than in a separation of their epiphyses. The lesion may happen at any period of life, prior to the completion of ossification, but is most common from the fifth to the fifteenth year. Its occurrence in middle-aged and elderly subjects is, for the reasons already mentioned, impossible. Girls are more prone to it than boys, owing, probably, to the fact that they are more frequently exposed to its exciting causes. The affection, like fracture, may be simple, compound, or complicated. Cases are noticed in which the diastasis is blended with fracture of the shaft of the bone, and it is by no means uncommon to find that small processes of bone are dragged away with the epiphyses.

The symptoms of this lesion do not differ essentially from those of fracture. Its existence may generally be suspected when an accident affecting a bone occurs in a young subject, in the neighborhood of a joint; when the ends of the fragments are transverse, or nearly so; when the articular piece retains its position, while the other moves about; and, lastly, when the crepitation produced by rubbing the ends of the fragments against each other is of an unusually dull, rough, grating character. Moreover, it will commonly be found that the parts, when once reduced, are less liable to be dragged asunder by the action of the muscles than in case of fracture.

The prognosis is generally favorable, union taking place quite as promptly as in fracture. The treatment is also the same as in the latter accident.

6. UNUNITED FRACTURES.

Fractures occasionally refuse to unite, either in consequence of causes inherent in the part or system, or on account of mismanagement growing out of the surgeon's want of attention and skill, or else out of the patient's own misconduct. It is practically important that a distinction should be drawn between a fracture that unites tardily and one that does not unite at all, or only through the medium of fibrous, ligamentous, or fibro-cartilaginous tissue. Slow consolidation is by no means uncommon; the parts may be loth to take on the requisite degree of ossific action, and the result may be that a fracture that is ordinarily repaired in four or five weeks, may, perhaps, be still imperfectly united at the end of twice that period. The process of restoration is only held in abeyance, neither advancing nor receding; by and by it begins again, and then often proceeds with its wonted rapidity. Such cases are frequently very trying to the surgeon's patience, but they generally turn out well in the end, provided sufficient care has been taken to preserve the parts in their proper relations. In the ununited fracture, on the other hand, the process of consolidation is either completely prevented, or, after having progressed for some time, is at length permanently arrested. Under these circumstances, the ends of the fragments are gradually rounded off by absorption, and remain either entirely loose and disconnected, or they become adherent through the medium of fibrous, ligamentous, or fibro-cartilaginous matter. Sometimes an adventitious joint is formed, as in fig. 355, provided with a more or less synovial membrane, thus permitting the ends of the bone to move with great facility.

Fig. 355.

Ununited fracture of the bones of the leg.

Want of reunion in a fracture may depend upon a great variety of causes, some of them resident in the parts themselves, others connected with the system. Thus, it may be occasioned by the interposition of a clot of blood, or of a piece of muscle, tendon, or bone. An instance is mentioned where the consolidation of a fracture was prevented by the presence of a musket ball. Fragility, softening, and other affections of the bones are usually enumerated as circumstances interfering with the reparative process, but it is not improbable that their influence has been greatly exaggerated; at all events, it is certain that in many cases of this kind, the fracture unites as readily as when the bones are perfectly healthy. Too much motion, the long-continued use of cold water, especially in persons of a nervous, irritable temperament, and tight bandaging, may also bring about this result. Some years ago, I saw a case in which, from the latter cause, the consolidation of a fracture of the thigh-bone was delayed for nearly a twelvemonth. The limb had become excessively atrophied from the protracted and injudicious employment of the roller, and it was not until after it had been entirely laid aside, and the man had been permitted to exercise upon crutches in the open air, that nature could be induced to commence the process of repair, from which she had been so long detained by this mode of treatment.

Old age is no barrier to reunion, provided the patient is in good health at the time of the accident, and the fracture is not complicated. I have met with several cases of fracture of the humerus, in persons after the eightieth year, in whom the consolidation took place in the usual time.

But the most common of all the local causes of tardy reunion, in injuries of this kind, are motion and imperfect apposition of the ends of the fragments. Either of these circumstances will inevitably interfere with, if not effectually prevent, the consolidating process, however favorable the condition of the system itself may be to a cure. Hence, as stated elsewhere, the absolute necessity, in every instance of fracture, of carefully guarding against these occurrences until the process of repair is so far advanced as to enable the fragments, so to speak, to take care of themselves.

Fractures situated at or near the entrance of the nutrient arteries unite less rapidly than those situated further off, owing to the fact that they interfere more or less with the circulation and nourishment of the osseous tissue. It is easy to suppose that the laceration of these vessels, as occasionally happens both in simple and compound fractures, might be a cause of non-consolidation, especially when conjoined with other unpropitious circumstances. Statistics show that, when the supply of blood is cut off, to any considerable extent, so as to impose upon the periosteum the exclusive duty of nourishing the fragments, either one or both pieces will become atrophied, their walls being visibly thinned, and their areolar structure rarefied.

Inadequate supply of nervous influence may be a cause of non-union. A case reported by Mr. Travers beautifully illustrates this point. A patient had a fracture in the arm and another in the leg, complicated with an injury of the spine which palsied the lower half of the body. The broken humerus readily united, but the tibia and fibula refused to heal.

Want of union is sometimes dependent upon the *absorption* of the ends of the fragments, or even of the greater portion of the fragments themselves. A very singular case of this kind came under my observation in 1856, in a man 53 years old. At the age of eighteen, he received two simple fractures of the right humerus, at an interval of three months, one being situated about the middle of the bone, the other an inch and a half higher up. The first was repaired in the usual time, but the second refused to unite, the ends of the fragments becoming rounded off, as in the formation of an artificial joint; the process gradually proceeding, the whole bone was finally absorbed, nothing remaining except its condyles and a little of its head. The period occupied in the absorption was about six years, the general health being all the while unimpaired. The muscles of the arm are well developed, and, when thrown into powerful action, are capable of diminishing the interval between the shoulder and elbow to the extent of

several inches. Although the man is unable to perform any of the usual movements of the limb, he can readily raise a weight of upwards of one hundred pounds, and can apply his hand to various purposes. The accompanying cut, fig. 356, represents the appearance of the arm during the contraction of its muscles.

Fig. 356.

Absorption of the humerus.

The principal *constitutional causes* which interfere with the reparative process are, debility, whether from loss of blood, want of nutritive action, or exhausting disease, as long-continued fever; a gouty, rheumatic, scorbutic, or syphilitic state of the system; and loss of nervous influence, however induced. Another cause, but one which, probably, seldom exerts much influence, is pregnancy. It is barely possible that, during this state, there may be such an abstraction of blood from the affected parts for the nourishment of the fœtus as to retard, and, perhaps, even temporarily prevent, the formation of callus. In the few cases of this kind that have fallen under my observation, I have not, however, witnessed such an effect, and I am strongly inclined to believe that this influence has been greatly magnified, if, indeed, it is not wholly chimerical. The same remarks are applicable to suckling. Another cause, probably much more efficient, as well as much more common, than the one just alluded to, is the protracted and inordinate use of ardent spirits, weakening the nutritive energies of the system, and rendering the blood and its vessels unfit for the performance of the important duties assigned to them in the reparative process.

Whatever the cause may be, great pains should be taken to discover it, with a view to its early and efficient rectification. Should it consist in debility, however induced, the patient must at once be put upon the use of nutritious food and drink, as porter, ale, wine, or brandy, aided, if necessary, by tonics, of which iron and quinine are generally the most eligible. A gouty or rheumatic state of the constitution is best remedied by purgatives, alkalies, and colchicum. Tertiary symptoms should be met by iodide of potassium, either alone or in union with mercury, the latter of which should sometimes be carried to the extent of slight ptyalism. Debility from drunkenness must be counteracted by the judicious employment of ardent spirits, similar, if possible, to what the patient was in the habit of using previously to the accident.

Sometimes a change of air proves very serviceable, especially such as attends a sea-voyage. An army surgeon, stationed in the West Indies, had under his care six cases of fracture which remained ununited for a long time, but were all promptly cured on their being sent to Europe.

The local treatment must be regulated by circumstances. The precise cause of the tardy or imperfect union must, if possible, be clearly ascertained, and promptly remedied by appropriate measures. If it depends upon too much motion, greater quietude must be insured; any defect of contact must be redressed by a more accurate adjustment of the ends of the fragments; cold applications, if injurious, must be discontinued; and any extraneous intervening substance must be removed, either by calling into requisition the agency of the absorbent vessels, by pressure and other means, or, as in the case of a piece of dead bone, by the knife and forceps. The cause of the defective union having been thus remedied, the case will be likely, of its own accord, to proceed to its termination, the ordinary principles of treatment being, of course, to be observed.

Quite a number of local remedies have been employed in this affection. Among these the most important are friction, acupuncture, cauterization, subcutaneous division, setons and ivory pegs, and excision of the ends of the bone.

if this
m.

1. *Cutaneous friction*, either dry or moist, by a piece of flannel, is sometimes serviceable, especially in the case of a recent fracture.

If moist, various liniments, lotions, or unguents may be employed, and often with decided benefit, inasmuch as they tend to excite capillary action in and around the ends of the fragments, thus promoting the formation of callus.

2. *Compression* is occasionally worthy of trial. It may be made with splints of leather, felt, or binder's board and the bandage; or by an apparatus expressly constructed for the purpose, and intended to concentrate the pressure at the seat of the fracture. It must be steady and persistent, as well as uniform and gentle.

3. *Blisters* and *iodine* now and then act beneficially. Their application is particularly indicated when the want of union is dependent upon undue vascular excitement, and is, of course, entirely restricted to cases of recent standing.

4. *Friction* of the ends of the fragments against each other was recommended by Celsus, and has often been successfully practised by modern surgeons. It should be performed very gently, and be repeated every four, six, or eight days, according to its effects.

5. *Acupuncturation* with a long slender needle may be tried; or a small incision may be made over the seat of the injury, and a heated wire thrust between the ends of the fragments.

6. *Cauterization* of the integuments over the seat of the fracture with some caustic alkali, was recommended and successfully employed, in 1805, by Dr. Hartshorne, of this city. Sometimes the ends of the bones may advantageously be exposed, and rubbed over with nitrate of silver.

7. *Subcutaneous division* of the ligamentous bands between the two ends of the fragments has been successfully practised. The operation is performed with an ordinary tenotome, used in such a manner as to cut the parts as thoroughly as possible, especially over the extremities of the broken pieces.

Fig. 357.

8. The introduction of *ivory pegs* was originally proposed by Dieffenbach. They are from an inch and a half to two inches in length, conical in shape, and inserted into the ends of the fragments, previously pierced with a gimlet, such as is seen in fig 357. They must be forcibly driven into the openings, and be retained until the consolidating process is well advanced. Excellent and rapid cures have repeatedly followed this plan in my hands.

9. The *seton*, introduced into practice in 1802, by Dr. Physick, is ordinarily, in obstinate cases, the most certain method. It should be passed between the ends of the fragments by a long, thin, flat needle, sharp and lancet-shaped at the point; or, when this is impracticable, as close to the site of the fracture as possible, for experience has shown that this mode of performing the operation is nearly as successful as the usual procedure. The foreign

body is retained for a variable period, but generally until it has excited supplicative action. The patient is carefully watched; and if the pain and swelling become severe, the seton is at once withdrawn. Immediately after the introduction, the fragments are properly adjusted, and steps taken, if necessary, to maintain extension and counter-extension. In the first case in which this treatment was employed, the seton was retained many weeks, and the patient recovered the perfect use of his limb. The practice of withdrawing the seton at the end of a few days, as advised by some, is, I think, objectionable, for the reason that it will hardly have sufficient time to excite the requisite degree of inflammatory action.

10. *Perforation* of the ends of the bone by means of a peculiar instrument, fig. 358, an operation proposed, in 1853, by Professor Brainard, is sometimes serviceable. It consists in piercing subcutaneously the extremity of each fragment at several points, and cutting up the intervening tissue, with a view of exciting ossific action. The instrument is introduced in such a manner as not to wound any important structure, and is not withdrawn until the bone has been deeply, and, if need be, even extensively drilled, compression being then applied

to prevent subcutaneous hemorrhage. The operation is repeated every eight, ten, or twelve days until reunion has occurred, the limb being in the meantime kept quietly at rest in splints, and the treatment being in other respects conducted upon general principles.

Fig. 358.

Brainard's perforator.

Dr. Brainard's plan is always to begin the treatment with a small instrument, and to make only three perforations. The size of the former and the number of the latter are afterwards gradually increased until he succeeds in exciting more or less tenderness, pain, and heat in the parts, which are then kept up for some period. In favorable cases, a single operation may suffice; in others, it may be necessary to repeat it four, six, or even eight times. By carrying out these rules, Dr. Brainard states that he had, up to May, 1860, cured sixteen out of seventeen cases of ununited fracture or delayed union.

11. Finally, *excision* of the ends of the fragments, an operation devised, and first performed in 1760, by Mr. White, of England, is occasionally employed. Such an operation, however, should never be resorted to without due deliberation, and until after the failure of the more ordinary and simple means. To say nothing of the difficulty of its execution, it is by no means devoid of danger; indeed, it has not unfrequently proved fatal. A very free incision is made through the soft parts down to the ends of the broken bone, which are then brought out at the wound and retrenched, either with a stout knife, a saw, or a pair of pliers. Sometimes the mere removal of the cartilaginous crust is sufficient for the purpose, an object which may be easily accomplished with a scraper.

To maintain the freshened ends in accurate and steady apposition, it was proposed by Horeau, in 1805, to connect them together by means of a wire, and to retain them in this position until the completion of the cure. The procedure, which has, I believe, been generally condemned by European practitioners, has been frequently employed in this country, in consequence, apparently, of the high authority of Dr. J. Kearney Rodgers, who was the first to perform it on this side of the Atlantic. It consists, first, in cutting off the rounded ends of the fragments; secondly, in drilling a hole through each; and, lastly, in tying them firmly together with a silver wire, so as to keep them closely and evenly in contact during the consolidating process. It is generally imagined that this procedure is necessarily followed by violent inflammation, jeopardizing both limb and life; but this is an error. If the operation is carefully performed, and the after-treatment conducted upon proper principles, I believe that it will commonly be found to be entirely free from danger, while the utmost confidence may be placed in its efficacy. In nearly every instance in which I have had an opportunity of employing this method very little pain, inflammation, or fever occurred, and the result in all, except one, was most satisfactory. The following is an outline of the first case. It may be premised that the fracture was situated about three inches above the condyles, and that various remedies, among others Dr. Brainard's, had been faithfully but fruitlessly employed for its relief.

The patient being placed under the influence of chloroform, a longitudinal incision, about three inches in length, was made on the posterior aspect of the arm, through the triceps muscle, over the site of the fracture. The lower fragment was found to overlap the upper about one inch and a half. The ends of the bone were surrounded by a strong fibrous membrane, which was firmly adherent to the neighboring parts, and formed a sort of shut sac, in which the bone was imbedded. About an inch of the lower portion of the upper fragment, and half an inch of the upper portion of the lower fragment, were removed with a delicate

saw; but on account of their firm adhesions, and especially the shortness of the inferior piece, some difficulty was experienced in bringing them fully into view. The fragments were conical, rounded, smooth, and invested by a thick, fibrous periosteum: no synovial membrane or fluid existed. The next step of the operation consisted in drilling a hole into each extremity of the bone with a common gimlet, when a piece of wire was introduced to maintain them in apposition. The ends of the wire were twisted together, and allowed to protrude from the wound, the edges of which were approximated by three sutures and adhesive strips. Two splints and a roller being applied, the arm was firmly supported in a sling. There was very little hemorrhage, and no vessels required ligation. As the patient suffered a great deal of pain, a grain of morphia was given immediately after the operation. Very little local or constitutional disturbance followed, and nearly the whole wound healed by the first intention. At the end of the eighth week, the process of reunion had advanced so far that there was scarcely any perceptible motion.

In a fortnight after this, the wire being removed, the patient went home perfectly restored, the arm being about an inch and a half shorter than the sound one. It is proper to add that, by frequent passive motion, the elbow-joint was gradually regaining its original function.

In another case, that of a man, aged thirty-two, I treated with equal success, by an operation of this kind, an ununited fracture of the humerus of twenty-seven months' standing. The ends of the fragments were connected by two silver wires, which were permanently retained. The case is reported at length in the *North American Medico-Chirurgical Review* for July, 1861.

In performing excision, it is of paramount importance not to strip off the periosteum from the ends of the bone. In a case in which this accident happened to me through the carelessness of an assistant, violent erysipelas and necrosis were the consequence, endangering the safety both of limb and life.

The results of some of the above operations have been placed in a striking and interesting light by the statistics of Dr. Norris. Thus, in forty-six cases in which the seton was used, thirty-six were cured, three died, three were partially relieved, and five experienced no benefit. Of thirty-eight cases of resection, twenty-four were cured, six died, one was partially cured, and seven received no benefit. Of eight treated by cauterization of the ends of the fragments, six were cured. Of eleven cases in which friction was employed all were cured. It is worthy of remark that the treatment by the seton is less successful in fracture of the femur and humerus, than in that of any other bones. The danger of the more severe operations, especially the seton and resection, follows the same laws as in amputation, increasing with the size of the limb and its proximity to the trunk.

Whatever plan of treatment is adopted, it is impossible to be too attentive during the after-management of the case, especially in securing repose and accuracy of apposition to the ends of the fragments. The limb should be promptly put up in appropriate splints, which should be taken off from time to time, and carefully readjusted, in the same manner as in the treatment of a recent fracture. If the affected bone is one of the lower extremity, as the femur or tibia, it will be well to let the patient walk about in the open air upon crutches, particularly if his health has suffered much, the limb being supported by the admirable contrivance of

Fig. 359.

Smith's apparatus for ununited fracture.

Professor Smith, of the University of Pennsylvania. The apparatus, delineated in fig. 359, is constructed upon the same principles as the ordinary club-foot apparatus, consisting of a shoe, and of a leg and a thigh-piece, connected by hinges, and fastened round the limb by straps and buckles.

If any of the more severe operations are performed, the treatment, for the first few days, must be strictly antiphlogistic, the patient being most carefully watched, lest the inflammation, running too high, induce fatal consequences. If abscesses form, they should be promptly opened, and the utmost attention should, throughout, be bestowed upon cleanliness. The great danger to be apprehended after such operations is from erysipelas, pyemia, and phlebitis.

When all the known remedies, after a thorough trial, fail, and the limb is utterly useless, the only resource is amputation. Few cases, however, demanding such a terrible alternative, will be likely to arise in the present state of the science.

7. VICIOUS UNION OF FRACTURES.

In consequence of inattention of the surgeon, or a want of co-operation on the part of the patient, the ends of a broken bone sometimes unite in a very unseemly and injurious manner, entirely at variance with the beauty and usefulness of the affected limb, as represented in fig. 360. The deformity thus arising may be produced by the overlapping of the extremities of the fragments, attended, of course, with corresponding shortening; or it may be owing to the imperfect contact of the two ends, thus occasioning a certain amount of angular displacement, without any abbreviation of the length of the bone. In whatever way the deformity may be induced, it is obvious that it should be rectified at the earliest possible moment; for the longer the case is permitted to remain on hand, the more difficult it will be to afford relief. There are several procedures by which this object may be attained: 1st. Compression and extension; 2d, forcible flexion, or rupture of the callus; 3dly, subcutaneous division of the connecting medium; and, lastly, resection of the ends of the fragments. These methods are not, of course, all equally adapted to every case.

Fig. 360.

Viciously united fracture of the leg.

1st. The safest as well as the most simple procedure, but one which is applicable only in the more early stages of vicious union, consists in applying pressure opposite to the seat of the deformity, in the direction of its convexity. This may be efficiently done by means of appropriate splints and bandages, or with special apparatus provided with pads and screws, and appliances for making extension and counter-extension, particularly if there is marked shortening. It is not necessary to give any descriptions of these contrivances, as they may be readily fabricated by any ingenious mechanic, or even by the surgeon himself. No preliminary treatment will be required. It is absurd to suppose that the

callus may be softened by cataplasms and fomentations. The compression and extension should be made, at first, in as gentle a manner as possible, and be gradually increased and steadily maintained up to the point of easy tolerance, being occasionally intermitted if productive of pain, or likely to induce excoriation.

2dly. If the preceding method fail, or is inapplicable, recourse may be had to forcible extension, or rupture of the callus, thus compelling the displaced fragments to retrace their steps. This plan is also chiefly applicable to recent cases, but has occasionally been employed at the end of six, eight, ten, or even twelve weeks. I have myself successfully employed it at the expiration of the second month, and repeatedly within the first three weeks. It would be difficult to say when it should be refrained from; much will necessarily depend upon circumstances, for in one case the union may be firm in a month, while in another, perhaps, equally simple, if not more so, twice or thrice that period may elapse before it becomes consolidated. Perhaps as good a guide as any would be the existence of slight mobility between the ends of the fragments; if the union is very strong, the attempt to break it might be attended with fracture of the bone above or below the seat of the callus, and so complicate the case. Besides, the operation, except in the more simple forms of the affection, should not be undertaken without some preparation of the system, as it is occasionally followed by violent inflammation, erysipelas, abscess, and even death.

The operation is easily performed, before the union has become consolidated, simply by bending the limb over the knee, the patient being completely narcotized by chloroform, or by placing it upon a table, and applying pressure upon the distal extremities of the fragments. When the case is of long standing, and the union firm, the callus can only be broken by the employment of force applied by some special apparatus, designed either to act directly upon the callus, or by means of a weight appended to the distal extremity of the bone, the fractured part projecting slightly over the edge of the table, while the portion of the limb containing the upper fragment is carefully held down by assistants. It has been ascertained by experiments, performed by Jacquemin, Bosch, Esterlen, and others, that the callus of a thigh-bone, broken fifty days previously, will require a weight of from fifty to sixty pounds to sever the fragments at the seat of the callus.

3dly. When the union is complete, and the preceding methods have either failed or are inapplicable, trial may be made of the plan of Dr. Brainard, consisting in the partial division of the bone, the object being to weaken it in such a manner as to admit of its more ready fracture, or gradual bending by systematic compression, as the new osseous matter becomes softened from the effects of the inflammation consequent upon the operation. The perforation is effected subcutaneously by means of a drill, the point of which is about one-fourth of an inch in breadth. If it is intended to break the bone, this should be done at once, and the limb immediately placed in a suitable apparatus. If, on the other hand, the rectification is to be effected by bending, no formal measures, for this purpose, should be adopted for the first eight or ten days, or until the osseous tissues have undergone a certain amount of softening. Several cases, including one by Dr. Brainard himself, have been successfully treated by this plan since he first directed attention to it in 1859.

4thly. Other means failing, the only resource is *excision* of the bone at the seat of the fracture, along with a portion of the callus. The procedure, which took its rise in the early part of the sixteenth century, consists in exposing the extremities of the broken bone, and removing, with the saw or pliers, a sufficient piece to admit of accurate coaptation of the raw surfaces. The case is afterwards treated as one of ordinary compound fracture.

Finally, when relief is impracticable by any of the means now described, and the limb is sadly in the way of comfort and usefulness, the individual being perhaps obliged to labor for his daily subsistence, the only alternative is either to abandon him to his fate or to resort to amputation.

In 1851, I met with an instance of compound fracture of the tibia, in a young man of nineteen, in whom about two inches of that bone, near its middle, had

been shot away, two years previously, by a rifle ball. The fibula had remained intact, and with the aid of a stiff leather splint, forming a case which reached from just below the knee to within a short distance of the ankle, progression was performed with tolerable ease, though not without the use of a crutch. If the deficiency of bone had been somewhat less, I should have been tempted to cut away a portion of the fibula, and, after refreshing the end of the tibia, to approximate the bones by silver wire; fully anticipating a good cure.

8. DISEASES OF THE CALLUS.

The callus, like all new tissues, is liable to different diseases, both during its development and after its completion, more or less hostile to its welfare and perpetuity. Some of these affections have a local origin, some depend upon the state of the constitution, and others, again, seem to partake of the nature of both of these. Deficiency of the callus, although not, properly speaking, a disease, may, nevertheless, become a source of great difficulty on account of its inability to subserve the purpose of a supporting medium. The causes which may induce this condition, and the means of remedying it, when it exists, have already been pointed out.

An exuberant callus is by no means uncommon; it occasionally arises without any obvious cause, but more generally it is dependent upon the separation of the ends of the broken bone, as if nature were determined to effect union, despite the neglect of the surgeon. The annexed cut, fig. 361, from a drawing of a speci-

Fig. 361.

Exuberant callus after fracture of the thigh.

men in the possession of the late Professor Cobb, of the University of Louisville, affords a graphic illustration of an excess of this substance, obviously produced in this way. The fracture, which was oblique, and situated just above the middle of the right femur, had evidently occurred several years before death. The callus was exceedingly porous in its structure, as well as very brittle, and was eleven inches in circumference at the widest part, by six inches in length. From its superior extremity projected two processes, which overlapped the upper fragment, and must have materially impeded the action of the muscles of the limb.

Exuberance of the callus is occasionally produced by the presence of pieces of dead bone, which it thus imprisons as foreign bodies are sometimes inclosed by a cyst, or a wall of plastic matter. The sheath thus formed, however, is always imperfect, openings existing in different parts of its extent for the purposes, apparently, of drainage. Neglected or badly-treated comminuted fractures, caused by gunshot, railway, and other severe injury, are not unfrequently followed by an extraordinary redundancy of callus; and as the effect of this substance is to incarcerate the fragments of the broken bone, profuse discharge, generally of an unhealthy, fetid, and sanious character, may be thus kept up for almost an indefinite period. The proper remedy obviously is the extraction of the dead fragments, a procedure occasionally of a very embarrassing character, especially when the callus is situated in a bone thickly covered by muscles, or in close proximity with important vessels and nerves. In a case under my charge many years ago, I removed not less than twenty-four pieces of this kind, some of considerable size, having previously made a long incision over the tumor in front of

the thigh. With the aid of chisels, gouges, and pliers, riddance was achieved with but little loss of blood, and with no pain, as the patient was thoroughly under the influence of chloroform. Although the number of dead pieces was unusually great, such was the size and firmness of the callus that, notwithstanding it was obliged to be divided in almost every direction, no separation of the ends of the broken bone ensued, and the patient, after having recovered from the immediate effects of the operation, was able to walk about as before. The fracture had been caused nine months previously by an escapette ball.

The callus is subject to extraordinary *brittleness*, arising from an excess of earthy matter. Such an event may occur at a comparatively early period, as a result of causes whose true nature is not always easy of detection. I believe, however, that fragility of the callus is more frequently met with in persons of a gouty, rheumatic, and syphilitic state of the system, than in any other class of individuals. However induced, the slightest injury, as a mere twist of the bone, or even muscular exertion, is generally capable of fracturing it, and, consequently, of re-separating the ends of the fragments.

Finally, callus is subject to *softening*, disintegration, and absorption, if not, also, to fatty degeneration. The causes under whose influence these changes are effected are not always, or, perhaps, even generally, distinguishable. In some cases they are plainly owing to undue compression, as from tight bandaging; in others, they are induced by premature exercise. Occasionally, the absorption can be distinctly traced to the inordinate use of mercury, carried to profuse salivation; or it may depend upon a syphilitic taint of the system, especially when this affection has reached its third stage, in which the bones and periosteum are so constantly, and often so seriously, involved. But the most common cause, perhaps, of all, is an impoverished and diseased state of the blood, from the use of improper food, and especially from the want of a sufficient quantity of fresh vegetables and subacid fruits. The influence of ill-health arising from this cause upon the condition of the callus, was strikingly exemplified in Lord Anson's voyage to the Pacific Ocean, in which many of the crew suffered severely from scurvy. It was noticed that those who had formerly had fractures were attacked with absorption of the callus, speedily terminating in separation of the ends of the broken bone. Cicatrices, whether the result of the healing of wounds or of ulcers, experienced a similar fate, the parts breaking out into open sores, remarkably pale, languid, flabby, and difficult of cure. Similar effects are occasionally observed to follow attacks of typhoid fever and anemic states of the system, however engendered.

The treatment of softening and breaking down of the callus must depend upon the nature of the exciting cause, due inquiry into which should, therefore, always be made as a preliminary step. Tight bandages and splints are removed; premature exercise is avoided; iodide of potassium and mercury are administered if the cause is obviously of a syphilitic nature; scurvy is relieved by a change of diet, especially the use of subacid fruits and vegetables; and anemia is met with tonics and stimulants, as iron and quinine, with milk punch and nutritious food.

SECT. XVII.—FRACTURES OF PARTICULAR BONES.

I. HEAD AND TRUNK.

FRACTURES OF THE NASAL BONES.

Falls and blows are the causes of this fracture, which may be either simple or complicated; oblique, transverse, or longitudinal; limited to one bone or extended over both. It is usually attended with severe injury of the soft parts, and sometimes with fracture of the ascending process of the superior maxillary bone. Occasionally, again, but more rarely, there is a separation of the nasal cartilages, or fracture of the ethmoid bone, the vomer, or turbinated bone. The symptoms are generally well marked, except when there is considerable swelling

of the integuments, in which case the nature of the lesion may easily be overlooked, perhaps much to the detriment of the patient. If an examination be made soon after the occurrence of the accident, the nose will be found to be out of shape, from displacement of the fragments, one of which may be depressed towards the nostril, while the other may form an unusual prominence beneath the skin. Crepitation is also commonly distinguishable, especially if the fracture is multiple, or the bone broken into several pieces. In all cases, the point of the finger should be passed over the surface of the nose, with a view of ascertaining whether there is irregularity or mobility, as there will be almost sure to be if there is a fracture. If, after this, there is still some doubt, it will be well to introduce a large probe, metallic bougie, or grooved director into the nostril, for the purpose of making counter-pressure, while pressure is applied in the opposite direction with the end of the finger. When there is a wound, denuding the bone, the diagnosis will seldom be difficult.

More or less bleeding generally attends this accident; occasionally, indeed, it is quite profuse, and in one instance it is said to have proved fatal. Another symptom which is sometimes present, is emphysema at the root of the nose, extending along the eyebrows. It usually comes on within a short time after the accident, and is owing to an escape of air from the nostril across a rent of the mucous membrane into the subcutaneous cellular tissue. It is in itself of no moment, as it usually disappears spontaneously in a few days. Sometimes violent cephalic symptoms attend these fractures, depending upon the intimate connection between the nasal and frontal bones, which permits the jarring effects of the blow or fall to be communicated to the brain and its envelops.

Fracture of the nasal bones is not always free from danger, although, in general, the patient recovers without any untoward symptoms. Real danger to life is to be apprehended only when there is serious cerebral involvement, as when the lesion is associated with fracture of the cribriform plate of the ethmoid bone, separation of the dura mater at the anterior part of the base of the skull, copious effusion of blood, or severe concussion of the brain. Under such circumstances, the patient may die from shock, from compression, or from inflammation. The prognosis should, therefore, be guarded, especially as the degree of danger cannot always be estimated by the amount of visible injury. If the fracture is multiple, or the bones are crushed in, more or less deformity may be expected after the cure.

The *reduction* is generally easy. The patient being seated upon a chair, with his head resting against the breast of an assistant, any depression that may exist is to be remedied by means of a female catheter or grooved director, inserted into the nostril, and made to bear against the displaced fragment until it resumes its proper level. Sometimes a good deal of pressure and counter-pressure will be necessary, while at other times hardly any manipulation will be required, the mere passage of the finger over the seat of the fracture being sufficient to adjust the fragments. When the nasal septum, or the perpendicular plate of the ethmoid, is thrown out of place, restoration may be effected by means of the finger, or some suitable instrument, introduced into the nostril.

When the fragments have been restored to their natural level, they will usually retain their position with little or no difficulty. Sometimes, however, they have a tendency to cave in, or to fall asunder, in spite of everything that can be done to counteract it. The best remedy is a stout, adhesive strip, carried across the bridge of the nose from one cheek to the other; the plaster promptly adheres to the skin, and assuming the shape of the nose, effectually prevents further displacement. The older surgeons were in the habit of counteracting this occurrence by stuffing the nostrils with dossils of lint, smeared with ointment, and frequently changed for the sake of cleanliness. Subsequently, metallic tubes were recommended, and in modern times tubes of gum elastic have been used. All such contrivances are now very properly dispensed with; or, if they are ever employed, it is in cases where it is impossible, in consequence of the manner in which the bones have been crushed, to remedy the displacement in any other way.

The symptoms which usually follow this accident, such as inflammation of the

pituitary membrane, and swelling of the nose and face, are combated by general and local bleeding, purgatives, and other antiphlogistics. The brain is carefully watched, and any untoward symptom met at the earliest possible moment. Hemorrhage is restrained by cold applications and elevation of the head and arms; if obstinate, by plugging up the nostrils.

FRACTURES OF THE NASAL CARTILAGES.

The nasal cartilages are sometimes broken, or broken and partially detached from the nasal and maxillary bones, the most common cause of the accident being a violent blow or fall, inflicting perhaps at the same time serious injury upon the soft parts. The nature of the case can seldom be mistaken. When the cartilages are displaced inwards the nose will necessarily be more or less flattened and depressed, and the effects will assume increased importance if the lesion is conjoined with fracture of the nasal bones and the cartilaginous septum. The treatment must be conducted upon general principles. The great aim should be to preserve the contour of the nose; hence, after having restored the parts to their proper relations, it may be necessary to plug the nostrils with lint, well oiled, a metallic tube having previously been inserted to facilitate respiration. Leeches may be required to moderate inflammation.

In the case of a man, aged forty, brought to the Clinic of the Jefferson Medical College, in 1861, by Dr. McWhinney, the septum, broken into several pieces four months previously, encroached so much upon the left nostril as to cause almost complete obstruction to respiration on that side. In order to afford relief I was compelled to cut away the whole of the offending part with a probe-pointed bistoury. The nose seemed to have been very little deformed by the accident.

FRACTURES OF THE UPPER JAW.

A fracture of the upper jaw implies the application of direct mechanical injury, in a concentrated and severe form. No ordinary force could produce such a result. In a few instances it has been caused by contre-coup, the head and lower jaw being wedged in between two hard, resisting bodies. Portions of the alveolar process, of variable shape, and even of large size, are sometimes broken off in extracting a tooth. There is nothing definite at all in regard to the situation of the fracture, since it may affect any portion of the bone, its body, ascending process, horizontal plate, or alveolar process. It is always accompanied by severe injury of the soft and hard parts, and is usually of easy recognition, simple inspection, or touch, commonly sufficing for the purpose. The accident is apt to be followed by violent inflammation, requiring prompt measures for its relief.

In the *reduction*, pressure and counter-pressure are chiefly relied upon, the parts being moulded gently into their natural position by the fingers, either alone, or aided, as in fracture of the horizontal plate of the bone, by the grooved director inserted in the nostril. If the alveolar process has suffered, it may become necessary to secure its proper maintenance by tying together several of the contiguous teeth with thin silver wire. Whatever may be the nature of the case, the rule is, if possible, to save all, and take away nothing.

FRACTURES OF THE MALAR BONE.

Fracture of the malar bone is so very rare as to require merely a passing notice. Like fracture of the upper jaw, it is always produced by direct violence, is invariably attended with severe contusion, if not with other injury of the soft parts, is, in general, readily recognized, is liable to be followed by high inflammation, and is easy or difficult of management according to the presence or absence of displacement. When the broken part is sunk down beyond its natural level, an attempt may be made to raise it, especially if there is already a wound denuding the bone, and admitting of the insertion of a suitable lever; if not, an incision is made, provided it seems probable that there will be unsightly deformity after the cure, if the fragment is left in its abnormal situation. Such a procedure,

is condemned by some authorities, is much better than leaving the bone exposed. Fracture of the zygomatic process of the temporal bone, also extremely rare, is treated upon similar principles.

FRACTURES OF THE LOWER JAW.

The lower jaw-bone may be broken in any portion of its extent, not excepting the symphysis. Fracture here, however, is unusual, and is met with chiefly in subjects, before the complete union of the two opposite halves of the bone. The most common site of fracture is the body of the maxilla, towards its

Fig. 362.

Fracture of the jaw.

anterior extremity, as in fig. 362, and next in point of frequency, at least according to my observation, its ascending ramus. The condyle, neck, and coronoid process are seldom broken. The fracture may be transverse, oblique, or longitudinal; single or multiple; simple or complicated. When the bone yields at two points, there will necessarily be three fragments, and cases occur in which the number is still greater, the bone being literally crushed. Thus, Houzelot has published the particulars of one in which the bone was broken, in a fall from a height, at both condyles, through both coronoid processes, and at the symphysis. Some-

times the lesion is limited to the alveolar process, or to this process and the body of the jaw. In either event, there will be involvement of the gums and teeth, with, in the former, extensive separation, if not complete evulsion, of the latter. Occasionally a longitudinal fracture of the body of the bone is intersected at each extremity by a transverse or oblique one. The accident, which rarely occurs before the age of manhood, is much more frequent in males than in females.

The most common cause of fracture of the inferior jaw is direct violence, as a blow, or kick. I have seen not less than four instances in which it was produced by a blow with the fist upon the chin or side of the bone, one of the cases being in a healthy lad between fifteen and sixteen years of age; the others, persons between twenty-five and thirty-two. A very common cause of this fracture is the fall of a horse. Dentists often break off portions of the alveolar process in their effort to extract teeth. Sometimes frightful injury is produced in this way. A violent action is capable of breaking the lower jaw. An old man, aged upwards of seventy, an out-patient of the Jefferson College Clinic, presented himself to Professor Pancoast in January, 1857, on account of a fracture of the neck of the jaw, caused the night before in a violent paroxysm of coughing. The symptoms were unmistakable. The explosion of powder in firing off a pistol in the mouth has also been known to give rise to the accident. Finally, the jaw is sometimes broken on one side by a blow upon the opposite, or by a stroke.

The symptoms of fracture of the body of the lower jaw are generally so well marked as to render it easy of diagnosis. Crepitation may almost always be felt in moving the fragments, and upon looking into the mouth the teeth will usually be found to have lost their natural relations. There is also a perceptible inequality at the inferior border of the bone, which may be increased by motion, and which is of itself sufficient to point out the site of the injury. When the jaw has given way on each side, the central fragment will be drawn downwards by the muscles of the throat, the front teeth will fall from their normal position, and the mouth will be open and distorted.

If the ramus of the jaw is broken, there will be a grating noise at the site of the fracture, and excessive pain near the ear. From the fact that the masseter muscle is attached to, and covers in, both fragments, there is usually any considerable displacement.

A fracture of the *neck* of the bone is easily detected, unless the subject is very fat, by the crepitation produced on moving the jaw, by the preternatural mobility in front of the ear, and by the manner in which the body of the bone is dragged forward by the action of the external pterygoid muscle. Similar symptoms will characterize fracture of the condyle of the bone.

In addition to the symptoms now described as indicative of fracture of different portions of the inferior maxilla, there will be more or less impediment in speaking and swallowing, difficulty in closing the mouth, and inability to masticate. The patient experiences severe pain at the seat of fracture, aggravated by motion and manipulation; the soft parts are usually considerably contused, if not also lacerated; and there is often smart hemorrhage, either from wound of the mucous membrane or rupture of the inferior dental artery.

Simple fractures of this bone usually get well in from four to five weeks, without ultimate deformity or functional impediment. Those of the neck require a longer time, and more care in their management, than those of the body and ramus. Complicated fractures of the jaw are often followed by severe suffering, caused either directly by the resulting inflammation, or by some of its more serious consequences, as abscess, caries, and necrosis. I have known, more than once, a patient to become much emaciated from his inability to take appropriate nourishment during the long confinement of the parts.

During the *reduction* of fractures of this bone, the patient should be seated upon a chair, his head being supported upon the breast of an assistant, and firmly held. The surgeon, passing his fingers along the base of the jaw, supposing that it is the body that is broken, moulds the parts into proper shape, and then, closing the mouth, sees that the lower teeth rest fairly against the upper. When the fragments overlap each other, they must be drawn in opposite directions, when the slightest pressure will generally suffice to effect their reduction. If any of the teeth are loosened, or partially forced from their sockets, and they are perfectly sound in other respects, they should by all means be retained, being secured, if need be, to the adjacent ones, by a strong ligature, or a thin silver wire. It was formerly the custom to treat such teeth as extraneous bodies, under the belief that they were incapable of re-adhesion; but more enlarged observation has shown the fallacy of this opinion, and the practice would, therefore, be highly reprehensible.

The fracture being reduced, as may always be known by the evenness of the dental arch and of the inferior margin of the jaw, a piece of pasteboard, or, what is preferable, of felt, is immersed in hot water, and accurately moulded to the base and sides of the jaw. This is then lined with wadding, and covered with a light compress, long enough to extend from the angles of the jaw nearly to the chin,

Fig. 363.

Gibbon's jaw bandage.

Fig. 364.

Barton's jaw bandage.

when it is confined by a roller carried round the top of the head in the form of the figure 8, one portion of the bandage lying in front, the other behind the ear.

The lower jaw being thus pressed firmly against the upper, the bandage is next conducted across the chin and the occiput above the ears, so as to give the fragments due support in front. This mode of dressing, which is as simple as it is efficient, I have employed for many years, in preference to every other of which I have any knowledge. If there is any unusual tendency to anterior displacement, it may readily be counteracted by a stout adhesive strip, extending from the chin along the lower part of the face to the side of the occiput.

The annexed cuts, figs. 363 and 364, represent the bandages of Gibson and Barton, formerly so much employed in this country. Their mode of application will readily be perceived by an examination of the drawings.

When there is no displacement of the fracture as sometimes, though rarely, happens, an equally simple, but less efficient contrivance will answer the purpose,

Fig. 365

Pasteboard compress.

as a pasteboard mould, fig. 365, and a four-tailed bandage. The centre of the bandage being applied to the chin, the posterior tails are pinned to the front, and the anterior to the back of the patient's night-cap. I had recently under my charge a case of fracture of this bone, unattended with displacement, where a rapid and perfect cure was effected without any dressing at all.

Professor Hamilton, in the treatment of fracture of this bone, employs an apparatus consisting of three straps, one of which, composed of firm leather, extends round the jaw and head in the direction of the coronal suture, while the other two, made of strong linen webbing, pass horizontally round the head, above the ear, the anterior being buckled to the forepart, and the posterior to the backpart of the vertical one. The great advantage of this contrivance, which is represented in fig. 366, is the strong support it gives to the parts, thus effectually preventing displacement of the ends of the fragments.

Fig. 366.

Hamilton's apparatus.

It was formerly customary, in bandaging fractures of the lower jaw, to fill up any irregularities that might exist between the two rows of teeth by the interposition of pieces of cork; but the practice, if I mistake not, is no longer pursued by the scientific surgeon, and yet it is easy to conceive of a case where, in consequence of the loss of all the incisor, cuspid, and bicuspid teeth, and the retention of some of the molar, some artificial support might become necessary for the proper maintenance of the fragments. In such an event the services of a skilful dentist should be called into requisition.

In fracture of the neck or condyle of the jaw, the maintenance of the reduction is always peculiarly difficult, on account of the action of the external pterygoid muscle. The most effective means of counteracting this disposition is to confine a thick, graduated compress behind the angle of the bone, the treatment being, in other respects, the same as in fracture of the body of the jaw.

When the fracture is comminuted, it will sometimes be found exceedingly difficult, if not impossible, despite our best directed efforts, to keep the fragments on a level with each other, such being their constant tendency to displacement. To rectify this tendency, it may be necessary to connect the contiguous teeth of the adjoining pieces with delicate silver wire; or, what is better, because

efficient, some of the teeth may be secured to a thin silver plate, interposed between them and the cheeks.

Wounds, contusions, and hemorrhage, complicating these fractures, are managed upon general principles; inflammation is combated by the usual antiphlogistics; loosened teeth and necrosed pieces of bone are removed as soon as they are detached; and the parts are kept steadily at rest, renewal of displacement being guarded against by the most sedulous attention both of the patient and the surgeon. The food should consist of slops, as grated cracker and milk, broths, gruel, and similar articles, introduced into the mouth with a small spoon. The custom which formerly prevailed of conveying nourishment into the stomach by means of a tube passed through the nose, has become obsolete, as well as the still more reprehensible practice of extracting one of the front teeth, to afford room for feeding the patient. After the case has advanced for several weeks, a semi-solid, farinaceous diet may be allowed.

In compound and comminuted fractures of the lower jaw, especially when caused by gunshot injury, the secretions of the mouth and of the salivary glands always become excessively foul and abundant, and are liable, if swallowed, to give rise to a low typhoid condition of the system, followed gradually, if not soon relieved, by death. In order to prevent such an occurrence, the greatest attention should be paid to cleanliness, the mouth be frequently washed with chlorinated soda, or Labarraque's solution, in union with honey, abscesses promptly opened, dead pieces of bone removed, and the strength supported with quinine, iron, opium, and alcoholic stimulants.

FRACTURES OF THE HYOID BONE.

Fracture of the hyoid bone is extremely rare. The cause of this immunity is to be found in the great mobility of this bone, and in the protection which it receives from the lower jaw. The accident is usually occasioned by falls or blows, or by the pressure of the thumb and fingers in attempts at choking. An instance is mentioned where it was produced by muscular action, the patient having fallen violently backwards upon his head. Persons who commit suicide by hanging occasionally break this bone with the rope. The fracture is generally seated in the large horns of the bone, sometimes in both, at other times only in one. It is liable to be complicated with injury of the larynx, lower jaw, and other parts, the skin being usually bruised and discolored. The patient is unable to swallow, to articulate distinctly, and to move his tongue, except in the most limited degree, and then not without great suffering, and, perhaps, a sense of suffocation. Crepitation is generally sufficiently evident, especially during deglutition and when the index finger is placed in the throat in contact with the smaller fragments, the corresponding finger resting upon the neck. The pain is very acute, and is aggravated by the slightest motion. Sometimes the patient is conscious of a peculiar crushing sound at the moment of the accident. Occasionally there is laceration of the mucous membrane of the fauces, followed by pretty copious hemorrhage, as in the interesting case reported by Professor Wood, of Cincinnati.

Fracture of the hyoid bone, although not in itself necessarily dangerous to life, often becomes so in consequence of its complications; but, even in the most simple cases, it is generally exceedingly troublesome on account of the great mobility of the fragments, and the tendency in the supervening inflammation to be followed by severe swelling. Occasionally abscesses form, the detached piece becomes necrosed, and the neck is pierced with fistulous orifices, which are slow in healing. The accident has hitherto been noticed chiefly in aged subjects, probably on account of the great brittleness of the bone at that period of life.

In the *treatment* of this fracture, attention must be paid to the position of the head, which should be inclined forward, and maintained in a state of the utmost quietude, by an appropriate bandage secured around the chest. If there is much displacement, readjustment should be attempted by means of the finger in the throat while counter-pressure is made externally. Perfect silence should be

enjoined. If there be much pain and swelling, leeches should be applied to the neck, followed by saturnine and anodyne fomentations; the bowels should be freely evacuated by stimulating injections, and fever should be combated, if need be, by bleeding at the arm. For the first few days, the patient should abstain as much as possible from food and drink; at all events, he should take no more than what is just sufficient to sustain life. If he cannot swallow, a stomach tube must be used, but, in general, this will not be necessary. After the swelling of the neck has measurably subsided, an attempt should be made to keep the fragments in place by compresses and adhesive strips. If necrosis occur the dead bone should be promptly extracted. In ordinary cases, the fracture will unite in from six to eight weeks.

FRACTURES OF THE LARYNX.

The cartilages of the larynx may be broken by external violence, as a blow, the kick of a horse, or the pressure of the thumb and fingers. The accident is most liable to happen in elderly subjects, after the partial ossification of these bodies, and the one which is most apt to suffer is the thyroid. The fracture may be simple, comminuted, or complicated. The only reliable diagnostic symptoms are crepitation, displacement of the fragments, and preternatural mobility. The common accompaniments are difficulty of articulation, breathing, and deglutition, loss of voice, cough, hemorrhage, and probably also emphysema, from an escape of air into the surrounding cellular tissue.

Most of the cases of this accident prove fatal, either soon after its occurrence from suffocation, or more or less remotely from the effects of inflammation.

Fractures of the laryngeal cartilages, unless attended with serious displacement, require little else than the ordinary antiphlogistic measures, with perfect quietude of the head and neck. When there is extensive separation of the fragments, interfering with respiration, laryngotomy may be required, both to afford an opportunity to readjust the broken pieces, and to prevent death by suffocation.

FRACTURES OF THE CLAVICLE.

The clavicle, owing to the delicacy of its structure, its exposed situation at the top of the chest, and its connection with the shoulder and arm, is extremely liable to break. Of 2358 cases of fractures of different pieces of the skeleton, referred to by Malgaigne, 228 occurred in this bone, and of this number nearly three-fourths were observed in the male, thus showing a remarkable disparity in regard to the relative frequency of the lesion in the two sexes. The accident is not peculiar to any particular period of life; I have witnessed it in a child under six months of age; and Dr W Keller, in 1860, showed me a case, in which it took place in the fœtus in the womb, in consequence of a fall of the mother upon the wheel of a carriage, at the eighteenth week of gestation. The child, at the time of my examination, was several months old, and the seat of the fracture, which had involved the right clavicle, near its middle, was indicated by a marked forward angular projection of the ends of the fragments, which, however, were firmly united, the consolidation having been completed before birth. A similar case was shown to me, in 1861, by Dr. William B. Atkinson, the fracture having been produced by a blow from a door upon the abdomen when the mother was gone seven months in pregnancy.

Fractures of this bone may be simple, compound, or comminuted; unilateral or bilateral; transverse or oblique; partial or complete. A transverse fracture of the clavicle is among the rarest of accidents; as for myself, I have never met with an instance of it, either in the living subject, or in any of the specimens in our museums. The bone nearly always gives way obliquely, the ends of the fragments being generally rather long and sharp, and often distinctly serrated. When very sharp, they sometimes project through the skin, or, at press against it with so much force as to cause severe uneasiness. It is very uncommon for the

several points; such an accident, in fact, can only happen from the application of direct force. Simultaneous fracture of both clavicles has been observed only in a few instances. I have two clavicles in my possession, from the same subject, which were broken at the same point, but whether by the same accident, I am unable to say.

The *seat* of fracture is usually at or near the middle of the bone, where it is thinnest and weakest. Of twelve preparations now before me, it is about this point in eight; in three it is towards the acromial extremity, and in one towards the sternal. Fracture of either end is, I suppose, very uncommon, as I have never met with an instance, either during life or after death.

Great *displacement*, as shown in fig. 367, generally attends fractures of the clavicle; now and then, however, we see cases where the broken ends maintain

Fig. 367.

Fracture of the clavicle.

their natural relations, as I have myself noticed in four instances. Such an event can occur only when the fracture is incomplete, as sometimes happens in children, or when the periosteum is only partially divided, and the patient has taken care not to permit any dragging of the shoulder. Generally the outer fragment will be found to be drawn downwards, forwards, and inwards, by the weight of the

limb and by the action of the deltoid, small pectoral, and subclavian muscles; the inner, on the contrary, is usually somewhat raised by the sterno-cleido-mastoid, but not so much as its extraordinary prominence would seem to indicate, its tendency to displacement in that direction being pretty effectually counteracted by the great pectoral muscle and the costo-clavicular ligament. These appearances are well seen in fig. 368. In fracture of the extremities of the clavicle, the loss of apposition is usually very slight, its occurrence being prevented by the manner in which the bone is attached to the scapula and the sternum. In comminuted fracture, the displacement may be so great as to render reposition impracticable, the middle fragment being occasionally tilted perpendicularly up.

Fig. 368.

Complete oblique fracture, near the middle of the clavicle.

When the bone gives way external to the coraco-acromial ligaments, the outer fragment is sometimes turned round at a right angle with the inner.

The accident is generally *caused* by indirect violence, as a fall upon the shoulder, in which the sternal extremity of the bone is impelled by the weight of the body, at the same time that the acromial end is thrust forcibly in the opposite direction by the object struck against. Not unfrequently, however, it occurs from direct injury, as a blow or fall. I remember an instance in which it was produced by the recoil of a shotgun. Children often break their collar bones by tumbling out of bed, or rolling down a flight of stairs. Several instances have been reported in which the accident was caused by the inordinate action of the pectoral and deltoid muscles. When both clavicles are broken, one generally gives way by indirect, and the other, immediately after, by direct force.

The symptoms of fracture of the clavicle are generally well marked. The

shoulder has a singularly sunken appearance, being drawn downwards, forwards, and inwards by the weight of the limb and the action of the muscles, especially the deltoid and small pectoral; the head and trunk are inclined towards the injured side; there is impossibility of rotating the arm, or of carrying the hand to the face; and the patient commonly supports the elbow in order to take off the weight of the limb from the broken bone. Upon examination, the seat of the fracture is generally readily discovered by the eye, the deformity being nearly always extremely conspicuous; and the finger, as it traces the outline of the bone, cannot fail to detect any existing irregularity. Crepitation is elicited by taking hold of the elbow and pushing the arm upwards, outwards, and backwards, in a direction opposite to that of the displacement. The same procedure will serve to efface the deformity, which, however, will be instantly reproduced upon the removal of the restraint. When the fracture is imperfect, or unattended with displacement, the diagnosis can be established only, as a general rule, by a careful digital examination, aided by the alternate elevation and depression of the shoulder.

Although, in general, the patient is unable, in fracture of the clavicle, to carry his hand to the head, I have met with some very striking exceptions to this rule, both in children and adults. In a man, aged forty, whom I saw along with Dr. Dennis O'Reilly, the patient could execute this movement with quite as much facility as with the other limb. He could even swing the limb about without any pain or inconvenience. The fracture, caused by a fall on the edge of a doorstep, was situated towards the acromial extremity of the bone, and was attended with marked displacement. Children, according to my observation, present this anomaly much more frequently than grown persons.

My experience is that fractures of the clavicle are seldom cured without more or less deformity, whatever pains may be taken to accomplish the object. In some of my cases I have found it impossible, despite all I could do, to effect accurate restoration of the ends of the fragments. This difficulty will, I think, be most likely to occur when the fracture is seated at or towards the acromial extremity of the bone, in which the outer fragment is frequently, if not generally, thrown backwards in such a manner as to render it almost impossible to bring it to its natural position. From the cases that I have seen of this fracture, as treated by other surgeons, and from the numerous specimens of it to be found in our museums, it is certain that a cure without deformity is very uncommon. It is gratifying, however, to know that deformity, even when considerable, does not generally at all impair the usefulness of the limb. Union will, of course, be materially retarded, but in time nature will succeed in rounding off the ends of the fragments, and in connecting them firmly together, either by an osseous clasp or a kind of bridge. When union fails to occur, the power of the arm is always weakened. In ordinary cases, consolidation takes place, in the adult, in about five weeks; in children, in eighteen or twenty days.

In the *reduction* of fracture of the clavicle, all that is generally necessary is to take hold of the elbow and to carry the arm upwards, outwards, and backwards, a procedure which rarely fails to effect approximation of the ends of the fragments. If anything more is required, the fingers may be passed along the broken bone, so as to assist in moulding the parts into a proper shape. During the treatment the indication is to maintain the shoulder in the position here adverted to; and for this purpose it will be necessary to support the limb in such a manner as to bring the elbow against the antero-lateral aspect of the chest, while the forearm rests against the front, the fingers lying across the opposite clavicle. To confine the parts in this position, the best dressing is plaster, cut into adhesive strips of appropriate length to reach round the limb and shoulders, so as to form, in the first place, a kind of immovable sling, and, secondly, to fasten the arm to the side of the trunk. When this dressing is carefully applied, it answers the object much better than any of the numerous contrivances that have been invented for the cure of this fracture. The strips, which should be an inch and a half to two inches in width, may be so arranged as to exert a certain degree of pressure, through the medium of a compress, upon the seat of the fracture, or, if this be deemed unnecessary, the same

may be kept under constant surveillance by letting it remain uncovered. The dressing need not be renewed oftener than once or twice during the treatment, if, indeed, at all. If the skin is covered with hair, the surface should previously be well shaved. When there is a tendency in the shoulder to sink forwards and inwards, it should be counteracted by a wedged-shaped pad in the axilla, the large extremity being directed upwards, and confined by suitable tapes to the opposite shoulder. In general, however, I have not found it necessary to resort to such an expedient.

Next to the adhesive strip dressing, which I have used and recommended for years past, in the treatment of fractured clavicle, I prefer a very simple contrivance, somewhat like that of Velpeau. It consists of a wedge-shaped pad, and an ordinary roller, carried round the limb, shoulder, and trunk, so as to confine the parts in the position already indicated. The different turns of the bandage should be secured to each other by a large number of pins, which thus serve to keep them effectually in place. I seldom use less than from thirty to forty, and I find that, when this is done, the bandage may be worn with great advantage for several successive weeks, without the slightest derangement. In warm weather, however, it should be removed at least every ten days for the sake of cleanliness, especially if the patient perspire much.

An ingenious apparatus for the treatment of fracture of the clavicle has been devised by Dr. R. J. Levis, of this city, which, combining most of the principles of that of Dr. Fox, so long and so extensively used in this country, commends itself by its simplicity, lightness, efficiency, and cheapness. It consists of a short, firm, axillary pad, fastened by two straps which are buckled to a broad band. From the front of this band, which crosses the upper part of the back, and descends on the anterior portion of the chest, giving a firm surface of support, is suspended a sling in which the elbow is sustained. On the back of the sling, behind the elbow, is fastened a strap which crosses the trunk obliquely, and coming in front on the sound side, is buckled there to the end of the broad band.

In adjusting the apparatus, the pad is introduced into the axilla by passing the arm through the opening between the straps above the pad. The wide band

Fig. 369

Levis's apparatus.

Fig. 370.

is then thrown across the shoulders, the elbow placed in the sling, and the long strap, connected with the posterior part of the sling, carried across the back and finally buckled at its front attachment to the broad band.

In removing the apparatus from the patient, it is only requisite to loosen the front attachment of the latter strap, which will allow the sling to drop from the elbow.

The extra buckle, which is noticed at the front end of the broad band, comes into use when the apparatus is reversed for the opposite shoulder.

The apparatus of Dr. Levis may be made of any strong material, as drilling, webbing, or soft leather, and the different pieces of which it is composed may be fastened together with buckles, buttons, or tapes, as may be most convenient. Fig. 369 exhibits the various parts of the apparatus, and fig. 370 a front view of its application.

The French surgeons were formerly much in the habit of using the stellate or figure-of-8 bandage, represented in fig. 371. It consists of a wedge-shaped pad and a long roller, carried alternately round each shoulder, after which the arm and forearm are secured to the side and front of the chest in the usual manner. The bandage of Desault, once so much employed in this country, has

Fig. 371.

Figure-of-8 bandage.

Fig. 372.

Boyer's apparatus.

Fig. 373.

Henton's yoke splint, modified by Day.

fallen into deserved neglect. Boyer's apparatus for fracture of the clavicle is represented in fig. 372.

Dr. Dugas, of Georgia, is in the habit of treating fractures of this bone simply with a triangular piece of thick, unbleached muslin, to each angle of which is attached a bandage from three to four yards in length by three inches in width. The apparatus, which is described at length in the *Southern Medical and Surgical Journal* for 1852, is applied in such a manner as to form a sling for the elbow and forearm, at the same time that the arm is firmly secured to the side. No pad is used.

When both clavicles are

tured, the treatment should be conducted upon the same principles as when one alone of these bones is broken. Import

such circumstances, from the use of a yoke, invented by Dr. Hunton, the end of the splint being furnished with holes, and allowed to project several inches beyond the shoulders, thus affording excellent points of support for the tapes of Fox's apparatus. The annexed drawing, fig. 373, represents this apparatus as modified by Day.

When an axillary pad is used in the treatment of fractures of this and other bones, care must be taken to avoid undue compression, otherwise it may occasion severe suffering and even gangrene. A case has been reported in which, from this cause, the brachial artery was obliterated.

FRACTURES OF THE SCAPULA.

Fractures of the scapula are extremely uncommon. Of 1,902 cases of fractures of different pieces of the skeleton, treated at the Middlesex Hospital, London, only 18, according to Lonsdale, occurred in the shoulder-blade. At the Hôtel-Dieu, at Paris, the scapula, in 2,358 cases, was broken only in 4. On the contrary, a remarkable disproportion of such cases sometimes occurs in the hands of particular surgeons. Thus, Dr. Dugas has met with four cases of this accident, and Dr. Bulloch, of Savannah, with not less than six, although neither has seen an unusual number of other fractures. The injury may show itself in various forms and directions, and may occupy either of the two processes of the scapula, its neck, its body, or its inferior angle.

a. The *acromion process*, fig. 374, being the most exposed portion of the scapula, is more frequently broken than any other part of this bone, the accident

Fig. 374.

Fracture of the acromion process.

being usually caused by a blow upon the top of the shoulder, or by violence applied directly to the process itself. It may also be produced by force transmitted along the humerus by a fall upon the elbow or palm of the hand. There is reason to believe that what is sometimes regarded as a fracture of this process is nothing but a separation of its epiphysis, which frequently fails to coalesce with the rest of the bone until late in life. I have seen quite a number of examples of this kind, and there is not a cabinet, however small, that does not furnish similar proof. The osseous consolidation is occasionally postponed until after the age of forty. The fracture is generally somewhat oblique, and its signs are so peculiar as to be characteristic. The natural rotundity of the shoulder is destroyed; the outer fragment is drawn down by the weight of the arm, which hangs motionless by the side of the body; the head of the humerus can be felt

in the axilla; there is a depression at the situation of the fracture; the distance between the shoulder and the top of the sternum is diminished; and a distinct crepitus may be detected on pushing up the arm in contact with the displaced fragment. In addition to these symptoms there is acute pain at the seat of the injury; the limb cannot be raised by its own efforts; and the patient inclines his head towards the affected side, and supports the forearm as in fracture of the clavicle.

The only accident with which fracture of the acromion process is liable to be confounded is dislocation of the humerus; but from this it may, in general, be easily distinguished by the sunken appearance of the shoulder, the mobility of the outer fragment, the existence of crepitation, and the ready effacement of deformity by the elevation of the arm, followed by its instantaneous recurrence when the surgeon relinquishes his hold. In dislocation, the acromion process stands out in bold relief, crepitation is absent, and the head of the humerus is firmly fixed in its abnormal position.

The union is usually ligamentous instead of osseous, owing to the difficulty which is experienced in preserving the contact of the fragments. This occur-

rence will be more likely to happen when the tip of the acromion is broken off than when the fracture is seated near its root.

The leading indications in the *treatment* of this lesion are, first, to secure the arm and forearm firmly to the antero-lateral part of the chest; and, secondly, to raise the humerus against the top of the shoulder-joint, so that its head may serve as a splint for the broken process. For this purpose, the same bandage is used as for fracture of the clavicle, but the axillary pad is dispensed with, lest the broken piece should be pushed too far outwards.

b. In fracture of the *neck* of the scapula, fig. 375, the coracoid process and glenoid cavity are detached from the rest of the bone in an oblique direction. The accident is one of great rarity, so much so that many surgeons have doubted the possibility of its occurrence. It can be produced only by great direct violence, though one case is known where it was caused by muscular contraction in a young lady, in the act of throwing her necklace over her shoulder, the bone having doubtless been exceedingly brittle from some organic defect.

The symptoms are always well marked. The acromion is unusually prominent, the head of the humerus is felt in the axilla, the shoulder has a flattened appearance, the limb is lengthened, the coracoid process is thrown down below the clavicle, between the deltoid and pectoral muscles, severe pain and numbness are experienced in the axilla, and a distinct crepitus is perceived on rotating the arm upon the scapula. The accident bears, at first sight, considerable resemblance to dislocation of the humerus into the axilla; but from this it may always be readily distinguished by the facility with which the parts may be restored to their natural situation, by the immediate return of the symptoms when the limb is left to itself, and by the existence of crepitus. From fracture of the neck of the humerus it may be known by the circumstance that, in the latter, the shoulder retains its rotundity, and that the limb, instead of being lengthened, is shortened; the acromion also is much less prominent.

In two cases of this accident, observed by Dr. Dugas, the fracture, produced by a blow upon the shoulder from a falling tree, was instantly followed by paralysis of the limb and cessation of pulsation in all its arterial trunks; a consequence, evidently, of injury done to the axillary nerves and vessels. Treatment having been neglected, no union took place, and the arms never recovered their functions.

This fracture is retained with difficulty, and is liable to be followed by stiffness of the shoulder-joint, atrophy and paralysis of the muscles of the arm, and other disagreeable symptoms. It is managed in the same manner as fracture of the clavicle, with an axillary pad, the elbow being kept well raised, and the scapula thoroughly steadied until reunion has occurred. If the parts are much contused, leeches, fomentations, and other antiphlogistics may be required. Passive motion should be instituted at the end of three weeks, and afterwards renewed every few days. Consolidation may be expected in two months.

It is not improbable that the edges of the glenoid cavity may occasionally be broken off, either by direct force, or in consequence of the sudden and violent propulsion of the head of the humerus. It is remarkable, however, that the existence of such a lesion has never been demonstrated by dissection. It is likely that some of the bad forms of luxation of the shoulder, in which the reduction is maintained with great difficulty, and which terminate in permanent ankylosis and ruin of the articulation, are

Fig. 375.

Fracture of the neck of the scapula.

tion? The subject is worthy of greater attention than it has hitherto received. In the annexed cut, fig. 376, copied from Mr. Fergusson, the fracture extends through the glenoid cavity.

Fig. 376.

Fracture of the glenoid cavity.

c. The *coracoid process* is sometimes broken in consequence of a severe fall or blow, generally a short distance from its tip, the fracture being usually accompanied with great contusion of the soft parts, and fracture of the

Fig. 377.

Fracture of the coracoid process.

acromion, clavicle, or humerus. The accident, which is of very rare occurrence, is characterized by inability to raise and adduct the arm, by preternatural mobility, by depression of the detached fragment by the conjoined action of the small pectoral, two-headed flexor, and coraco-brachial muscles, and by the detection of crepitus on moving the arm upon the shoulder, the finger being placed between the deltoid and great pectoral muscles. The adjoining sketch, fig. 377, taken from a preparation in Professor Neill's collection, afford an illustration of a well-marked specimen of fracture of the coracoid process.

The treatment consists in confining the arm and forearm to the anterior part of the chest by means of a bandage and sling, care being taken to keep the elbow well raised, so as to fix the top of the scapula, and support the broken part. By this proceeding, the pectoral and flexor muscles of the arm are relaxed, and prevented from acting injuriously upon the tip of the coracoid process.

Violent inflammation, occasionally terminating in profuse suppuration, and even in death, is apt to follow this accident, owing to injury inflicted upon the pectoral muscles and the axillary vessels, nerves, and glands. The matter being deep-seated, has great difficulty in reaching the surface, and is, therefore, disposed to burrow extensively among the surrounding structures. The proper remedy is an early and free incision at the most dependent portion of the abscess.

Fig. 378.

The ordinary situation of fracture of the body of the scapula.

d. The *body* of this bone, fig. 378, rarely suffers from fracture, and then only from great direct violence, causing at the same time serious injury in the soft parts. In one case, recorded by a foreign writer, the accident is said to have been produced by muscular action. The fracture exhibits no regularity in regard to shape, is often multiple, and is rarely attended with displacement.

Fracture of the body of this bone occasionally extends through its spine, so as to divide it into two nearly equal vertical parts, as in a case which I attended, in 1860, with Dr. Rohrer. The patient was a strong laboring man, aged thirty-seven,

who, in a fall from a scaffold, struck his right shoulder violently against the corner of a plank, fracturing the scapula through its spine and body near its centre. Five days had elapsed when I first saw him. The parts were then much swollen and ecchymosed, the top of the shoulder was depressed and forced forward, and there was a marked irregularity between the ends of the fragments, the outer being drawn downward and forward, so as to form with the posterior a kind of triangle, thus , with distinct crepitation upon the slightest motion. The man was unable to put his hand to his head, but could easily touch the opposite shoulder. He experienced great pain at the time of the accident.

To steady the shoulder-blade, which is the leading indication in the treatment of this accident, two large, narrow, and moderately thick compresses should be placed along its axillary and vertebral borders, and confined by a broad roller carried round the upper part of the trunk; or, instead of this, they may be secured by means of large adhesive strips. The arm and forearm are then fastened to the anterior part of the chest, as in fracture of the clavicle.

In the case above described, apposition was easily maintained by a modification of Desault's apparatus.

e. Fracture of the *inferior angle* of this bone is occasionally met with; it is marked by preternatural mobility, by displacement of the smaller fragment by the action of the great serrated muscle, and by acute pain at the seat of the injury. The diagnosis may readily be established by fixing the top of the scapula and moving the lower angle; if they follow each other, it will be an evidence that there is no fracture, and conversely. The treatment is the same as in fracture of the body of the bone.

FRACTURES OF THE RIBS.

The central ribs, from their exposed and fixed position, are much more liable to be broken than the upper and lower; the former being safely protected by the collar-bone, the scapula, and numerous thick and strong muscles, while the latter, from their great shortness and mobility, can readily glide out of the way of any injury that might otherwise affect their integrity. However this may be, they usually yield at their more prominent points, in an oblique direction, a transverse fracture being here, as elsewhere, an unusual occurrence. The accident is most frequent in elderly subjects, children and young persons seldom suffering. The causes are twofold, external violence and inordinate muscular action. The first produce their effect either in a direct or in an indirect manner; most commonly in the former, as when the ribs are struck by a fall or a blow, or when the body is traversed by the wheel of a carriage. In the second case, the ribs, being impelled by forces operating upon their extremities, break at or near their middle, as when, for example, the back of the chest is pressed against a wall by a railroad car. When these pieces are acted upon directly, their curvature is diminished, but increased when the violence is applied indirectly. I recently attended an old lady who had the eleventh rib of the left side fractured by her granddaughter, a stout girl of fourteen, by throwing her arms round the body, in a friendly embrace, on going to bed. In 1837, a number of persons met with severe injuries of this kind, by being severely squeezed in a crowd in the Champs de Mars, at Paris. A rib has occasionally been broken by mere muscular contraction in the act of coughing and sneezing, but such an occurrence is unusual, and implies an abnormal condition of the osseous tissue.

The number of ribs broken at any one time is variable. The largest number I have ever met with was eight; sometimes, however, it is still greater. In a specimen in my collection, from the body of a woman, aged upwards of seventy, who threw herself out of a second story window, there are not less than fifty-nine fractures, twenty-seven on the right side and thirty-two on the left.

The fracture may occur simultaneously upon both sides, as in the case just mentioned; and it may be either simple, or complicated with other injury, as rupture of the intercostal artery, wound of the soft parts, and laceration of the pleura and lung.

A fracture of the more superficial ribs is often easily detected simply by placing the hand upon the part where the violence is supposed to have been inflicted, and requesting the patient to cough. The bones being thus obliged to undergo a sudden motion, the lesion, if any exist, will almost be sure to show itself by the occurrence of crepitation and preternatural mobility. If, however, the fracture is placed under cover of a large quantity of muscular and fatty matter, as it will be in certain situations in robust and corpulent subjects, the surgeon may find it very difficult, if not impossible, to detect it. Should this be the case, the examination should be repeated again and again, until the diagnosis is satisfactorily determined. The difficulty will be increased if only one rib is broken, or if the broken bone retains its normal position; on the other hand, the diagnosis may be established at a glance if the injury is extensive, and attended with marked displacement, as when it has been inflicted by a fall, or by the kick of a horse. Finally, the patient, as he takes a deep inspiration, is occasionally sensible of a peculiar cracking noise at the site of the fracture.

The pain which attends the fracture of a rib is generally very acute, and, without being strictly limited to the seat of the injury, is always more severe there than anywhere else; it is exasperated by the respiratory movements, and is commonly so violent as to compel the patient to breathe entirely with the aid of the diaphragm. Every attempt at a full inspiration, coughing, or sneezing, is followed by exquisite suffering. In very aggravated cases, the pain resembles that of pleurisy, and is accompanied with intense thoracic oppression. If the lung has been wounded by a spicule of bone, or the projecting end of the broken rib, there will probably be spitting of blood, if not hemoptysis, and, perhaps, also emphysema. In the latter case, the air may fill the cavity of the chest, causing a hollow sound on percussion, and total extinction of the respiratory murmur, attended with great increase of dyspnoea. Should the air escape into the subcutaneous cellular tissue, as when there is injury of the costal and pulmonary pleuræ, it will form a diffused tumor, soft and crackling, and at once indicative of the nature of the case. More or less copious hemorrhage will be present when there is laceration of an intercostal artery, the blood sometimes passing into the chest, but more generally escaping externally.

The ribs being firmly connected to the costal cartilages in front, and to the vertebræ behind, it is impossible for them to undergo any shortening when they are fractured, or for the ends of the fragments to overlap each other, as in fracture of the long bones. Derangement, however, may take place in almost any other direction, although the angular displacement is by far the most common, and this may be either outwards, as in fig. 379, or inwards, as in fig. 380, according

Fig. 379.

Angular displacement outwards.

to the manner in which the injury was inflicted, the latter being usually produced by direct violence, the former by indirect. It is seldom, however, that more than one end of the bone is displaced in this direction at the same time. The Mütter

cabinet contains several specimens in which one of the fragments projects above the level of the others.

Fig. 380.

Angular displacement inwards

Fractures of the ribs are not always devoid of danger, even when they are perfectly simple, or apparently free from all complications. Their number may be so great as to cause severe shock, or such an amount of local and constitutional disturbance as to produce alarming illness and even death. The danger is generally greater, other things being equal, in fracture of the upper ribs than in fracture of the middle and lower, because a greater degree of violence is generally required to produce it. A fracture complicated with injury of the lung and pleura must be looked upon as a serious occurrence, as it is sure to be followed by more or less inflammation, if not by hemorrhage and pneumothorax. An escape of air beneath the skin is a matter of no consequence, except as indicating serious lesion within the chest. Hemorrhage from a wound in an intercostal artery is usually rather troublesome than dangerous.

The following case, which fell under my observation in 1854, strikingly illustrates the danger of fracture involving a number of ribs, without any very serious complication.

A tall, slender woman, aged fifty-four, fell, while the railroad cars were in the act of running off the track, against the top of one of the seats, breaking eight of the ribs on the left side. The second, third, fourth and fifth bones were fractured in front, about two inches and a half from their cartilages, while the eighth, ninth, tenth and eleventh had given way behind, within a short distance of the spine. There was no displacement of any of the fragments, excepting the posterior one of the tenth rib, which projected slightly inwards towards the chest, and pierced the pleura. Excessive pain, dyspnoea, crepitation, and preternatural mobility marked the accident. The cough was violent, and the patient was unable to lie in bed. The ordinary treatment was pursued, but without any material benefit, and the woman died exhausted at the end of the fourth day. The left side of the chest contained about three ounces of coagulated blood, evidently furnished by the wounded pleura, but there was no sign of inflammation, except at the seat of the upper fracture, where the serous membrane was a little roughened by lymph and slightly ecchymosed. The lung was free from disease. All the other organs were sound.

Fracture of the ribs, without complication or displacement, is best managed by encircling the chest with a broad bandage, drawn sufficiently tight to compel the patient to perform respiration chiefly by the diaphragm. The intercostal muscles, and consequently, also, the ribs, must be rendered perfectly passive. The bandage should be from eight to ten inches in width, and long enough to extend at least twice round the body. The ends being fastened by two pieces of tape, a scapulary is attached to prevent the cloth from slipping. Or, instead of this, the chest may be encircled once and a half with broad strips of adhesive

plaster, so arranged as partially to overlap each other, and drawn with sufficient firmness to keep it perfectly motionless. Female patients may wear, with great advantage, their usual corsets, a triangular piece being cut out in front and below to allow due play to the diaphragm. In addition to the bandage, I usually employ a thin, flat compress, as a small folded napkin, to give greater support to the broken bone.

Similar dressings will answer when there is outward displacement of the fragments, only that it may be necessary to employ a somewhat thicker compress; but how are we to proceed when the end of the broken bone is driven inwards towards the chest, perhaps into the pleuritic sac and the lung? Should it be let alone, or should we follow the practice of the older surgeons, and make an attempt to elevate it with the finger, the gimlet-screw, or the trephine? It is evident that counter-pressure by means of thick compresses applied to the extremities of the rib can be of no use. If there is a wound, it might be easy enough to insinuate a small lever, and raise the bone, if not to its proper level, at least out of harm's way. As for myself, I should certainly not meddle with the case, even if the depression were very considerable, unless the symptoms were most urgent, and not then until I had given a fair trial to other means, as the bandage and ordinary antiphlogistics, especially the lancet and full doses of anodynes. If relief did not soon follow, or if the suffering, instead of diminishing, rapidly increased, and it was perfectly obvious from the violence of the pain, cough, and expectoration, that a piece of rib had been forced into the substance of the lung, I should then not hesitate to make an attempt to raise the offending fragment, or, failing in this, to remove it altogether. Cases requiring such heroic measures must be exceedingly rare, and hardly deserve formal mention in a work of this kind.

Wounds, contusions, and hemorrhage, consequent upon these accidents, must be treated upon general principles. If air collect within the chest in sufficient

Fig. 381.

Fractured ribs united by osseous matter.

quantity to cause excessive respiratory embarrassment, it should be let out with a delicate trocar, introduced through a valve-like opening in the skin. Pain and cough are relieved in the usual manner. If the local distress is urgent, leeches may be used, followed by the application of a large opiate plaster. The patient observes the semi-erect posture in bed, and remains within doors until he feels that he can exercise with impunity. If his bandage become

insupportable, he must not lay it aside, but simply slacken it.

The annexed drawing, fig. 381, affords an illustration of the manner in which the ribs are sometimes tied together by bony matter after fracture. It was taken from a specimen in my collection.

Cases occasionally occur where the rational symptoms of fracture of the ribs exist, but the characteristic signs are absent. Under such circumstances the rule is to treat the patient precisely as if the bones were really broken.

FRACTURES OF THE COSTAL CARTILAGES.

Fracture of the costal cartilages is so uncommon that a long time elapsed before surgeons were willing to believe it a possible occurrence. That it does take place, however, is a fact fully established by modern observation; and, what is remarkable, experience has shown that it is not always necessary for these bodies to be ossified before they can be broken, although this is usually the case. The accident is invariably produced by external violence, either directly or indi-

rectly applied, and is observed chiefly in elderly subjects. The fracture is usually single, and the pieces which are most liable to suffer are the fifth, sixth, and seventh, owing probably to their great length and to their exposed situation. The direction of the fracture is commonly somewhat oblique; the ends of the fragments often overlap each other, the posterior passing in front or behind the anterior, which, from its connection with the sternum, serves as the fixed point.

The symptoms of a fractured costal cartilage are similar to those of a fractured rib. The accident may be simple or complicated, but, in general, it is comparatively free from danger. The broken ends are united through the intervention of a clasp or ferule of bone, in which the cartilaginous tissue remains measurably unchanged. The reduction and maintenance of this fracture are often very difficult, but by a careful observance of the rules laid down in speaking of fracture of the ribs, the surgeon may usually succeed in effecting a cure in six or eight weeks. Malgaigne advises the use of a broad truss for keeping the fragments together, the pad making direct but gentle pressure upon their extremities. In obstinate cases, the ends of the fragments might be united with silver wire.

FRACTURES OF THE STERNUM.

This bone may give way in almost any portion of its extent, but more commonly near its middle, the direction of the fracture being generally somewhat oblique. A few instances of longitudinal fracture of the sternum have been observed. Diastasis of this bone is exceedingly infrequent, and no well authenticated example of fracture of the ensiform cartilage has been recorded.

Blows, kicks, and falls are the ordinary causes of fracture of the sternum. Chaussier relates a case which was occasioned by violent muscular contraction during labor, and several examples of a similar nature have been related by more recent observers. In 1858, Dr. Rohrer showed me a case, in a large, heavy, muscular man, aged forty-seven, who had received a transverse fracture of the upper part of this bone, from inordinate contraction of the sterno-cleido-mastoid muscles, in jumping, in a state of intoxication, off a shed eleven feet high. The heels striking the ground obliquely, threw the body violently backwards, the head and neck coming in contact with the edge of a board. The fracture was, doubtless, occasioned by the effort which the man made to regain his equilibrium.

The ends of the fragments either preserve their natural relations, or, if there is any displacement, it will be in the direction of the thoracic cavity; and when this is the case the broken bone may lacerate some of the contained viscera, cause effusion of blood into the anterior mediastinum, and perhaps induce emphysema by wounding the lungs.

When the fracture is attended with displacement, it may usually be detected at a glance, or by merely passing the finger over the line of injury. Grating, sometimes audible at a considerable distance, and increased at every respiratory effort, is generally present. The pain is excruciating; recumbency is, for a time at least, impracticable; and there is great dyspnoea, along with cough, spitting of blood, and other symptoms of internal injury.

In Dr Rohrer's case there was, even several days after the accident, a marked depression at the site of fracture, with considerable irregularity of the ends of the fragments, which was much increased when the patient sat up in bed. During recumbency, when he coughed hard, the hand, placed over the seat of the injury, could distinctly feel the fragments ride over each other, the upper evidently moving more freely than the lower. It seemed as if their edges had been beveled off obliquely, that of the lower piece from above downwards and from before backwards, that of the upper in the opposite direction. Two or three times, as the man coughed, a distinct grating noise was heard. Percussion upon the spine, immediately opposite the fracture, had also the effect of displacing the ends of the fragments, and a similar result followed when firm pressure was made upon the anterior surface of the fragments. When the case was first seen, the upper fragment was thrust backwards towards the thoracic cavity, fully one inch behind the level of the other; but it was easily restored to its natural situation.

by bending the chest backwards over a thick pillow. The pain at the seat of fracture was comparatively slight; but very distressing in the back of the neck and head. There was neither cough nor emphysema, and the fever that followed was slight.

The *prognosis* varies. When the thoracic organs have sustained much violence, the patient may die from shock, hemorrhage, or emphysema; or, if he is so fortunate as to survive the immediate effects, he may perish from the secondary consequences of inflammation of the lungs, abscess of the mediastinum, or disease of the bone itself. In the Mütter Museum there is a skeleton in which a fracture of the sternum, near its middle, had undergone perfect repair, although not without considerable deformity from the want of accurate apposition. Evidence of fracture exists in a number of other bones, and there must also have been a remarkable predisposition in the individual to the development of exostoses.

The *treatment* is, in great measure, restricted to the application of a compress and bandage, to afford support to the chest, and assist in securing the quietude of the intercostal muscles. If there is serious internal complication, local and general bleeding, active purgatives, antimonials, and anodynes, may be required, along, perhaps, with medicated fomentations. If the fracture is simple, no attempt should be made to rectify the depression of the offending fragment, unless it is perfectly clear that it is causing compression of the heart or lung. In such a case, and also when there are loose pieces of bone projecting into the chest, restoration should promptly be effected at all hazard. To accomplish this, the patient may lie across a table, upon a kind of double inclined plane, in order to extend the spine, and afford the muscles attached to the extremities of the sternum an opportunity of drawing the ends of the broken bone asunder. While this is being done, pressure should be made upon the parts in a direction opposite to that of the displacement, at the same time that the lungs are, if possible, thoroughly distended with air. Or, this failing, the bone, the body being still in this position, may, perhaps, be raised by a small, delicate elevator, used subcutaneously, supposing a wound does not already exist. If this also prove unsuccessful, I should not hesitate, in view of the urgency of the case, to apply the trephine, or to remove a sufficiency of bone with a Hey's saw. A similar proceeding may become necessary when matter forms in the anterior mediastinum, or when a portion of the sternum is ulcerated or necrosed.

FRACTURES OF THE VERTEBRÆ.

The vertebræ are so compactly constructed, so strongly articulated, and so thickly covered by muscles as to render their fracture a matter of great difficulty. The most common causes are violent blows or falls, giving rise at the same time to severe injury of the soft parts. Occasionally the lesion is produced by contre-coup, as when a person falls from a great height and alights upon his feet, the force being transmitted along the extremities and the pelvis to the spinal column, where, concentrating itself upon a particular bone, it breaks its substance or severs its ligamentous connections. Any part of such a bone may give way, its body, plates, and processes being all liable to yield under the influence of the causes here mentioned. The symptoms and effects of this lesion must be considered with reference to the different divisions of the vertebral column, as the cervical, dorsal, and lumbar, each possessing certain peculiarities growing out of its relations with the spinal cord and the nerves which are detached from it.

In fracture of the *cervical vertebræ*, the symptoms vary according to the situation of the affected bone. Thus, if the lesion is above the fourth piece, or the principal origin of the phrenic nerve, and the spinal cord is at all compressed, the diaphragm will be paralyzed, the respiration will be more or less embarrassed, and death will follow, either immediately, or within a short time after the accident. If, on the other hand, the fracture is seated below this point, there will be paralysis, to a greater or less extent, of the superior extremities, difficulty of breathing, relaxation of the anal sphincters, incontinence of urine, and tympa-

nitic distension of the abdomen. When the fracture is oblique, one arm is sometimes more disabled than the other. Recovery may ensue if the injury done to the soft parts is not very severe, but in most cases death takes place in from three to five days.

In fracture of the *dorsal vertebræ*, the upper extremities will be free from paralysis, unless the injury is seated very high up, when they may participate in this affection with the sub-diaphragmatic portions of the body. The bowels, in either case, will be torpid and distended with gas, and the bladder will be unable to expel its contents. Life is seldom prolonged beyond a fortnight, although in some rare cases it lasts for several months. In this event, the bowels and bladder may partially regain their original tone, but the urine soon becomes loaded with phosphatic matter, and the lining membrane of the bladder suffers from chronic inflammation, adding thus greatly to the patient's distress.

When the *lumbar vertebræ* are broken, the lower extremities are generally deprived both of volition and sensibility, the feces pass off involuntarily, and the bladder is unable to contract upon its contents. Life usually lasts longer than in fracture of the dorsal vertebræ, the paralysis not extending so high up, and consequently not involving so many important organs. In the majority of cases, the patient dies in five or six weeks; but sometimes, though rarely, he survives a much longer time, his bladder, meanwhile, suffering as in fracture of the other divisions of the spine.

Priapism is an occasional symptom; it is evidently dependent upon lesion of the spinal cord, and is most liable to occur when the fracture is situated in the neck. It is generally associated with paralysis, and is nearly always an early phenomenon, manifesting itself within the first forty-eight hours, and often continuing, more or less obstinately, up to the moment of dissolution. It is sometimes present even when the patient is completely deprived of sensibility and consciousness.

The symptoms here enumerated may follow fracture of any portion of a vertebra, except, perhaps, that of the spinous process, when the suffering is generally comparatively slight, unless the lesion is complicated with serious mischief of the spinal cord.

Fracture of the *spinous processes* of the vertebræ occasionally occurs independently of the bodies of these pieces, as seen in fig. 382, the usual exciting cause being a blow, fall, or kick. Preternatural mobility and lateral displacement, with more or less contusion and discoloration of the soft parts, are the most reliable phenomena.

Fig. 382.

Fracture of the spinous process.

Fig. 383.

Fracture of the vertebral arch.

Fracture of the *arches* of these bones, of which the accompanying cut, fig. 383, affords a good illustration, is often comminuted and attended with depression of the fragments, some of which may be driven into the substance of the spinal cord, crushing and pulpifying it. It is generally produced by violence directly

applied, and is frequently quite as dangerous as a fracture of the bodies of the vertebræ.

The *transverse* processes of the vertebræ can only be broken, as a general rule, by excessive force, as the passage of a ball, or a fall from a considerable height. Hence the result of such accidents is commonly very unfavorable.

The *diagnosis* of fracture of the spine is usually a matter of inference rather than of positive conviction. Its most important elements are the mode of production of the injury, and the paralysis of the extremities, but it should be recollected that this symptom may depend entirely upon lesion of the spinal cord, unconnected with fracture of the vertebræ. Owing to the small size of these bones and the manner in which they are covered in by the muscles of the back, it will generally be impossible to detect either crepitation, deformity, or preternatural mobility. All these phenomena may, however, be present in fracture of the spinous processes.

Dissection, after an injury of this kind, will usually reveal more or less displacement of the broken bone, which is sometimes quite comminuted, laceration of the connecting ligaments, and injury of the spinal cord, with more or less extravasation of blood in the spinal canal and the surrounding parts. The cord is compressed, bruised, pulpified, perhaps nearly completely severed, pieces of bone sometimes being imbedded in its substance, as shown in fig. 384.

The *prognosis* of these accidents may be inferred from what has been said respecting their symptoms and effects. If the patient escapes immediate destruction, he will almost certainly succumb under his

suffering at no very remote period; or, if his life should be spared, he will be doomed to carry on a miserable, bedridden existence, palsied and otherwise crippled in the exercise of some of his more important functions.

In the *treatment* of this accident, very little is to be done in the way of restoring displaced fragments, all such attempts being not only uncertain, but, even if successful, likely to aggravate the danger by the additional mischief that is inflicted upon the spinal cord. The same remark is applicable to the operation of cutting down upon the injured part, and removing the offending portion of bone with the trephine or saw, as originally proposed by Mr. Henry Cline, of London, and practised by him and other surgeons. In all the cases, amounting probably to about a dozen, in which this procedure has been employed, including those of Barton, Rogers and Potter, no particular benefit has followed; a circumstance that might have been expected

when it is recollected how seriously the spinal cord is generally injured by the depressed fragments. The operation, although not without difficulty, on account of the great depth at which the offending bone is situated, may be executed with but little loss of blood; and, I must confess that, notwithstanding the want of success which has hitherto attended it, I should feel very much tempted to resort to it, if the symptoms were such as to render it certain that the lesion was accompanied by depression.

Whether an operation is performed or not, it is the duty of the surgeon to adopt prompt measures for the prevention of inflammation. With this view blood is taken freely from the arm, and also by leeches from the seat of the injury; the bowels are relieved by purgatives, or stimulating enemas, and pain is alleviated by full doses of anodynes, combined, if there is much fever, with antimonials. The bladder is carefully watched, and the urine, if retained, is drawn off regularly twice or thrice a day, instead of allowing the catheter to remain permanently in the bladder. The patient is kept on his back, upon an air-bed, his head resting upon a low pillow, and his position being as seldom changed as possible. Great care is taken not to turn him upon his side, as he might be almost instantly asphyxiated while in this situation, from the imperfect descent

Fig. 384.

Fracture of the vertebræ.

of the diaphragm, caused by the pressure of the abdominal viscera, on account of the paralyzed condition of the abdominal muscles, and their consequent inability to offer any resistance to the weight of the body. After the lapse of a few weeks, the back and limbs should be frequently rubbed with stimulating liniments, and a large issue should be established in the vicinity of the injury with the Vienna paste or the actual cautery. Along with these means, trial may be made of small doses of strychnia, in union with iron and quinine. All treatment of this kind will, of course, be useless when the spinal cord has been crushed.

When the lesion is confined to the spinous processes, the fragments must be moulded into shape, and retained by two long, thick compresses, stretched along the side of the spine, and secured with a circular bandage, fastened by a scapulary. If the broken pieces, however, are much shattered, so as to preclude the possibility of their reunion, they should be removed.

Fracture of the *odontoid process*, although very uncommon, is sometimes met with, and generally proves promptly fatal from injury done to the spinal cord. Now and then, however, a remarkable exception is found. Thus, in a case related by Dr. Willard Parker, the patient survived the accident five months, when he suddenly expired from displacement of the process, during some inadvertent movement of the head, a result favored by the destruction of the occipito-axoid ligament. The dissection showed that the odontoid process had been completely broken off, and that its lower extremity had been turned backwards towards the spinal cord, as exhibited in fig. 385. The patient, a man, forty years of age, had been thrown violently from his carriage, alighting, about fifteen feet off, upon his head and face. After recovering from the immediate effects of the accident, he was able to resume his business as a milkman, which he followed, diligently and uninterruptedly, every day for four months. He complained, however, constantly of pain in the occipito-cervical region, and was always obliged to support his head, which he was incapable of rotating. The only visible deformity was a protuberance of the neck, just below the base of the occiput, to the left of the median line, with a corresponding indentation.

Fig. 385.

Fracture of the odontoid process of the axis, a, broken surface; b, odontoid process.

FRACTURES OF THE PELVIC BONES.

a. The *innominate bone* may give way in various parts of its extent, but the one which is most apt to suffer is the upper crest, owing probably to its exposed situation. The acetabulum is sometimes broken by a severe blow upon the hip, or by a counter-stroke, as when a person falls upon his knee or foot, thereby driving the head of the femur into the pelvis. In the adjoining cut, fig. 386, from a preparation in the possession of Professor Neill, the fracture runs in a semicircular direction through the acetabulum.

In young subjects, the innominate bone is occasionally separated at the acetabulum into its three primitive pieces. Whatever may be the site, form, or extent of the fracture, it can happen only through the agency of direct mechanical violence, which, at the same time, generally seriously compromises the soft structures, both

Fig. 386.

Fracture of the acetabulum.

outside and inside the pelvis. The most frightful accidents of this kind that have fallen under my observation have been the result of railway injury, caused by the body being jammed in between a car and a wall, literally crushing the bone, and fatally implicating the bladder and other organs.

The *symptoms* will necessarily vary according to the seat and extent of the fracture. When the bone has given way at the cotyloid cavity, the nature of the case may usually be recognized by the circumstance that the head of the femur is drawn upwards, and the great trochanter somewhat forwards, so that the limb is diminished in length, and the foot inverted. When the head of the thigh-bone is impacted in its new position, the limb may be firmly fixed, as in dislocation, but, in general, it will be found to be more or less movable, and to afford a distinct crepitus when an attempt is made to rotate it.

b. In fracture of the *pubic* and *ischiatric* bones, the corresponding limb is either somewhat shortened, or it retains its natural length; the fragments are

Fig. 387.

Fracture of the pubic and ischiatric bones.

pushed either directly downwards, forwards towards the femur, or backwards towards the acetabulum; the patient is unable to sit, stand, or walk; and on placing one hand upon the ilium, and the other upon the pubes, crepitation may usually be perceived. A well characterized fracture of the pubic and ischiatric bones is delineated in fig. 387, from a preparation in the collection of Professor Neill.

c. Fracture of the crest of the *ilium* is characterized by more or less displacement,

preternatural mobility, and crepitation; the pain is severe, and progression impracticable. The nature of the accident is sometimes rendered apparent by the existing deformity and by slight manipulation.

Fracture of these bones is generally produced by severe injury, and hence it is nearly always complicated with serious lesion of the soft parts. Cappelletti met with a case in which their branches were broken by violent muscular contraction, as the patient, a man, aged fifty-four, was jumping out of his carriage while the horses were running away.

Besides the above symptoms, denotive of fracture of different parts of the innominate bone, there is always more or less contusion of the external soft parts, and not unfrequently, also, serious injury of the pelvic viscera, followed by loss of motion of the inferior extremities, retention of urine, and other distressing affections. The prognosis should, therefore, be very guarded, as such accidents are generally fraught with danger, death often occurring in a few days from inflammation or extravasation of urine, or at a later period from abscess, phlebitis, and other mischief.

Of 65 cases of fracture of the pelvic bones, analyzed by Dr. J. W. Lyon, 41 recovered, and 24 died, one-half of the latter having labored under rupture of the bladder.

Owing to their peculiar character, it is usually found very difficult to reduce these fractures, or to prevent relapse after this has been done. To effect restoration, our main reliance must be upon pressure, while the maintenance is best accomplished by well arranged compresses, secured by a body bandage. When no displacement exists, all such dressings may very properly be dispensed with. In either case, the utmost quietude is enjoined; the patient must lie upon his back, his shoulders being elevated, and the thighs flexed, to relax the muscles about the pelvis; inflammatory action is promptly dealt with, and the bowels are relieved by stimulating purgatives and enemata. The bladder is carefully watched, retention of urine being relieved by the catheter.

d. The *sacrum* may be broken by falls, blows, gunshot violence, and similar injury. The fracture is generally discoverable, especially when there is displacement, by mere manual examination, as the patient lies upon his abdomen. It is attended with severe pain at the affected part, and great difficulty in walking,

accompanied, when there is lesion of the sacral nerves, with paralysis of the lower extremities, retention of urine, and involuntary discharge of the feces. The danger attending this accident is always considerable, on account of the mischief done to the soft parts; hence, even if the patient survive the immediate shock of the injury, he may perish afterwards from the effects of inflammation of the pelvic viscera.

When there is displacement of the fragments inwards, reposition may be attempted by the insertion into the rectum of a stout bougie, a lithotomy scoop, or a vesical sound, care being taken not to do any injury to the mucous membrane; or, if the displacement is very slight, the bone may be left in its new situation, as no harm can be caused by so doing. Backward displacement may easily be remedied by pressure with the finger, relapse being prevented by a compress and a T bandage. Recovery is promoted by rigid recumbency and antiphlogistics.

e. The *coccyx* is sometimes broken by a fall, by a kick upon the buttock, and by the passage of the child's head in labor. The accident is most common in elderly subjects, in whom the joints of this bone have been destroyed by a deposit of osseous matter. The characteristic signs are preternatural mobility, acute pain, and crepitation on introducing the finger into the rectum. During labor, the occurrence of the accident is sometimes rendered evident by a sense of yielding and a peculiar noise perceived by the attendant as he is engaged in supporting the perineum. If displacement exist, it is remedied by pressure upon the surface and counter-pressure with the finger in the rectum. It is very important, especially in the female, that the *coccyx* should be preserved in a continuous line with the sacrum, otherwise serious deformity of the pelvis may ensue, interfering with defecation and parturition. After the reduction has been effected, the parts should be supported with a compress, confined by adhesive strips; perfect quietude and lateral recumbency should be observed; and the bowels, without being acted upon at all frequently, should be maintained in a strictly soluble condition.

2. SUPERIOR EXTREMITY.

FRACTURES OF THE BONES OF THE HAND AND FINGERS.

The symptoms of fracture of the bones of the thumb and fingers are so obvious that anything like a formal account of them is quite unnecessary. The treatment is best conducted by a leather, felt, or gutta-percha splint, accurately moulded to the shape of the member and the palm of the hand, to which it must be well secured by appropriate rollers.

The *metacarpal* bones are sometimes broken by machinery, and I have met with two instances in which the fourth and fifth of these pieces had given way under a blow of the fist, the part struck being, in one of the cases, the face, and in the other the forehead. There was marked displacement upon the back of the hand, from the projection of the anterior fragment, with distinct crepitus and swelling of the soft parts, but hardly any pain. The treatment consisted in the use of a well-padded tin case for the palm of the hand, extending from just above the wrist, and of a short, narrow splint for its dorsal surface, firm pressure being made with it over the seat of fracture. Union occurred in a month, with no apparent deformity.

The *carpal* bones are never broken, except by direct violence, which always seriously implicates the soft parts, not unfrequently necessitating removal of the hand. The nature of the accident is usually apparent from the attendant deformity, the excessive pain, loss of function, and crepitus on manipulation. Reposition of the fragments having been effected by pressure and counter-pressure, retention is secured by means of two splints, either of binder's board or wood, long enough to extend from the middle of the forearm to the ends of the fingers, the hollow of the hand being well padded, and the limb supported in a sling.

FRACTURES OF THE SHAFTS OF THE RADIUS AND ULNA.

The radius and ulna may be broken conjointly by direct violence, or, as more frequently happens, by a counter-stroke, as when a person falls upon the hand, and the force is concentrated by transmission upon the forearm. The fracture, although it may occur at any point, is most common in the inferior half of these bones, and rarely takes place at the same level, whatever may be its cause. In general, too, it is oblique, and not transverse, as is usually supposed. The nature

Fig. 388.

Mal-approximation of the ends of the fragments in fracture of the ulna and radius.

Fig. 389.

Fracture of the shaft of the radius, with vicious union.

of the accident is commonly sufficiently apparent from the angularity of the fragments, as seen in fig. 388, and their preternatural mobility, to say nothing of the facility of eliciting crepitas on rotating the hand. The patient experiences an inability to supinate and pronate the limb, the forearm is in a state of semi-flexion, and acute pain is felt at the seat of the injury.

The chief danger in this fracture, as it ordinarily exhibits itself, is from the tendency of the ends of the fragments to sink inwards into the interosseous space, and to become united by a common callus, thereby materially impeding the usefulness of the limb, by destroying the functions of supination and pronation. With ordinary care, however, such an accident is not likely to happen, and, in most cases, the consolidation is completed in from thirty to thirty-five days, without any deformity, or ultimate inconvenience. The vicious union here mentioned is well shown in fig. 389, from a preparation in my collection.

The fracture having been adjusted in the ordinary manner, the forearm is bent at a right angle with the elbow, and enveloped by a roller, extending from the fingers upwards. Two thick binder's board splints are next applied along the anterior and posterior surfaces of the broken bones, and secured with the remainder of the bandage. They should be a little wider than the limb, and long enough to reach from just below the elbow to the extremities of the fingers,

both being well covered with wadding, and accurately moulded to the parts. The hand and forearm are then suspended in a broad sling, and confined to the chest in such a manner as that the thumb shall look directly upwards.

In my own practice I have, for many years, entirely dispensed with the compresses upon which so much stress has been laid by practitioners for counteracting the tendency which the ends of the fragments have to approach each other at the interosseous space. I am satisfied that they are not needed for this object, and that all the compression that can be required, at least in ordinary cases, may be effected by the two splints which are always employed in the treatment of fracture in this situation. The bandage, too, has received a great deal of unjust blame in these cases, it being alleged that, if applied directly to the surface, it will force the bones together, and thus lead to vicious union. It would unquestionably be easy enough to produce such an effect, but it need hardly be added that this would be an abuse, and not a proper use, of the bandage, its appropriate office being to afford equable support to the muscles of the broken limb for the purpose of preventing swelling and spasmodic action. Whenever it causes such an amount of compression as to force the fragments towards each other, it cannot fail to excite pain and inflammation, if not still worse consequences. It is the manner, then, in which the application is made, and not the application itself,

that is objectionable in the treatment of this fracture. As to the splints, they should be carefully moulded to the shape of the limb, a narrow interval being left between them at its radial and ulnar borders. When binder's board splints cannot be obtained, light pieces of wood may be used.

When the fracture is multiple, consisting, for example, of three fragments, the intermediate one, having lost its support, may have a tendency to sink in towards the interosseous space. To counteract this disposition, a thick, narrow pad may be placed along the mesial border of the loose piece, in an opening in the anterior splint, so as to enable the surgeon to make the pressure more firm and direct. But even here such an expedient will rarely be necessary, if the parts have been moulded into position prior to the application of the apparatus.

FRACTURES OF THE ULNA.

Fractures of the ulna may with great propriety be divided into those which take place at its body, its inferior extremity and its two principal processes, the olecranon and coronoid.

1. *Shaft.*—The body of the bone is most commonly broken in the lower half of its extent, in an oblique direction, as exhibited in fig. 390, from causes acting directly upon the forearm. The accident may, however, be produced by a counter-stroke; and one instance is known where it was occasioned by muscular action in wringing clothes, the patient being a stout, healthy girl of eighteen. The fracture is evinced by a marked depression at the inner border of the forearm, by the mobility of the fragments, and by the crepitus on rotating the hand. The lower fragment alone is generally displaced, being drawn over towards the interosseous space by the inferior pronator muscle, while the other, in consequence of its firm connection with the humerus, remains stationary. An exception to this is seen in the adjoining figure.

Fig. 390.

Great care is necessary in the treatment of this fracture, lest the upper end of the lower fragment retains the vicious position into which it is forced at the time of the accident, and is induced ultimately to become soldered to the inner margin of the radius. To prevent this occurrence, the hand should be permanently inclined towards the thumb, the means for doing this being two splints, the extremities of which are rendered somewhat sloping from behind forwards, in a direction opposite to that of the splints employed in the management of fracture of the corresponding end of the radius. Such an expedient will be much more efficient than the use of the long, thick, and narrow compress, generally recommended for that purpose.

The head of the ulna is sometimes broken off, either separately, or along with the head of the radius. The circumstance is easily detected by the mobility of the part, by the disabled condition of the wrist-joint, by the severity of the pain, and by the concomitant distortion. The treatment is conducted with two splints, aided, if necessary, by two compresses applied directly over the seat of the fracture.

Fracture of the shaft of the ulna.

2. *Olecranon Process.*—Fracture of the olecranon, seen in fig. 391, is caused

Fig. 391.

Fracture of the olecranon process.

either by direct violence, or by the inordinate action of the three-headed extensor muscle, attached to its upper extremity. Situated at various points of its

extent, the fracture may be transverse or oblique, single or multiple, simple or complicated.

The *symptoms* are semiflexion of the limb, impossibility of extending the forearm, a hollow at the back of the elbow, fig. 392, and a movable prominence at the postero-inferior surface of the arm, along with more or less pain and swelling. The interval between the two fragments varies from one and a half to two inches, and may be augmented or diminished at will by moving the forearm. The radius may be rotated upon the ulna, and crepitus may be elicited by the approximation of the extremities of the broken bone. Sometimes the very tip of the olecranon is severed, and then there is no separation of the fragments. The same thing may happen when the fracture is oblique, or transverse, provided it is not below the ligamentous expansion of the extensor muscle.

Fig. 392.

Fracture of the olecranon process.

The *union* of this fracture is generally fibro-ligamentous, as seen in fig. 393, from a specimen in my collection. The causes of this occurrence are want of

Fig. 393.

Fracture of the olecranon process united by fibrous matter.

proper nourishment of the upper fragment; difficulty of maintaining apposition; and inordinate deposit of synovial fluid, all, but especially the first, interfering with the healing process. I have, in a few instances, seen osseous union; but this is extremely rare, and is not at all likely to happen if there is any considerable separation of the fragments, or when the fracture extends through the lower part of the process. The period required for the repair of the injury varies from six to eight weeks, and many months generally elapse before the patient regains a good use of his limb. When the lesion is of a complicated nature, violent inflammation of the elbow-joint may arise, ending in permanent ankylosis, or in caries and necrosis of the bones.

The *treatment* consists in maintaining the limb in the extended position, by means of a wooden splint, long enough to reach from the fore part of the middle of the arm to the same point of the forearm, as represented in fig. 394. A roller

Fig. 394.

Apparatus for fracture of the olecranon process.

having been applied from the fingers upward, the small fragment is drawn into its proper place, where it is confined by a few long adhesive strips and a compress, the whole being firmly secured by carrying the roller round the joint somewhat in the form of the figure 8; or, instead of this, the arm is bandaged from

the shoulder downwards, so as to obtain a more perfect control over the extensor muscle, the great agent in effecting displacement. Passive motion is instituted at the end of three weeks, and frequently renewed, to prevent ankylosis. If the fracture is associated with severe injury of the soft parts, leeches, fomentations, and other antiphlogistic measures must be employed.

3. *Coronoid Process*.—A considerable number of cases of fracture of the coronoid process of the ulna, exhibited in fig. 395, have been reported, both in

Fig. 395.

Fracture of the coronoid process.

systematic treatises and in medical periodicals, but it is very questionable whether even a minority of them should be considered as true examples of that lesion. I have myself never met with the accident in the living subject, and I am not aware that a solitary specimen of it exists in any of the osteological collections, private or public, in the United States. Professor Hamilton, who has investigated the subject with great care, is very decidedly of opinion that most of the published cases are unworthy of acceptance, either because they were badly observed or imperfectly reported, and because the existence of scarcely any of them has been verified by dissection. Some years ago, I saw an instance of supposed fracture of the coronoid process in a young man; but, although the symptoms were such as are usually described as characteristic of that lesion, I was by no means satisfied that it really was of that nature. In the case of a boy, about nine years of age, treated by Dr. A. A. Scott, of Missouri, by whom the particulars have been kindly communicated to me, the coronoid process is stated to have formed a distinct prominence upon the anterior and inferior surface of the humerus, a short distance above the joint, movable from side to side, the olecranon being at the same time displaced slightly backwards, and the forearm somewhat flexed. The accident was caused by a fall upon the hand while the arm was forcibly extended.

If we may credit the reported cases of this fracture, it is evident that it takes place mostly in young subjects. It has generally been supposed that it may be caused by inordinate contraction of the anterior brachial muscle; but as this muscle is not attached to the coronoid process it is impossible for it to produce such an effect. The most reasonable conclusion, therefore, is that fracture of this prominence is always the result either of direct injury, as by the passage of the wheel of a carriage, or, as probably more commonly happens, of force applied to the hand, impelling the ulna and radius violently upwards against the lower extremity of the humerus while the forearm is in a state of extreme extension.

In whatever manner the fracture is produced, the *symptoms* are generally less clearly marked than might at first be supposed. That this is the fact is sufficiently evident from a study of the reputed cases of the accident, in which the diagnosis was always attended with unusual difficulty. The ulna, having lost its purchase in front, will necessarily be drawn backwards and upwards by the action of the three-headed extensor muscle, so that the accident will present all the appearances of a dislocation of the bone in this direction, the prominence of the olecranon being characteristic. The patient is unable to flex the limb, and the detached portion of bone may be felt just above the elbow, where it may be readily grasped and moved about, especially soon after the accident, before any swelling has come on. By bending the forearm at a right angle with the arm, and drawing down the fragment of bone, crepitation might possibly be elicited, but this must, in any event, be very faint and indistinct. The accidents with which this lesion is most liable to be confounded are fracture of the humerus and dislocation of the ulna and radius backwards.

The *union* of this fracture must always be fibro-ligamentous, as is sufficiently

evident when we reflect upon the small size of the detached fragment, the difficulty of keeping it in place, its imperfect nourishment, and its close connection with the joint; circumstances which are so many impediments to the formation of osseous matter. In young subjects, and under proper management, a cure may generally be looked for in four or five weeks.

Fig. 396.

Apparatus for fracture of the coronoid process.

The *treatment* is quite simple, being conducted with a view to the thorough relaxation of the flexor muscles of the arm. For this purpose, the forearm, after having been properly bandaged from the fingers up as far as the elbow, and the arm from the shoulder downwards, in the opposite direction, is placed at a right angle, as seen in fig. 396, in a tin-case or suitable splints, and supported in a sling, care being taken to prevent the radius

and ulna from slipping backwards, away from the condyles of the humerus. The fulfilment of this indication will generally be materially aided by the use of adhesive strips, carried round the joint in the same manner as in fracture of the olecranon. Passive motion should be instituted at the end of three weeks, and perseveringly renewed from time to time, lest ankylosis ensue.

FRACTURES OF THE RADIUS.

1. *Shaft*.—Fracture of the body of the radius may take place independently of that of the ulna, as shown in fig. 397, and is the more frequent accident of the two; its most common seat is the inferior half of the bone; its ordinary cause

Fig. 397.

Fracture of the shaft of the radius.

a fall upon the palm of the hand. Dr. Packard, has reported a case of fracture of the upper portion of the radius, caused by violent muscular exertion in driving a pair of horses.

The *symptoms* are usually well marked, there being more or less deformity, preternatural mobility, inability to perform the motions of pronation and supination, and crepitus upon rotating the hand. The ends of the fragments have a singular tendency to approach the interosseous space, and hence, if the case is not judiciously managed, there is apt to be permanent distortion, with partial loss of function of the limb. One of the evil consequences of this tendency is the want of osseous union, or the formation of a false joint within two and a half or three inches of the wrist. I have seen a number of well-marked examples of this kind, and I know of no fracture where an unskilful surgeon may show his ignorance to greater disadvantage.

The limb, being bandaged in the usual manner, is steadied by two splints extending as far forwards as the extremities of the fingers, the hand being inclined inwards towards the ulna, and maintained in a state midway between pronation and supination. For this purpose, the ends of the splints should be shaped somewhat like the handle of a pistol, as this arrangement will afford an opportunity of bearing upon the radius in such a manner as to force the lower fragment

outwards in contact with the superior, thereby counteracting the tendency above alluded to. If this point be strictly attended to, the cure can hardly fail to be perfect. Ordinarily consolidation may be looked for in four weeks.

2. *Superior Extremity.*—This bone is occasionally broken at its superior extremity, the fracture detaching its rounded head, or extending through its neck. It is very rarely that the bone gives way at the bicipital tubercle. The injury could hardly be produced in any other way than by direct violence. Owing to the manner in which the parts are enveloped by the muscles, the symptoms are usually indistinct, and the diagnosis is, consequently, rather difficult.

The usual symptoms are deformity just below the elbow-joint, caused by the flattening of the muscular prominence in that situation; the projection of the upper end of the lower fragment in front of the limb, being drawn thither by the two-headed flexor muscle; impossibility of executing the functions of rotation; and the rapid supervention of severe swelling. To render the diagnosis certain, the best plan is to grasp the head of the radius with the thumb and index finger of one hand, and to rotate the forearm with the other. If there is fracture, its existence will be rendered evident by the head of the bone refusing to obey the motions of the inferior fragment. By adopting this manoeuvre, it will hardly be possible to mistake the nature of the case, unless there is so much swelling as to prevent the bone from being felt, in which event the examination must be repeated as soon as the tumefaction has measurably subsided.

In the treatment of fracture in this situation, the limb is placed at a right angle with the arm, in a state midway between pronation and supination, and the same splints are employed as in fracture of both bones of the forearm, care being taken to extend them as high up as possible, in order that they may afford adequate support to the upper fragment. When there is great disposition in the pronator muscle to draw the lower fragment over towards the interosseous space, a compress may be used, but not otherwise.

The annexed drawing, fig. 398, from a preparation in my collection, exhibits a rare form of fracture, in which a portion of the head of the radius has been chipped off, and permanently united to the contiguous border of the coronoid process of the ulna. The specimen was obtained in the dissecting-room, and, therefore, nothing is known of its history.

Inferior Extremity.—The frequency of fracture of the lower extremity of the radius, its liability to be confounded with dislocation of the wrist-joint, and the imperfect recovery of the functions of the hand which so often follows it, sufficiently attest the importance of the subject, and afford a satisfactory reason for the extraordinary attention that has been accorded to it by modern surgeons. Among those who have particularly interested themselves in its elucidation may be mentioned Dr. John Rhea Barton, who, in a short, but graphic paper, in the Philadelphia Medical Examiner for 1838, was the first to describe, with any degree of accuracy, the nature and treatment of fracture of this bone at the radio-carpal articulation. In 1814, Mr. Colles, of Dublin, gave an account of a fracture which he had repeatedly found at the distance of about an inch and a half above the joint; and more recently the whole question has been examined anew by some of the French and British surgeons, particularly Mr. R. W. Smith, of Dublin.

Two circumstances powerfully contribute to the production of this fracture, namely, the large amount of spongy substance in the inferior extremity of this bone, and the peculiarity of its connection with the wrist-joint. The relative quantity of this matter in its lower and middle portions, and also the difference in their compact structure, are very striking. These appearances, which are sufficiently conspicuous even in young subjects, are remarkably prominent in

Fig. 398.

Fracture of the head of the radius.

elderly persons, in whom the spongy substance of this part of the bone is generally exceedingly rarefied and infiltrated with oily matter, while the compact is often merely a thin crust, hardly as thick as an egg-shell, and scarcely less brittle. The singular mechanism of the wrist-joint cannot fail to arrest the attention of the surgeon. From the intimate manner in which the radius is articulated with the scaphoid and semilunar bones, any shock received upon the palm of the hand is readily communicated to it, causing it, if the force is at all severe, to give way under its influence; whereas the ulna, which has no such close relation, generally escapes injury.

Although fracture of the lower extremity of the radius may happen at any period of life, it is most common in middle-aged and elderly subjects. As a result of indirect violence, I have not seen an instance before the eleventh year.

Respecting the *site*, direction, and extent of fracture of this part of the radius, the greatest possible diversity exists. Generally the injury is situated low down, within a short distance of the joint, or within the joint; but the line of fracture is often considerably higher up, as an inch, an inch and a quarter, and even an inch and a half, at the junction, or even beyond the junction, of the lower extremity of the bone with its shaft. Sometimes the seat and direction of the fracture correspond to the line of union of the epiphysis.

In regard to its *direction*, the fracture is generally oblique, extending from above downwards, and from the dorsal to the palmar surface. Of 47 cases analyzed by Mons. Goyrand, of Aix, 43 were of this description, the degree of obliquity varying much in different instances, the fissure being sometimes almost horizontal.

The fracture of the lower end of the radius is frequently *multiple*, or comminuted; indeed, I am inclined to believe that this form of injury is more common than the simple. In the annexed drawing, fig. 399, from a preparation in the pathological collection of the New York Hospital, there are four fragments, and in several cases I have seen as many as five and six. Occasionally there are two fissures, one transverse, or nearly so, and the other vertical, detaching the head of the bone from its shaft. In Barton's fracture, the lesion always extends through the articular surface of the bone, affecting more particularly its posterior margin, and is frequently attended with separation of the styloid process.

Fracture in this situation may be *complicated*, first with fracture of the styloid process of the ulna, or of the head and shaft of that bone;

secondly, with dislocation of the wrist-joint; and, thirdly, with serious injury of the soft parts. Some years ago I attended, along with Dr. Chenoweth, a young man in whom this bone was split in two by a transverse and an oblique fissure, the larger fragment being completely detached, and thrown forwards and inwards over the ulna, whence, as it was impossible to replace it, I removed it by incision. A good recovery took place with hardly any impairment of the functions of the wrist-joint. In my private collection is a specimen of transverse fracture of the lower extremity of the radius, extending into the joint, and detaching the head of the bone by several small, vertical fissures. In this case I had an opportunity of dissecting the parts in consequence of the removal of the forearm, above its middle, by another surgeon, several weeks after the occurrence of the accident. The hand and wrist were much swollen, and infiltrated with pus, which was also freely diffused through the sheaths of the flexor tendons, while the cellular tissue along the inner part of the palm contained a good deal of blood. The joint was filled with matter, and the scaphoid and semilunar bones, as well as the ulna, which was dislocated backwards, were almost completely divested of cartilage.

Fig. 399.

Multiple fracture of the lower extremity of the radius.

The ends of the broken pieces are sometimes *impacted* in this fracture, the superior being driven into the cancellated structure of the inferior; but such an occurrence, although said to be common, is, if I may judge from the cases that I have had an opportunity of examining, quite infrequent. When the force causing the impaction is very great, the inferior fragment may literally be crushed by the superior.

The accident nearly always results from a fall upon the hand, in which the patient, stretching out the limb, receives the shock upon the palm, whence it is transmitted to the inferior extremity of the radius. Occasionally, though much more rarely, the fracture takes place by a fall upon the back of the hand. The lesion is also produced by direct violence.

The most conspicuous *symptom* of this fracture is the singular deformity of the hand, giving the limb the appearance of a dislocation of the wrist-joint, as exhibited in fig. 400. This is owing to the fact that the lower fragment along

Fig. 400.

Fracture of the lower extremity of the radius.

with the carpus is drawn upwards and backwards, from an inch to an inch and a half above the joint, by the action of the extensor muscles of the thumb, while the upper fragment forms a slight projection on the palmar aspect of the forearm. Immediately above the posterior prominence is a well-marked depression, which gradually slopes off towards the ulna, and is generally sufficiently large to receive the little finger. These appearances are always very striking when the limb is held in a situation midway between pronation and supination, and are easily effaced by extension and counter-extension, although they are promptly reproduced when these forces cease to act. The lower extremity of the forearm has a rounded form, from the increase of its antero-posterior diameter; the fingers are usually flexed, and the patient is unable to supinate the hand, which is, moreover, completely powerless; the pain is excessive, and considerable swelling soon arises, especially along the palmar aspect of the limb. Crepitus may usually be detected by pressure just above the wrist-joint. With these phenomena before him, a surgeon must be exceedingly stupid if he does not speedily detect the nature of the injury.

Instead of being thrown backwards, the inferior fragment is sometimes forced in the opposite direction, forming a projection in front of the forearm, beneath the flexor tendons. Another tumor, more conspicuous, and consisting of the lower extremity of the superior fragment of the radius, occupies the dorsal surface; it extends across the entire breadth of the limb, and is bounded above by a well-marked furrow, more distinct internally than externally. The accident, which is exceedingly rare, closely simulates dislocation of the carpus forwards, but may readily be distinguished from it by the presence of crepitus, and the facility with which the symptoms can be made temporarily to disappear under slight manipulation.

The adjoining sketch, fig. 401, represents a fracture of the inferior extremity

Fig. 401.

Fracture of the lower end of the radius.

of the radius, complicated with luxation of the ulna. The signs of both injuries are characteristic. The drawing was taken from a private patient.

The *prognosis* of this fracture is greatly influenced by the nature of the case and the manner in which it is managed. If, as occasionally happens, there is no displacement, or serious complication, consolidation may be looked for in from twenty-five to thirty days, without deformity or permanent impairment of function. Under opposite circumstances, nothing but the utmost care and circumspection will be likely to insure a successful cure. In any event, the patient must not expect to regain the complete use of his wrist and fingers for several months, as there is a great tendency, in almost every case of the kind, in the resulting inflammation to extend to the synovial membrane of the digital articulations and of the sheaths of the tendons. This fact should always be explained to the patient at an early stage of the treatment, otherwise the surgeon may be unjustly censured for what he cannot possibly avoid.

Among the various contrivances for maintaining the contact of the fragments, may be mentioned the excellent one devised by the late Dr. Henry Bond, of this city, which I can recommend, from my own experience, as well calculated to fulfil every indication that can be presented by such an injury. It consists, as shown in figs. 402 and 403, of two splints, one of medium-sized binder's board,

Fig. 402.

Bond's splint, being the part for the back of the forearm.

and the other of thin, light wood, furnished with a block and edges of thin sole-leather, about an inch in height, the whole presenting somewhat the appearance

Fig. 403.

The same, for the front of the forearm and hand.

of a shallow trough. They are long enough to reach from a short distance below the elbow to within an inch of the knuckles of the metacarpal bones, the block of the latter resting in the hollow of the palm, and both being well padded with wadding. Having encircled the thumb and each finger with a narrow bandage, the better to control the resulting swelling, and the fracture having been adjusted by pressure and extension, a roller is next passed round the limb as high up as the superior part of the forearm, special care being taken that it shall not produce the slightest constriction anywhere. The splints are then placed in their proper position, and fastened in the usual manner. If there is any tendency to displacement, which, however, rarely happens after the first few days, a narrow, square compress, not more than a third of an inch in thickness, is laid over the projecting fragment, to give greater concentration and effect to the pressure of the apparatus opposite to the seat of fracture. Sometimes it is found necessary to use a compress on each side of the wrist; but such is the accuracy with which the palmar splint fits the parts that this portion of the dressing may generally be dispensed with. There is no use, in any case, of an interosseous compress, as

there is never any tendency in the fragments to inward displacement. The advantage of the apparatus of Dr. Bond is that, while it maintains the thumb perfectly at rest, and consequently prevents its extensor muscles from disturbing the fragments, it permits the patient to move his fingers about freely in front of the block; a circumstance of no trifling importance in an accident so liable to be followed by inflammation of the sheaths of the tendons. The hand and forearm are, of course, supported in a sling.

In the absence of Dr. Bond's apparatus, a good dressing may be made of two thin pieces of wood, or stout binder's board, a little wider than the forearm, well padded, and of the same length as the preceding, care being taken, in applying them, to fill up the hollow of the hand and the intervals between the splints and limb with cotton. It will also be well, in this case, to give the anterior extremities of the splints a sloping inclination from above downwards, so as to put the extensors of the thumb slightly upon the stretch, as in fig. 404.

Fig. 404.

Dressing for fracture of the lower end of the radius.

A very simple but efficient method of treating fractures of the inferior extremity of the radius has been suggested by Dr. John Swinburne. It consists in confining the forearm upon a single splint, stretched along its posterior aspect from the elbow to the metacarpo-phalangeal joints, and composed of a thin piece of wood, the width of the limb, and provided with two compresses, one of which fills up the concavity of the carpus, while the other supplies the deficiency in the straight line of the arm above. The splint is secured with adhesive strips, the application being commenced at the elbow, and then continued, at intervals of several inches, down the limb to the hand, which, the displaced parts having previously been adjusted, is firmly fastened in such a manner as to allow perfect freedom to the thumb and fingers. The annexed cuts, figs. 405, 406, and 407, afford a good idea of the apparatus and of the appearance of the limb after its application.

Fig. 405.

Fig. 406.

Fig. 407.

Dr. Swinburne's apparatus for fracture of the radius.

The above dressings will answer equally well, whatever may be the character of the displacement, whether backwards or forwards. Passive motion is instituted at the end of a fortnight, proper support being given to the fracture while this is being made. The operation is afterwards repeated every other day, until the end of the fourth week, when the apparatus may generally be discontinued, the bandage alone being used. If the joints of the fingers are stiffened, they should receive special attention at each dressing.

FRACTURES OF THE HUMERUS.

Fractures of the humerus are of frequent occurrence, and are of great practical importance, from the difficulty which so often attends their diagnosis and treatment. They may take place in the shaft of the bone, at its surgical neck, at its head within the capsular ligament, and at its condyles.

1. *Shaft.*—The simplest fractures of the humerus are those which occur in its shaft, as they are most easily detected and treated, and least liable to be followed by deformity and loss of function. Caused occasionally by direct violence, they more frequently result from falls upon the palm of the hand, in attempts to save the body from more serious injury. In several instances that have come under my observation, and which are alluded to in another part of this section, the accident was produced by muscular contraction; in one case, while the patient was in the act of throwing a chip. The fracture is usually oblique, a transverse one, properly so termed, being exceedingly uncommon. A complicated fracture of the shaft of the humerus is occasionally met with, as a consequence of the explosion of firearms, the contact of machinery, or the passage of the wheel of a carriage.

The *symptoms* of fracture of the humerus in this situation are usually characteristic, the deformity, preternatural mobility, and crepitus being well marked. In general there is some shortening, but the amount of this varies very much, according to the obliquity of the fracture and the development of the limb: in ordinary cases, it is very slight, the weight of the arm being sufficient to counteract the action of the muscles, at least to a considerable extent. The direction of the displacement is regulated by the line of fracture; if this is below the insertion of the deltoid, the inferior fragment will be drawn inwards, but outwards if it be above that point. However this may be, any deformity that is present is easily effaced by extension and counter-extension. The limb is completely powerless, and is always supported by the patient at the wrist.

The *treatment* of this fracture is very simple, the only apparatus necessary being two splints, and a roller applied from the fingers up. The splints may consist of two stout pieces of uncoiled sole-leather, or binder's board; one extending from the axilla to within an inch of the internal condyle, and the other from the shoulder-joint to the corresponding point of the outer condyle, the two, when applied, nearly meeting each other. By soaking them in hot water, they may be accurately moulded to the shape of the limb, and, when this is done, it is impossible to conceive of anything better adapted for the treatment of such a case. The forearm and hand are, of course, supported in a sling; and, for the sake of greater security, the arm may be fastened by a few turns of bandage to the side of the trunk, though this is not at all essential. Special care is taken not to

raise the elbow, as a certain degree of weight is necessary to prevent overlapping of the fragments. This mode of dressing fractures of the shaft of the humerus I have practised for many years, and it requires no argument to show its superiority over the old four-splint apparatus, still used by many surgeons. If the lesion is simple, reunion will generally occur in a month.

2. *Inferior Extremity.*—Fracture of the condyles may be caused by a fall upon the point of the elbow, by a blow, or by the passage of the wheel of a carriage. I have repeatedly known it to be produced by a fall upon the palm of the hand, the limb being at the time in an extended position. The accident may be simple, or, as not unfrequently happens, complicated with serious mischief to the joint and soft parts. Both condyles may be broken, as seen in fig. 408, or one only may be affected. In the former case, a longitudinal fracture usually

Fracture of the condyles of the humerus.

extends some distance along the centre of the bone, and then terminates, probably an inch and a half to two inches above the joint, in an oblique or trans-

verse fissure in the lower portion of the shaft of the humerus, thus producing three fragments. Not unfrequently, however, there is a separation merely of one of these prominences, the fracture being then usually directed obliquely downwards into the joint. In a third series of cases, the small projection over the inner condyle is broken off, either obliquely or perpendicularly, without any involvement whatever of the articulation.

The *symptoms* of fracture of this portion of the humerus vary according to circumstances, as might be expected from a consideration of the structures of the elbow-joint. When both condyles are severed just above the articulation, the radius and ulna project backwards, a hollow exists at the bend of the arm, the forearm is slightly flexed, and the distance between the elbow and wrist is sensibly diminished. When the fracture involves both the condyles and the inferior extremity of the shaft of the bone, there will be, in addition to these phenomena, an increase in the width of the bend of the arm, and an appearance of greater flattening. The accident, whether accompanied by this occurrence or not, is liable to be mistaken for dislocation of the radius and ulna backwards; but the diagnosis may generally be readily determined by the fact that the symptoms which mark the former lesion promptly disappear on extending the limb, and that crepitus may be produced when the forearm is rolled upon the humerus.

When the inner condyle alone is detached, as exhibited in fig. 409, the ulna

Fig. 409.

Fracture of the internal condyle.

projects backwards, but resumes its natural position on extending the limb; the condyle forms a tumor at the back part of the elbow; crepitus is perceived on bending the forearm; and, if the forearm is extended, the humerus will advance in front of the ulna as the latter recedes.

Fracture of the external condyle, shown in fig. 410, is characterized by the

Fig. 410.

Fracture of the external condyle.

existence of a tumor at the outer and back part of the elbow, by crepitation on rotating the radius, by the supine position of the hand, by the inability to move the joint, and by the constant semiflexion of the forearm.

When the tubercle over the internal condyle is broken off, the diagnosis is easily established by the great mobility of the fragment, the ready production of crepitus, and the other ordinary signs of fracture. The accident is usually caused by a fall upon the elbow, and is unaccompanied by any displacement of the bones of the forearm.

Whatever may be the nature or extent of these fractures in the vicinity of the elbow-joint, there is always severe pain with complete inability to move the limb. Considerable swelling soon follows, and effusion rapidly takes place within the articulation, obscuring the characteristic features of the injury, and rendering the diagnosis proportionately difficult. When such a state of things exists, leeches, fomentations, and other antiphlogistic measures may be necessary before the parts will be sufficiently tolerant of the requisite manipulation.

The inferior extremity of the humerus occasionally gives way just above the condyles, generally in a more or less oblique direction, as seen in fig. 411. Such an occurrence may, unless great care is taken, be readily confounded with dislo-

Fig. 411.

Fracture of the lower end of the humerus.

cation of the ulna and radius backwards, which its symptoms, at first sight, closely resemble. The signs of distinction are the mobility of the limb and the facility with which the parts can be restored to their natural position, followed by the immediate return of deformity upon discontinuing the extension. The accident, which should be treated on the same principles as fracture of the shaft of the humerus, is extremely liable to be succeeded by stiffness of the joint.

In children, prior to the completion of the ossific process, there is sometimes a separation of the epiphysis of the inferior extremity of the humerus, induced by falls upon the hand or elbow. The symptoms resemble those of fracture in this situation in the adult, there being an unnatural projection at the back of the joint, caused by the retraction of the lower fragment along with the bones of the forearm, and the ready production of crepitus on extending the limb. The accident is treated as if it were a fracture.

I know of no fractures which I approach with more doubt and misgiving than those of the inferior extremity of the humerus, involving the elbow-joint. I know of none which are more liable to be followed by severe inflammation of the synovial membrane, extensive effusion, ankylosis, and deformity. Even in the more simple forms of these injuries, where the treatment has been most skilfully conducted, there is generally great risk of an unfavorable result; at all events, a long time will be sure to elapse before there will be anything like a good use of the articulation. The prudent surgeon will, therefore, inform his patient, at the commencement of the attendance, of the nature and probable consequences of the case. From five to six weeks is the average period necessary for the reunion.

The nature of the deformity, in badly-treated fracture of the condyles of the humerus, may exhibit itself in quite a variety of ways, depending upon the peculiar mode of management. Sometimes a posterior projection remains, caused by the displacement of the lower end of the bone backwards; not unfrequently the limb has a strangely twisted appearance, either in the direction of pronation or supination; occasionally it is permanently flexed or extended; and sometimes, again, the limb is greatly increased in breadth.

Most practitioners, I believe, are agreed upon the propriety of treating these fractures with the forearm in the rectangular position. There are but few that pursue the opposite plan, and the arguments which they have adduced in its favor have by no means convinced me that it is at all equal to the ordinary method. To maintain the limb in this situation, I have long been in the habit of employing a light, well-shaped tin-case, extending from the axilla to the metacarpo-phalangeal articulations. This, being properly lined with wadding, affords an admirable support to the limb, and effectually prevents displacement of the fragments, whatever may be their size or number. Great care should be taken to protect the inner condyle from pressure, otherwise it may become seriously inflamed, if not ulcerated. To obviate this occurrence, a small gap may

occasionally be made with advantage in the apparatus, opposite this ledge of bone. A case made of gutta-percha, felt, thin wire, or sole-leather answers quite as well as one of tin, and is even superior to it, inasmuch as it admits of more accurate adaptation to the irregularities of the limb. The forearm is supported in a sling, in a state midway between supination and pronation.

There are no fractures which require more constant vigilance after their adjustment than those about the elbow-joint. The dressings should, therefore, be examined for some time, from day to day, in order that they may be changed whenever they become either too tight or too slack, and special pains must be taken that the bandage, in the first instance, is applied very loosely, due allowance being always made for the resulting swelling. If some time has elapsed since the occurrence of the injury, and the pain and tumefaction are very severe, measures should be used to reduce the inflammation before the limb is put up. Passive motion is commenced at the end of two weeks, and repeated every forty-eight hours until all danger of ankylosis is passed. As soon as the fracture is sufficiently repaired to bear the change, the rectangular apparatus is taken off, and a more obtuse one substituted.

Fig. 412.

Complicated fracture of the elbow.

Fractures of the elbow are often of a *complicated* character, fig. 412, especially when caused by railway injury, or falls from a great height, penetrating the joint, extensively lacerating the soft parts, and, perhaps, comminuting the bones. Such accidents are always fraught with danger, both to limb and life, and usually promptly require amputation. Even supposing that the limb could occasionally be saved under such circumstances, the patient's recovery will be extremely tardy, and when, at length, he does get well, it will be found, as a general rule, that the joint will be worse than useless, only serving as a hindrance.

3. *Superior Extremity.*—The superior extremity of the humerus includes the hemispherical head of this bone and its two necks, the anatomical and surgical; the former being the narrow, constricted portion between the head and its tuberosities, and the latter all that portion which intervenes between these prominences and the insertion of the broad dorsal muscle, its length varying from an inch and a half to two inches, according to the stature of the individual.

a. *Fracture of the Head.*—Fracture of the head of the humerus is so extremely uncommon that its possibility was for a long time a matter of controversy among surgeons. The cases, however, that have been reported by Bichat, Astley Cooper, Dorsey, Gibson, R. W. Smith, Malgaigne, and others, have effectually dispelled all doubt upon the subject. I saw, myself, many years ago, in a patient of Dr. George McClellan, an instance of the kind, which had been mistaken by the attendants for a fracture of the acromion process, and the true nature of which was not detected until several years after the occurrence of the accident, when the man, who was upwards of forty years of age, died of another disease, and an opportunity was thus afforded of examining the parts. The fracture had extended obliquely from above downwards through the head of the bone; and,

although it had become perfectly consolidated, there were several rough prominences which, while they unmistakably indicated the seat of the injury, greatly impeded the movements of the shoulder-joint. The accident had been caused by a fall from a carriage.

In a specimen in my private collection, obtained from the body of an insane woman, upwards of seventy years of age, whose skeleton presented the appearance of having been broken in numerous places, the head of the humerus is completely detached from the anatomical neck, the articulating surface, which retained its smooth and polished aspect, being tilted over the great tuberosity against the posterior surface of the bone, to which it is firmly and inseparably united by osseous matter, the fracture having evidently happened a long time before death. Directly opposite to the prominence thus formed, on the inner surface of the humerus, is another large projection, fully an inch in length, having the character of a stalactitic exostosis. The bicipital groove is completely effaced. The whole bone is extremely light, its weight being hardly two ounces and a half. The annexed cut, fig. 413, conveys a good idea of the distinguishing features of this remarkable, if not unique, specimen.

Fig. 413.

Fracture with detachment of the head of the humerus.

When the head of the humerus is completely detached from the tubercles along the anatomical neck, it must necessarily act as a foreign body, speedily perishing from the want of nourishment. In some cases, however, it is enabled to preserve its vitality, although imperfectly, by remaining in connection with the rest of the bone through the intervention of a few bands of fibrous tissue.

b. Fracture of the Anatomical Neck.—In children, prior to the completion of ossification, the head of the humerus is occasionally separated from the shaft of the bone, very near the point of attachment of the capsular ligament, or at the anatomical neck. The accident is generally caused by a fall on the elbow, or by violence applied to the shoulder, and is very liable to be mistaken for other injuries. In old persons, the head of the bone, fig. 414, is sometimes not only broken off, but thrown down into the axilla, where it forms a distinct tumor that may easily be felt by the hand, but which does not obey the movements of the arm. Such an accident always seriously complicates the case.

Fig. 414.

Fracture of anatomical neck of the humerus.

in a diagnostic point of view.

c. Fracture of the Surgical Neck.—Fracture of this portion of the humerus is uncommon, but may take place from the same causes as fracture of the shaft

of the bone; sometimes from a fall upon the hand or elbow, sometimes from direct violence, and sometimes, although rarely, from muscular action. The injury is always attended with marked displacement, forming an important feature in its history. The superior fragment, yielding to the influence of the spinatus muscles of the scapula, is generally drawn outwards and slightly backwards,

Fig. 415.

Fracture of the surgical neck of the humerus.

while the inferior one is directed inwards towards the side of the trunk by the pectoral, broad dorsal, and large teres muscles, attached to the inner border of the bicipital groove. At the same time that this portion of the humerus is dragged inwards, it is usually somewhat raised by the joint agency of the muscles that pass from the scapula to the forearm; the extent of the displacement, however, is commonly trivial, inasmuch as the weight of the limb is almost sufficient to counteract its occurrence.

The *diagnosis* of these different fractures is not always so easy as might, at first, be supposed. Their character is often greatly obscured by the swelling, and the consequent difficulty of making a thorough examination. In general, there is marked deformity at the shoulder-joint, the deltoid muscle is flattened, the arm is twisted upon its axis, and, if the injury is situated on the outside of the capsular ligament, there is usually slight shortening of the humerus, with distinct projection of the upper end of the lower fragment. If extension and counter-extension be made, so as to draw the parts in place, crepitation will be elicited, followed by a recurrence of all the previous symptoms the moment the surgeon relinquishes his hold. In cases of doubt, the best plan is to grasp the head of the humerus firmly with the thumb and fingers of one hand, while with the other we seize the elbow and move the arm on its axis. If fracture be present, it will almost be sure to be detected by the crepitation produced by this manœuvre, whereas, if there is a dislocation, no noise will be perceived, and there will also be little or no mobility. When the head of the bone is fractured, and thrown off the glenoid cavity, the symptoms will be of a compound character, the crepitation and abnormal mobility coexisting with flattening of the deltoid muscle, extraordinary saliency of the acromion process, and a remarkable fulness in the axilla, caused by the presence of the displaced bone, at the same time that the upper extremity of the inferior fragment projects prominently upwards and inwards.

Fig. 416.

Welch's shoulder splint.

Treatment.—Fractures of the superior extremity of the humerus must all be treated upon the same general principles as fractures of the shaft of the bone. The limb being bandaged from the fingers up, two splints, broad and hollow, made of un-oiled sole-leather, binder's board, gutta-percha, or gum sheeting, are applied, one on the outside, and the other on the inside of the limb, the former being long enough to extend from the external condyle to the top of the shoulder, which it should cover well in, since it is of paramount importance to give firm support to the broken parts, as in fig. 416. The inner splint should be carefully padded at its superior extremity, in order that it may not chafe the skin or exert any disagreeable pressure upon the axillary vessels and nerves. No cushion will be required for the axilla. The arm is carefully secured to the side of the chest, and the forearm is supported in a sling, but the elbow is left free, in the hope that its weight may tend to prevent overlapping of the fragments. Passive motion is instituted at the end of the

third week, and firm union may reasonably be expected in a fortnight more. A long time, however, will elapse before the joint will completely regain its functions, if, indeed, it ever does. Permanent lameness will almost be inevitable, if the fracture be intra-capsular and comminuted, owing to the difficulty of readjusting the fragments.

When fracture of the superior extremity of the humerus is complicated with *dislocation*, the proper plan, of course, is to restore the displaced bone to its natural position before an attempt is made to adjust the ends of the fragments. The operation, however, will necessarily be one of extreme difficulty, on account of the shortness of the superior piece, which thus deprives the surgeon of the advantage of a suitable lever. His whole reliance must, therefore, be upon well-directed pressure and counter-pressure, while the patient is fully under the influence of an anæsthetic, complete muscular relaxation being of paramount importance to success. When the operation fails, it has been recommended to let the dislocated head of the bone remain in its unnatural situation, and to bring the upper extremity of the lower fragment in contact with the glenoid cavity, in the hope that, in time, as the bone becomes rounded off, it will contribute to the restoration of the motion of the limb. Such an idea, however, it seems to me, must be perfectly delusive; for it is impossible to see how, under such circumstances, nature could make anything like a good or useful joint. Instead, therefore, of pursuing such a practice, I should not hesitate, if a case of the kind were to present itself to me, to cut down upon the dislocated bone, and push it back into its natural position. The broken pieces being placed in contact, and the wound carefully closed, I should not apprehend any bad results from inflammation and its consequences. Excision of the head of the humerus is seldom followed by serious effects; and, although the two cases are not exactly parallel, I should neither expect to lose my patient, nor make him a stiff joint.

Fractures of the surgical neck of the humerus are occasionally *impacted*, the upper extremity of the inferior fragment being forcibly driven into the cancellated structure of the lower end of the superior fragment. Such an occurrence is most common in old subjects, after the age of fifty-five, in consequence of interstitial absorption of the osseous tissue, and may be produced either by a blow upon the shoulder, or, what is more common, by a fall upon the elbow. The extent of the impaction varies from a few lines to half an inch or more. As the bone retains its continuity, the symptoms of the accident are usually very obscure, there being neither mobility nor crepitation, unless the fragments are unlocked by being forcibly pulled asunder. Nevertheless, there is generally some deformity perceptible upon firmly grasping the humerus, and an alteration in the axis of the limb, which often looks as if it were twisted, together with severe pain, and usually also more or less contusion of the soft parts. If the impaction is extensive, there will, in addition, be some degree of shortening of the arm, or a slight diminution in the distance between the shoulder and elbow. These circumstances, conjoined with the fact that the patient has received a severe injury, that there is loss of motion in the joint, and that all the symptoms of dislocation are absent, afford sufficient evidence of the probable nature of the case.

The impacted fracture requires no special treatment on its own account. Nothing, certainly, can be gained by pulling the fragments forcibly asunder, except mischief and trouble. Instead, then, of such interference, the surgeon contents himself with supporting the limb, and combating inflammation by leeching, fomentations, and other means. In due time passive motion is instituted, lest ankylosis of the shoulder-joint should arise.

d. Great Tuberosity.—Fracture of this portion of the humerus, although uncommon, is probably not quite as infrequent as is generally supposed, the obscurity of its symptoms rendering it extremely liable to be mistaken for other lesions in and around the scapulo-humeral articulation. The accident may occur at almost any period of life, except, perhaps, in early childhood, and is always caused by a fall or blow upon the forepart of the shoulder, the force being concentrated upon the upper extremity of the humerus so as to separate the large tubercle from the hemispherical head and shaft of the bone. The existence of

the fracture is denoted by considerable flattening of the deltoid muscle, by a remarkable increase in the width of the upper portion of the arm, which is nearly double what it is in the natural state, and by the presence of two osseous prominences, one of which, consisting of the detached tuberosity, is situated at the superior and outer part of the joint, and the other, formed by the head of the humerus, at the upper and inner part. The acromion is abnormally salient, and the arm is separated from the side, but may be approximated to it without difficulty, and readily pronated in every direction by the surgeon.

The most important *diagnostic* signs are the great increase in the breadth of the articulation, the refusal of the thumb to sink into the glenoid cavity, as it always does in dislocation of the shoulder, the preservation of the length of the limb, and the production of crepitation upon rotating the humerus by seizing it just above the elbow while the surgeon encircles the head of the humerus with both hands. Another important evidence is the fact that the deformity is readily effaced by manipulation, but instantly reappears when it ceases.

Reparation, generally of an osseous character, is effected in from four to six weeks, according to the age of the patient, and the amount of the resulting inflammation, which is always very considerable, in consequence of the concomitant contusion of the soft parts. Owing to this circumstance, the motions of the joint usually remain imperfect for many months; and in not a few cases, even when the greatest vigilance is exercised, they are never completely regained, owing to a redundancy of callus and the formation of osseous excrescences around the articular surfaces.

In the *treatment* of this fracture, one of the leading indications is to neutralize the action of the muscles which are attached to the tubercles of the humerus, the larger one receiving the insertion of the two spinate and the small teres, and the lesser the subscapular, which necessarily tend to draw the fragments away from each other, the subscapular being materially aided in this by the action of the broad dorsal, the great pectoral, and the short head of the flexor of the arm. To accomplish this object, the limb should be put up in two felt, leather, or binder's board splints, the inner of which is nicely padded above to prevent undue pressure upon the axillary vessels and nerves, while the outer is bent well over the top of the shoulder. No cushion will be necessary, especially if the arm and forearm are properly secured to the chest. The elbow is supported in a sling, but not so firmly as to push the head of the bone too high up towards the acromion process. For the first five or six days after the accident, leeches and fomentations may be required. Passive motion should be instituted at the end of three weeks.

3. INFERIOR EXTREMITY.

FRACTURES OF THE FOOT.

Fractures of the bones of the foot do not require any special notice, as their management is conducted upon the same principles as that of fractures of the hand. From the fact that they are generally complicated, the treatment must be largely antiphlogistic, and the surgeon will have cause to congratulate himself if he is not occasionally obliged to amputate the foot, or exsect some of its bones. It need hardly be added that any loose and displaced fragments should always be promptly removed, even when there is no external wound, and when it might be perfectly easy to effect replacement; for such pieces would not only be likely to act as foreign bodies, but they might, in the event of vicious reunion, seriously interfere with the wearing of a boot.

The *calcaneum*, or heel-bone, notwithstanding its exposed situation, the importance of its functions, and the manner in which it lies beneath the tibia and fibula, is seldom the subject of fracture. Direct violence is the most common cause of the accident, which is often attended with severe lesion of the neighboring structures, both soft and hard. Falling from a great height, in which the person alights upon his heel or foot, is the manner in which it commonly happens. The bone being thus forcibly acted upon, on the one hand, by the weight of the

body, and, on the other, by the resistance offered by the surface struck, yields at its weakest point, breaking, perhaps, into several pieces. More rarely the accident is produced by the inordinate contraction of the muscles of the calf, as in dancing and leaping; but in this case it is only the posterior extremity of the bone that suffers, its tip being the part generally torn off. The amount of displacement varies according to circumstances, being necessarily very slight when the fracture extends across the body of the bone, whereas it is always very considerable when it involves its back part, on account of the action of the gastrocnemial muscles, which, exerting their influence through the tendo-Achillis, sometimes draw up the posterior fragment from an inch and a half to two, three, and even four inches. Authors speak of an impacted fracture of the calcaneum, but such an occurrence must be extremely uncommon.

The *symptoms* of this fracture are always sufficiently characteristic when the posterior portion of the bone is broken off, the hollow at the heel, the protuberance at the lower and back part of the leg, and the impossibility of extending the foot, being unmistakable evidences of the nature of the accident. Upon bringing down the upper fragment in contact with the inferior, crepitus may be obtained, though it will be very faint if the tip only of the bone has been detached. The diagnosis will be more difficult when the fracture extends across the body of the calcaneum; for then there will be no displacement, the lateral and interosseous ligaments keeping the posterior fragment in position. In general, however, it may be determined by the history of the case, and by making pressure upon the calcaneum in different directions, thus eliciting crepitation if fracture actually exist.

A fracture of the calcaneum from the laceration of its fibres is usually slow in *uniting* on account of the difficulty of keeping the fragments in contact, the muscles of the calf constantly tending to separate the upper from the lower. For this reason, the union will frequently, if not generally, be ligamentous instead of osseous, and a long time will, therefore, be required for the complete restoration of the functions of the foot. When the fracture is caused by direct violence, the repair is effected in the ordinary manner.

When there is much contusion of the soft parts, it may be necessary to use antiphlogistics for moderating the inflammation, before applying permanent *dressings*. The nature of these dressings must depend upon the presence or absence of displacement. In the former case, the chief obstacle to the cure is the contraction of the gastrocnemial muscles, which must, therefore, be effectually controlled until the consolidation has advanced sufficiently to enable the upper fragment to maintain its position independently of extrinsic aid. The least objectionable contrivance for fulfilling this indication is a short splint, of stout tin, well padded, and adapted to the shape of the limb, the anterior part of which it should cover from the middle of the leg nearly as far as the toes. When tin cannot be obtained, wood, sole-leather, or binder's board may be used. The object of this splint is to maintain the leg and foot in a permanently extended position, for in proportion as this is effected will be the relaxation of the muscles of the calf. To maintain the upper fragment in place, the leg and foot may be bandaged in opposite directions, adhesive strips and a compress having previously been applied around the heel and sole. This position should be continued for at least six weeks, or until there is reason to believe that the connecting medium is firmly established. The apparatus of Petit, formerly so popular in the treatment of this form of fracture, should not be used, as the tendency of the cord and slipper is to displace the upper fragment, and to irritate the soft parts about the heel.

In the other variety of fracture, as there is no displacement, all that is necessary is to subdue inflammatory action, and to keep the foot and leg in a quiet and relaxed position with a tin-case, or two light side splints, the limb lying upon its outer surface over a pillow.

Fracture of the *astragalus* is very uncommon, especially the simple variety; in general, the accident is complicated with fracture of the tibia and fibula, severe injury of the soft parts, and dislocation of the fragments. The latter lesion

existed in eight cases out of ten of fracture of the astragalus collected by Dr. Monahan.

In consequence of the severe injury inflicted in this accident upon the foot and leg, primary amputation will generally be required. If this be neglected, the patient may perish from erysipelas, pyæmia, mortification, or hectic irritation. When the fracture is complicated with dislocation, without serious lesion of the ankle-joint and soft parts, an attempt should be made, by extension, counter-extension, and pressure, aided, if necessary, by the subcutaneous division of the resisting structures, to restore the fragments to their proper position; if this fail, recourse must be had to excision.

FRACTURES OF THE TIBIA.

The tibia, like other long bones, is liable to give way at various points of its extent, but more frequently below its middle than anywhere else. A fracture of its condyles is unusual, and its occurrence is always denotive of great direct violence. Occasionally the bone is broken near its upper extremity, from an inch to an inch and a half below the knee. The internal malleolus is sometimes detached by a twist of the ankle, by a fall upon the sole of the foot, or by direct injury.

Most fractures of the shaft of the tibia are oblique, very few, if any, transverse; nevertheless, as the fibula retains its integrity, there is seldom any considerable displacement, the sound bone acting as a splint to the broken one. It is not often, however, that the fragments completely retain their apposition; in general, there is some degree of separation, which may always be easily detected, even when there is a good deal of tumefaction, by passing the finger along the tibia, and tracing its outline. If there is a fracture, it will manifest itself by an abnormal depression at some particular point, or by an unnatural projection, sufficiently obvious to establish at once the nature of the case. The amount of this projection is occasionally very great, especially when the upper fragment is very long, sharp, and oblique, in which event it is generally extremely prominent, and with difficulty prevented from piercing the skin. The annexed drawing, fig. 417, from a preparation in my collection, conveys a good idea of this form of the injury. For the reason just mentioned, there will usually be an absence of crepitation, or if there is any evidence of this kind, it will be very faint and unsatisfactory. The fracture, if perfectly free from complication, unites in from four and a half to five weeks.

Fig. 417.
Oblique fracture of the tibia.

Fracture of the internal malleolus is met with in various forms. In some cases, the process is broken off at, or close to, its connection with the lower end of the tibia; in others, near its free extremity; but the most common site of the lesion is about the centre of the process. Its direction is nearly always oblique; rarely, if ever, strictly transverse or perpendicular. Occasionally the process is broken at several points, thus constituting a comminuted fracture. Finally, cases occur, although rarely, in which the fracture coexists with fracture of the lower extremity of the fibula. The diagnosis is easily established by the position of the foot, which is always turned upwards and inwards, as if it were partially dislocated, and by the facility with which the detached piece of bone can be moved about with the thumb and finger; a procedure which also readily elicits crepitation.

The most simple contrivance for the *treatment* of fracture of the tibia is a tin-case, fig. 418, accurately shaped to the limb, provided with a foot-piece, and reaching a few inches above the knee. A bandage is applied in the usual manner, and any tendency to displacement is easily counteracted by means of a

compress, arranged so as to bear gently and equably upon the ends of the fragments. I have never found it necessary to employ any other apparatus than

Fig. 418.

Tin-case.

count of their light, airy, and pliable character.

this, no matter where the tibia was broken. When the fracture involves the malleolus the foot-piece will effectually prevent displacement. In fracture of the superior extremity of the tibia, extending into the condyles, the plan usually adopted is to place the leg and thigh in the straight position, so as to compel the condyles of the femur to support the broken bone, extension and counter-extension being made with two long splints. Such a contrivance, however, will be altogether unnecessary, if we employ the tin-case, especially if it is made sufficiently long to embrace the inferior third of the thigh, thereby completely counteracting any tendency on the part of the muscles of the limb to draw the upper fragment backwards into the popliteal space. An efficient apparatus for these fractures will also be found in Dr. Welch's splints, fig. 419; and in the wire splints of Dr. Bauer, fig. 420, the latter being particularly valuable on

Fig. 419.

Dr. Welch's splint.

Fig. 420.

Dr. Bauer's splint.

FRACTURES OF THE FIBULA.

Fracture of the fibula is, relatively considered, a sufficiently common occurrence, its frequency being due apparently to the slender form of this bone, to its superficial situation, and, above all, to the important part which it plays in the formation of the ankle-joint. The accident may take place at any portion of the bone, but is by far most common in the inferior fifth of its extent, owing to its

intimate connection with the astragalus, which, constituting the pivot of the foot, readily receives and transmits the various shocks to which the latter is so continually exposed. Of fractures of the shaft and head of the fibula, no particular description is necessary, since they are always easy of detection, and the treatment does not differ materially from that of similar injuries of the tibia. But it is different with fractures of the inferior fifth of the bone, where, as just stated, the lesion is most common, and where, from being usually associated with other mischief, it is extremely liable to be followed by deformity and permanent lameness. For these reasons, fractures in this situation require to be studied with more than ordinary care.

Fractures of the fibula are much more common on the right side than on the left. In 207 cases collected by Dupuytren, more than two-thirds involved the right leg. The statistics of Malgaigne show that it is most frequently met with between the ages of twenty-five and fifty, and that men are more than four times as liable to it as women. Of 104 cases examined by this author, not a single one occurred before the fifteenth year.

The causes of fractures of this portion of the fibula can only be properly appreciated by a careful examination of their mechanism. The tibio-tarsal articulation, being a hinge-joint, admits chiefly of flexion and extension, its lateral movements being restrained by the two malleoli, and the ligaments by which the bones of the leg are connected with those of the foot. Hence, the latter cannot be turned outwards or inwards to any considerable extent without producing a fracture of the former, the site of injury being determined by the particular inclination of the limb. Thus, when the foot is forcibly abducted, its inner edge resting on the ground, the upper surface of the calcaneum will be pressed violently against the external malleolus, in a direction parallel to the fibula, which will, consequently, yield at its weakest point, which is about an inch and a half above the joint, at the part sometimes called the neck of the bone. In most cases there is a rupture of the deltoid ligament, if not also a fracture of the internal malleolus. When the foot is forcibly adducted, the astragalus becomes the immediate cause of fracture, for this bone, turning upon its antero-posterior axis, escapes from the arched cavity formed by the tibia and fibula, and, pressing against the outer malleolus, breaks the fibula nearly at the same level as in the preceding case, the direction of the fissure being usually somewhat oblique. The external lateral ligament is either torn or violently stretched.

The most ordinary cause of this fracture is a fall upon the foot, in which this portion of the limb is forcibly inclined laterally, at the moment the weight of the body impels the bones of the leg forcibly against those of the foot, rendered stationary by the resistance offered by the ground. The fibula may also be broken across by violence applied directly to the part, as a blow, or the passage of the wheel of a carriage. Of 207 cases of this accident recorded by Dupuytren, 120 were the result of forcible adduction, and 60 of forcible abduction, the rest being caused by direct violence.

However the fracture may be induced, the superior extremity of the inferior fragment is always thrust inwards against the tibia, while the inferior extremity of the superior fragment either remains fixed, or inclines in the same direction. The latter usually happens when the injury is direct, the former when it is indirect.

The inferior extremity of the fibula is sometimes broken almost vertically; such an occurrence, however, must be extremely uncommon, and I have seen only two instances of it, both of them being in the Mütter collection. In one, represented in fig. 421, the bone looks as if it had been split, the fissure extending upwards, almost in a straight line, fully an inch and a half; the posterior, longer, and larger fragment being pushed considerably backwards, so as to form with the other an intermediate triangular space. In the other bone the fracture is also vertical, but the separation is much less.

Fig. 421.

Fracture of the
Fibula.

The *symptoms* of fracture of the lower extremity of the fibula vary according to the circumstances of the case. When this bone alone is severed, the chief signs will be slight eversion of the foot, a depression at the site of injury, and some change, usually not very conspicuous, in the contour of the ankle-joint. When the internal malleolus is broken off, or when the tibia has given way a short distance above the articulation, these characters will exist in a more marked degree, and point out unerringly the nature of the lesion. The foot will be so much abducted as to present the appearance of being dislocated outwardly; the width between the two malleoli will be much increased; the hollow at the line of fracture will be quite deep; and the external margin of the foot will be considerably elevated, while the internal will be proportionately depressed. Upon taking hold of the foot, it will be found that it is unusually movable, and that it can easily be restored to its natural relations, but that the moment we cease our grasp it will return to its former position. In performing these manipulations crepitus is very easily felt; and, upon tracing the outline of the lower portion of the bone, the finger usually sinks in at the seat of fracture, owing to the fact, previously mentioned, that the upper end of the lower fragment always falls over towards the tibia. A good deal of ecchymosis is often present, and a considerable amount of swelling quickly follows, obscuring the characteristic features of the injury, and embarrassing the diagnosis. The only accident with which fracture of the inferior extremity of the fibula is liable to be confounded is a sprain of the ankle-joint, from which, however, it may always readily be distinguished by the great distortion which attends it, and by the presence of crepitus.

A simple fracture of the fibula in the inferior fifth of its extent will, if properly treated, usually unite in a month, without any deformity of the limb, although even then a considerable time will elapse before the ankle-joint will perfectly regain its functions. When the injury is complicated with rupture of the ligaments, fracture of the corresponding portion of the tibia, or other serious lesion, the repair will be much slower, and there will be danger, unless the case is managed with the most consummate skill, of permanent deformity and lameness, the former manifesting itself in an overted condition of the foot and in increased width of the ankle-joint.

The material point of the *treatment* of fracture of the fibula in this situation is to maintain the foot in a position the reverse of that which it assumes in consequence of the injury. To accomplish this object, which is designed to draw away the upper extremity of the lower fragment from the tibia, and to restore it to its proper relations, the limb, after having been enveloped in the ordinary bandage, with the precaution of not compressing it opposite the site of fracture, is placed in a tin-case, the foot being directed permanently inwards. The requisite inclination may easily be imparted by means of a piece of roller, or a few adhesive strips, carried round the instep and heel, and attached to the inside of the leg. Or, instead of this, the fracture may be treated with Dupuytren's apparatus, fig. 422, consisting of a light wooden splint and a wedge-shaped cushion;

Fig. 422.

Dupuytren's apparatus.

the former reaching from the upper third of the leg to about three inches below the sole of the foot, and the latter from the same point to a level with the ankle. The limb being bandaged in the same cautious manner as in the former case, the apparatus is stretched along its inner surface with the tapering end of the pad upwards, and secured, first above, and then below, the roller being passed round the foot and ankle in such a manner as to turn the internal margin of the foot

upwards and inwards. The limb may afterwards be kept in the extended position, or, what is preferable, be placed, half bent, upon its outer surface over a large pillow. The parts are diligently watched, the dressing being changed as occasion may seem to require, and passive motion instituted at the end of the third week.

FRACTURES OF BOTH THE TIBIA AND FIBULA.

Fractures of both bones of the leg are sufficiently common, particularly in young and middle-aged subjects, and are deserving of special attention, on account of the difficulty of their management, and their liability to be followed by deformity and lameness.

Much diversity obtains in regard to the *seat* of these fractures, as well as their direction, and the nature and extent of their displacement. In twenty-two specimens, contained in the Mütter collection and my own, I find that in ten the tibia and fibula were broken at their inferior extremity, the line of separation in none of them extending beyond three inches above the joint. In four the tibia gave way at its lower third, and the fibula at from two to three inches and a half from its head, or junction with the upper end of the tibia. In six of the cases the tibia was broken from two to three inches above its inferior articulating surface; in two of these the fibula had yielded at its middle, and in the remaining four at different points of its extent. In only two cases had both bones been broken at the same level; in one of these the fracture occurred at the middle of these pieces, and in the other a little below that place.

In the twenty-two cases the tibia had been broken only twice above its middle; whereas the fibula had given way above this situation in six cases. In sixteen of the cases the seat of fracture of the tibia was either at the ankle-joint, or below the middle of the bone, generally in its inferior fourth or third. In ten cases of fracture of the fibula the seat of the injury was either at the joint, or within the first three inches from its articulating extremity.

From the above examinations it follows: first, that the tibia and fibula rarely break on the same level; secondly, that both bones are most liable to yield either at the ankle-joint, or, at all events, within the first three inches above that joint; and, thirdly, that the fibula is more frequently fractured at its superior extremity than the tibia.

An examination of these specimens has supplied me with some other interesting facts. Thus, I have found that the fracture in nearly all was more or less oblique, the line of separation in fifteen specimens of broken tibia extending from above downwards, and from without inwards. As a natural consequence of this occurrence, the superior extremity of the inferior fragment projected outwards towards the fibula, which it touched in several of the preparations, on account of a want of proper adjustment during the treatment; the lower extremity of the upper fragment, on the contrary, projected inwards, and had apparently generally been much the sharper of the two. The fibula, in most of the specimens, afforded evidence of having been broken across more abruptly than the tibia, but still with a considerable degree of obliquity in almost every instance that I inspected.

In recent fracture of the tibia, complicated with fracture of the fibula, the inferior extremity of the upper fragment is generally remarkably sharp, and, in consequence, often protrudes through the integuments at the time of the injury, the same cause that produces the lesion forcing it across the soft parts. Or, if it is pushed out at the moment of the accident, it frequently escapes afterwards, through ulceration, induced by the pressure which it exerts upon the soft parts. The obliquity of fractures of the tibia is often very extraordinary, and there are few cases in which it does not become a source of great suffering to the patient, and of annoyance to the surgeon, on account of the trouble that is experienced in keeping the fragments in their proper relations.

A rare form of fracture of these two bones is represented in fig. 423, from a specimen in my collection. The tibia, it will be perceived, is broken off just above its articulating surface without affecting the internal malleolus, while the

fibula has given way about an inch and a quarter above the joint. The foot

Fig. 423.

Fracture of the tibia and fibula at the ankle-joint.

Fig. 424.

Fracture of the bones of the leg at the ankle-joint.

is characteristically everted. In fig. 424, also from a specimen in my possession, the fracture embraces both the extremity and the malleolus of the tibia: the fibula is broken off a few lines above the joint. Fig. 425 exhibits

Fig. 425.

Broken articulating surface of the tibia.

the appearance of the broken articulating surface of the tibia.

The causes of fractures of both bones of the leg are either direct or indirect, precisely as when these pieces suffer separately. A very common mode in which the accident occurs is a fall upon the pavement, as when an individual slips upon the ice, or when, as he is rapidly walking, the foot is suddenly caught in a hollow, or between two hard resisting objects, so as to throw the whole weight of the body upon the leg. It may also be produced by a fall from a considerable height, as when a person is precipitated from a scaffolding, or by jumping out of a carriage under full speed. In many cases it is occasioned by direct violence, as by the passage of the wheel of a wagon, the kick of a horse, the caving in of a sand bank, or the fall of a heavy stone.

The symptoms of the injury, however induced, are generally well marked, if not positively unmistakable. In nearly every case the limb is shortened from one and a half to three inches, and there is also, generally, great deformity in its diameter, both depending upon the overlapping of the fragments, which, as already stated, is frequently very extraordinary. Besides, upon making extension and counter-extension, it is generally easy to elicit crepitation. When the fracture is very oblique, the lower end of the superior fragment may usually be felt immediately beneath the integuments, forming a sharp, prominent projection in front of the limb, or at its inner aspect. Sometimes the soft structures are much bruised and ecchymosed. Another remarkable symptom, one, indeed, which is seldom absent, is a spasmodic twitching of the limb, coming on soon after the accident, and frequently lasting for several weeks, much to the annoyance and distress of the patient.

When the fracture is situated just above the ankle, the foot will usually be a good deal everted, causing an appearance of dislocation outwards, as exhibited in fig. 426.

The *prognosis* of fracture of both bones of the leg may be gathered, in part, from what precedes. In the more simple forms of the injury, attended with but little obliquity, a good cure may generally be effected in from four to five weeks. If, however, the obliquity is uncommonly great, it will be found extremely difficult, if not impossible, to effect consolidation in a manner altogether unexceptionable, however skilfully and zealously the treatment may be conducted. More or less deformity will almost be inevitable, either in the length or in the diameter of the limb; owing to the remarkable tendency which the ends of the fragments have to overlap each other, and which it is often impossible to counteract successfully, whatever means may be adopted for the purpose.

Fracture of the lower end of the tibia and fibula.

Old fractures of the tibia and fibula, like those of the bones of the forearm, are occasionally connected by a bridge of callus, or of new osseous matter, which does not, however, so far as can be determined, impair their usefulness, as must always necessarily be the case with the latter. I have several times met with this occurrence when the lesion was confined to one of these bones, and I am not able to say whether one is more liable to give rise to it than the other. Moreover, it does not seem to be necessary to its production that there should be any approximation of the ends of the opposite fragments, as it may take place when they are perfectly straight, although the former condition no doubt acts as a predisposing cause.

Fractures of both bones of the leg, if attended with shortening of the limb, require to be treated by extension and counter-extension, steadily and persistently maintained throughout, otherwise, as just stated, deformity will almost be inevitable. If, on the other hand, the fracture is transverse, or nearly so, such a procedure may of course be dispensed with, the object being attained by confining the leg in a tin-case, or fracture-box, care being taken to keep the great toe constantly on a line with the inner border of the patella, the surest evidence that there is no rotation of the ends of the fragments upon each other. Any tendency to forward, backward, or lateral displacement is generally easily counteracted by means of compresses and short splints. The limb may then be placed in an easy position upon a slightly inclined plane, made of a bolster or pillow, or it may be suspended by a cord and pulley to the tester of the bed, as may be found most agreeable or convenient.

Counter-extension may be made when the fracture is oblique, by means of a box provided with a foot-board, and two lateral splints, one extending to the perineum, and the other to the axilla, as I have generally myself preferred; or with the contrivance of Dr. Neill, consisting of a box, reaching as high as the middle of the thigh, the counter-extension being made with adhesive strips,

Fig. 427.

Dr. Neill's apparatus for fracture of the leg.

passed through holes at the upper part of the apparatus, and tied on the outside, as exhibited in fig. 427.

The use of the gaiter, fig. 428, in the treatment of fractures of the leg and

thigh, attended with shortening and deformity, cannot be too pointedly condemned, as it is almost impossible, in any case, however carefully watched, to

Fig. 428.

Application of the garter.

Fig. 429.

Application of the handkerchief.

prevent chafing, and other inconvenience. A similar remark is applicable, only more forcibly, to the handkerchief, fig. 429, at one time so much employed for this purpose. Both appliances should be proscribed, especially as an admirable substitute may always be found in adhesive strips, secured to the sides of the limb, fig. 430, and tied at the bottom of the foot-board.

The annexed cut, fig. 431, represents the method of treating oblique fractures

Fig. 430.

Application of adhesive strips for making extension.

of the leg, recommended by Dr. Swinburne. A narrow, delicate splint and foot piece are fastened by means of adhesive plaster, while counter-extension is made from the knee by strips of the same material looped about the limb below the joint. A strong cord is then passed through this loop, and thence on through a hole in the side splint, opposite the lower part of the thigh, in order to afford the

Fig. 431.

Dr Swinburne's apparatus.

requisite degree of tension. If, after the apparatus has been applied, the limb is not sufficiently steady, adhesive strips must be used, as represented in the engraving.

Suspension of the leg may sometimes be advantageously practised, both as it respects the comfort of the patient and the welfare of the fracture. It may be done according to the method recommended, many years ago, by Professor N. R. Smith, or the very simple contrivance of Mr. Salter, of England, depicted in fig. 432, representing the limb surrounded by the apparatus and slung to the tester of the bed. The case in which the leg rests is made of light metal; and the whole contrivance is so arranged as to admit of lateral motion, and also of sliding up and down, simply by the rolling of the pulley-wheels upon the horizontal bar.

The apparatus of Dr. Smith may be used for fractures of any of the long bones

of the lower extremity, whether simple, compound, or complicated. It consists,

Fig. 432.

Salter's apparatus for suspending the leg.

as is seen in fig. 433, of two pieces, united by a hinge, after the fashion of a double inclined plane, one corresponding with the thigh, and the other with the leg, the latter supporting a shoe, which is attached by a thumb-screw, and is so arranged as to be rotated outwards or inwards, thereby elevating or depressing

Fig. 433.

Dr. N. R. Smith's suspending apparatus.

the toe, as may be deemed most desirable. The two pieces are supplied with side boards, joined by bows of iron beneath; and they are so constructed, both at the knee and at the foot, that they may be elongated or shortened at pleasure. Moreover, a short crutch, movable and well padded, is secured to the inner and upper extremity of the thigh portion, in order to prevent injurious pressure upon the perineum. Another piece, well padded, movable, and composed of iron, is appended to the superior and outer part of the apparatus, and is fastened round the trunk by a strong band. The thigh and leg rest on slings attached to the side-pieces, the latter being confined in the apparatus by its own weight, aided by a bandage, while the former is supported in front by a well padded, flexible splint. The whole contrivance is suspended to the ceiling, or the tester of the bed, by a single cord, attached below the knee, near the centre of gravity of the limb and apparatus. The cord ascends with a slight obliquity from the trunk, so as to effect the requisite extension, by making gentle traction on the limb, which is completely grasped by the apparatus, and consequently firmly held by it. In this manner, the member is compelled to obey all the accidental and

necessary movements of the body, thus obviating all strain and tension at the seat of fracture.

COMPLICATED FRACTURES OF THE LEG.

Fractures of the leg are not unfrequently complicated, whether involving both bones or only one, as in fig. 434. In the latter case, the tibia, much more frequently than the fibula, is the piece that is most liable to suffer. Such accidents are produced in various ways; sometimes by violence applied to the foot, as when a man jumps out of a second story window, or falls from a scaffolding; but more generally by direct force, as the passage of the wheel of a carriage, a blow from a stone, or the kick of a horse. When produced by these and

Fig. 434.

Complicated fracture of the leg.

similar causes, the lesion is usually situated in the inferior portion of the leg, towards the ankle-joint, which is not unfrequently penetrated. Fractures of the leg, occasioned by railway violence, are always of a comminuted character, the bones being extensively crushed, and the soft parts severely lacerated and contused, if not actually pulpified. Hemorrhage, both venous and arterial, often sadly complicates such injuries, and, along with the shock, sometimes proves speedily fatal, the system, perhaps, never fairly reacting after the accident. Complicated fractures of the leg, of a very bad character, are also frequently produced by machinery in rapid motion, and by gunshot violence. Sometimes, again, especially when there is unusual brittleness of the osseous tissue, the bones are frightfully broken by causes so trivial as to surprise us how they could have induced such a result.

In whatever manner complicated fractures of the leg may happen, the ends of the fragments, particularly those of the tibia, are extremely liable to protrude at the wound; the latter often in such a manner as to render it very difficult to effect replacement, owing to its being tightly girt by the edges of the opening in the integuments, and also to the great length which so frequently distinguishes it. The symptoms of such accidents are always sufficiently characteristic, since there is usually not only great deformity, but likewise, as just stated, exposure of the ends of the broken pieces. Nevertheless, although no difficulty can attend the diagnosis, under such circumstances, so far as the existence of fracture is concerned, yet the surgeon should always institute a most careful and searching examination, with a view of ascertaining the real condition of the soft structures, the welfare of which is often much more deeply interested than that of the bones themselves. The first object, in every case of the kind, should be to determine what should be done; whether an attempt should be made to save the limb or to cut it off. As a general rule, it may be stated that when—if I may use an antithetical and apparently contradictory expression—the complicated fracture is simple, that is, without any serious lesion of the soft parts, an effort should always be made to preserve the limb, especially if the patient is young and robust, and the bone not comminuted, although perhaps broken at several differ-

ent points. It is true, such cases sometimes terminate unfavorably, both as it respects limb and life; and it should also be borne in mind that the injury sustained both by the soft and osseous tissues may be much greater and more serious than the eye and hand can possibly trace. The dangers, too, from tetanus, pyemia, erysipelas, secondary hemorrhage, and profuse and exhausting suppuration, are not to be overlooked by the surgeon in his laudable endeavors to save a patient from mutilation; nor is he to forget that such lesions, especially when seated near the ankle-joint, are extremely liable to be followed by ankylosis.

When the bones are severely comminuted, the soft parts terribly lacerated, or the ankle-joint extensively opened—in short, when the limb has been frightfully bruised, torn, and crushed—no one would hesitate to use the knife the moment sufficient reaction has taken place to enable the system to withstand the additional shock. The case even then is frequently a bad one, the patient often rapidly sinking from exhaustion, or soon after from the effects of pyemia.

When an attempt is made to preserve the limb, the first indication is to arrest hemorrhage; the second, to coaptate the ends of the broken bone; the third, to place the limb in an easy, comfortable, retentive apparatus; and the fourth, to moderate the resulting inflammation. These intentions are to be fulfilled in conformity with the general principles laid down under the head of general observations on fractures. If the ends of the fragments are unusually long and sharp, and disposed to protrude despite the ordinary precautions, the best plan will be to retrace them; being careful, however, to cut off as little as possible. The edges of the wound are accurately approximated by suture and collodion, every effort being made to exclude the air. The best fracture apparatus is the wooden box, *fig. 435*, so much used in this city, both in private and hospital practice, consisting of four pieces, one corresponding with the back of the leg, and two with its sides, the fourth being intended for the foot. The latter, projecting nearly perpendicularly, is provided with two mortise holes, for the reception of the extending bands. The two lateral pieces are secured each by two hinges to the back board, so as to admit of being opened or shut at pleasure during the application and removal of the dressings. The limb, enveloped in the bandage of *Scultetus*, is carefully laid into the box, previously closed, and partially filled with coarse bran, which is afterwards piled on until the whole leg and the spaces on each side of it are completely covered in. The advantage of the bran, thus used, is that it affords not only easy, equable, and comfortable support to the broken bones, but also that it readily absorbs the discharges, and prevents the deposit of the ova of the fly, so common during the hot months of this and other countries. Substitution is effected whenever the substance becomes soiled and caked. For a knowledge of this mode of treating compound fractures of the leg, the profession is indebted to *Dr. John Rees Barton*, and there is no question that it is one of the most valu-

Fig. 435.

Fracture-box.

Fig. 436.

Complicated fracture of the leg, dressed.

able improvements that have been introduced into the management of this class of injuries at the present day, whether it be viewed merely with reference to the comfort of the patient, the safety of the limb, or the convenience of the surgeon.

The necessary extension and counter-extension are easily effected by adhesive strips. For the first week or ten days, leeches and cold water-dressing will generally be required. Should suppuration arise, the most soothing application will be a linseed poultice.

A very common mode of dressing compound fractures of the tibia alone is by M'Intyre's screw splint, represented in fig. 436, well padded, and extended; an opening being left in the bandage opposite the wound.

FRACTURES OF THE PATELLA.

Fracture of the patella, figs. 437 and 438, although comparatively uncommon, is of great practical importance, from its proximity to the knee-joint,

Fig. 437.

Transverse fracture of the patella.

Fig. 438.

Oblique fracture of the patella.

and the imperfect manner in which it is usually repaired. It may extend through the bone in any direction, transversely, obliquely, or vertically, the frequency of the occurrence being in the order here stated. When the fracture is comminuted, the fissures often exhibit the most irregular arrangement.

The causes of the accident are two, external violence, and muscular action. The transverse fracture is

nearly always produced by the latter, or by the joint agency of the two, while the oblique and vertical are invariably the result of direct injury, as a fall, blow, or kick. In the latter case, consequently, there is frequently severe contusion of the soft parts, and sometimes the knee-joint is even laid open. The transverse fracture is produced by falls in which the leg is strongly flexed upon the thigh, while the body is thrown suddenly and forcibly backwards, thereby putting the extensor muscles powerfully upon the stretch, the line of fracture usually taking place just above the middle of the bone. Jumping out of a carriage, and falling backwards upon the ground, is one of the most common ways in which the accident is occasioned. Circus-riders and ballet-dancers sometimes break this bone in the act of leaping in the exercise of their profession.

The symptoms of fracture of the patella are generally well marked. In the transverse form of the lesion, the nature of the accident is at once detectable by the change in the contour of the knee, by the inability to extend the limb, and

Fig. 439.

Fracture of the patella.

by the displacement of the upper fragment, as seen in fig. 439. In many cases the person is conscious, at the moment of the injury, of something having given way, and perhaps he may have even heard the peculiar characteristic snap. If he attempts to get up and walk, he will be almost sure to fall, from his inability to extend the leg and support the weight of the body upon it. The displacement is usually considerable, the superior fragment being drawn upwards upon the fore part of the thigh by the extensor muscles. The height to which it may be carried varies according to the extent of the destruction of the ligamentous connection of the tendon of these muscles. When the separation is complete, it may amount to two and a half, three, and even four inches, while under opposite circumstances it may not exceed six, eight, or ten

lines. The distance between the two fragments is always increased by bending the leg. The front of the knee has a flattened appearance, and upon passing the finger over it its point will be found to sink down abruptly as it were into the joint. The lower fragment is stationary, but the upper is easily moved, and may, by thorough extension of the limb, be brought down into its normal situation, so as to enable us to detect crepitus. If some time has elapsed since the occurrence of the accident, considerable swelling may be present, obscuring somewhat the diagnosis.

In respect to its mode of union, the transverse fracture of the patella holds the same relation as a similar injury of the olecranon. In both cases the nutrition of the fragments is seriously impaired by the laceration of the vessels, and in both great difficulty is experienced in maintaining coaptation. Hence the union always takes place by ligament and not by bone. In all the examples of this fracture that I have been able to examine, both in the living subject and in museums, I have not met with any in which the consolidation was completely osseous. A few such cases, however, have been described by surgeons. In the inferior animals it is not uncommon, if care is taken to keep the ends of the bone accurately in contact. When the interval between the broken pieces is very considerable, as, for example, when it amounts to two inches, the union is established by the aponeurotic tissue which naturally covers the patella, and which, in this event, extends from one fragment to the other, the plastic matter which is poured out in consequence of the injury not being capable of becoming organized and converted into ligamentous matter. Whatever may be the nature of the connecting medium, it is important that it should be as close and perfect as possible; for it is found that the joint will always be weak and unprotected precisely in proportion to its length and thinness.

The annexed cut, fig. 440, represents a specimen of fracture of this bone in the cabinet of Professor Pancoast. It will be seen that the patella is broken into three pieces, the superior one being drawn up in front of the thigh, far away from the joint, and nearly four inches from the inferior, which consists of a mere little strip, hardly two lines in width, corresponding with the lower edge of the bone. No union followed, owing, doubtless, to bad management or neglect, and the consequence must have been a very imperfect use of the limb.

The treatment of transverse fracture of the patella is attended with serious difficulty on account of the trouble experienced in controlling the action of the extensor muscles, whose tendency constantly is to draw the superior fragment upwards away from the lower. To counteract this tendency, therefore, constitutes the chief indication of the treatment. This can be effected only by maintaining the leg steadily and faithfully in a complete state of extension, the thigh being at the same time flexed upon the pelvis, and the body kept in the semi-erect posture. In this manner, the extensor muscles are thoroughly and effectually relaxed. The most efficient contrivance for insuring this position of the limb is a strong, well padded tin-case, long enough to reach from the middle of the thigh to the corresponding point of the leg, a roller having previously been applied from the toes upwards, and another from the groin downwards. The superior fragment, having been brought into place, is next confined by numerous adhesive strips, carried round the bone above and below the joint, and connected afterwards by vertical and transverse pieces. The dressing is completed by the application of a long, thick, and rather narrow compress, extended round the upper border of the patella, and confined by the two rollers passed round the joint in the form of the figure 8. Managed in this way, it is hardly possible for the fracture to suffer the slightest displacement, or

Fig. 440.

Old fracture of the patella, showing the separation of the fragments.

to conceive of anything better calculated to fulfil the end in view. The tin-case maintains the limb in the extended position, the adhesive strips and compress retain the upper fragment in contact with the lower, and the two rollers, applied in opposite directions, aid powerfully in controlling muscular contraction.

When a suitable case cannot be procured, the object may be attained by the use of a wooden splint, well padded, and stretched along the posterior part of the thigh and leg. The adjoining drawing, fig. 441, represents the mode of dressing transverse fractures of the patella, pursued by Professor Hamilton, and also, with slight modifications, at the Pennsylvania Hospital. The plan is an

Fig. 441.

Apparatus for fracture of the patella.

excellent one, and seldom fails to effect a good cure; often with hardly any interspace between the ends of the fragments. The letters require brief explanation: *a* is the bed; *b*, floor of the splint; *c*, foot-piece, provided with holes and side-pins; *d*, inclined plane, constructed so that it may be raised or lowered at pleasure; *e*, cushion, thicker under the knee than at either end; *f*, roller, not completely applied, to secure the limb to the inclined plane; *g*, adhesive strips, laid over a compress, and crossed under the splint, those from above passing through a notch in the board behind the knee; *h, h*, ends of the compress.

As ankylosis is one of the occurrences most to be dreaded after this fracture, passive motion should be employed as soon as the union is sufficiently advanced to admit of it. This will usually be by the end of the third week. It should afterwards be repeated, at first every other day, and then every day, until all risk of this accident is passed. The limb must not be used for the ordinary purpose of progression for three or four months, experience having shown that, if it is exercised too early, the connecting bond will become gradually more and more elongated, and thus materially interfere with the restoration of the functions of the joint. At the expiration of four weeks, the tin-case may be taken off, and a leather splint substituted, the patient walking about upon crutches.

A portion of the patella may be broken off obliquely, and, suffering no material displacement, may readily unite by bony matter, as any other fracture. A similar result generally follows when the fissure is vertical, with little or no separation of the fragments, the tendency to which is very slight, as the broken pieces are not influenced by muscular contraction. The prognosis is, therefore, other things being equal, always favorable, although, owing to the proximity of the knee-joint, a considerable period will usually elapse before there will be perfect restoration of the functions of the limb.

The signs of these fractures are sometimes very obscure, especially if there is much swelling of the soft parts. In general, however, the nature of the case may be determined by the impaired motion of the knee-joint, by the fixed character of the pain, and by making pressure upon the patella in opposite directions.

The limb, having been enveloped in a bandage, should be kept at rest in an

elevated and extended position until there is complete subsidence of inflammation, when the starch dressing should be applied, the patient being permitted to move about upon crutches. If the fracture is vertical, or nearly so, it will be necessary to support the fragments by means of two compresses, stretched along the lateral borders of the bone, and confined by adhesive strips and a roller. When the fissure is very oblique, the displacement may be such as to demand a course of treatment similar to that necessary in a transverse fracture.

When the patella has once been broken transversely, it is exceedingly liable to a recurrence of the accident from comparatively slight muscular contraction. The patient should, therefore, always be put upon his guard in this respect. The fracture may occur at the same point, but generally it takes place a little higher up. Finally, when one patella has been broken, the other is apt to suffer in a similar manner, owing to the imperfect use of the affected limb, and the consequent liability of the patient to fall.

FRACTURES OF THE FEMUR.

Fractures of the femur deserve the most attentive study; for not only are they of frequent occurrence, but they present themselves under every possible variety of form, and there are no injuries of the kind which, to use the language of Pott, "so often lame the patient and disgrace the surgeon." Any portion of the bone may give way, and hence it is customary, in treating of the subject, to speak of fractures of the shaft of the femur, of its condyles, and of its superior extremity, or of its neck, and of its trochanters.

1. FRACTURES OF THE SHAFT.

The shaft of the femur may be broken in any portion of its extent, but there are three points which are particularly obnoxious to fracture. These are the upper fourth of the bone, the middle, and the inferior fourth, the relative frequency of the accident being in the order here stated, although it is generally asserted that the bone yields more frequently at or near its middle than anywhere else. This idea, however, accords neither with the results of my observations upon the living subject, nor with my examinations of specimens of fractured bones in different collections. The relative difference, however, is, no doubt, very slight. A brief account of the lesion, as it occurs at these several points, will suffice to place the subject in a proper practical light, and serve to prevent those sad mistakes, often so disastrous both to the patient and the attendant.

Fractures of the Upper Fourth of the Shaft.—The most common site of fracture of this portion of the bone is from two and a half to three inches and a half below the small trochanter; the line of fracture is almost always oblique, extending from behind forwards, and from above downwards, being frequently from an inch and a half to two inches in length. A transverse fracture here is an exceedingly rare occurrence. It is also very uncommon to see the bone give way just below the small trochanter, and it is worthy of note that, when it does break at this point, it is generally complicated in its character, or associated with extra-capsular fracture, properly so termed.

The *symptoms* of fracture seated in this portion of the femur are generally so obvious as to indicate at once the nature of the injury, the characteristic signs consisting of great shortening and angular deformity. The shortening varies from two to four inches, and usually exists in full force immediately after the receipt of the injury. The superior portion of the limb is remarkably distorted, being convex on its external surface, with a corresponding concavity internally, occasioned by the overlapping of the ends of the broken bone, the upper nearly always lying in front of the lower, and both being usually directed somewhat outwards. In ten specimens of fracture of the upper fourth of the shaft of the femur, now before me, I find that in all, except one, the upper fragment is in front of the lower, the reverse being the case in the other. In these ten speci-

mens the superior piece is drawn forwards and outwards in six; in two it is tilted upwards and inwards; and in two it is raised up and in a straight line with the lower, or without any lateral deviation whatever. The distance of the fracture from the small trochanter ranges from two inches and two-thirds to three inches and a quarter.

In the six specimens in which the superior fragment is directed forwards and outwards, the lower fragment is also inclined outwards in four, the junction between them being such as to give the bone more or less of an arched appearance, the convexity being external and the concavity internal. In the two specimens in which the upper end is directed forwards and inwards, the lower end, in one, is inclined inwards also, and in the other it is straight, or in a line with the superior fragment. In seven of the eight specimens in which the displacement is lateral, the inferior fragment is more or less strongly everted, and, consequently, the knee and foot, during life, must have been in the same position.

The fractures, so far as can be determined, were all oblique, the line of disjunction, in nine, extending from behind forwards, and from above downwards, one only being in the opposite direction, and in this the lower fragment lies in front of the upper, overlapping it four inches. The distance at which the ends of the bone are separated anteriorly varies from half an inch to an inch and three-quarters. The angle which the superior fragment forms with the inferior does not, in any of the ten specimens, exceed 45° , while in most it falls considerably short of this.

I have been thus particular in giving the results of these examinations, on account of their practical bearing upon fractures of the superior extremity of the shaft of this bone. Sir Astley Cooper, and those who have adopted his views, have evidently formed very erroneous ideas, not only as regards the extent and direction of the displacement of the upper fragment, but also of its causes. Thus it has been asserted that the upper end often overlaps the other almost at a right angle, which is not the case in any of the specimens that I have examined; on the other hand, it has been alleged that the two pieces are usually inclined outwards, which the specimens alluded to also disprove, there being no lateral deviation whatever in two, while in two others the projection was inward, leaving thus only six cases of outward displacement. The displacement forwards of the upper end is due to the joint action of the psoas and iliac muscles, assisted perhaps by the pectineal and the short head of the adductor, while it is dragged outwards mainly by the agency of the external rotators. The lower fragment, on the contrary, is drawn up by the action of the flexor muscles of the thigh, and outwards by the tensor, vastus, and gluteal muscles. That the direction of the fracture materially influences the direction of the displacement is shown by the fact that, in the only specimen out of the ten examined by me in which the line of fracture extended from before backwards, and from below upwards, the lower fragment overlapped the upper, and that to a great extent.

Although the specimens here described are, I conceive, of great pathological and practical value, yet it must not be forgotten that any inferences deducible from their examination are impaired, in some degree, by the fact that the displacement which characterizes them may have been influenced more or less by the nature of the treatment. Thus, in consequence of the use of splints, the ends of the fragments, originally inclined inwards or outwards, may have been pushed and held in the opposite direction, thereby completely reversing the primitive order of the deformity, as caused by the direction of the fracture, the weight of the limb, and the action of the muscles.

The annexed drawings, two of which are from my own preparations, will serve to illustrate the nature of the displacement so often met with in fractures of the superior portion of the shaft of the femur.

Fractures at the Middle of the Shaft.—A fracture at the centre of the shaft of the femur is, according to my observation, an uncommon occurrence; most generally the bone gives way some distance above or below this point. The line of fracture is, for the most part, very oblique, extending from behind forwards and from above downwards, and the consequence is that the superior fragment

nearly always overlaps the inferior, the upper extremity of which is drawn backwards, and usually, also, somewhat outwards, by the action of the flexor muscles, causing thus an amount of shortening of from two and a half to three and even four inches, with more or less angularity at the site of injury, and marked eversion

Fig. 442.

Fig. 443.

Fig. 444.

Fracture of the shaft of the femur; upper portion.

of the limb. The lower end of the superior fragment, on the contrary, forms a prominent projection on the fore part of the thigh, easily perceived by sight and touch. The symptoms are of course characteristic.

A perfectly horizontal fracture of the shaft of the femur is an extremely uncommon occurrence; so much so that, although the phenomena might be such as to lead to the suspicion of its existence, the idea that it really is an injury of that kind should not be carried out in practice, lest, the requisite extension and counter-extension being omitted, permanent shortening should follow. When there is no marked tendency to displacement, it will generally be found that the fracture, instead of being transverse, is slightly impacted, or that its extremities, being denticulated, are interlocked with each other, and thus held in place. Comminuted fracture of this portion of the shaft is not uncommon, especially in old subjects, laboring under fragility of the osseous tissue.

The accident may be the result of direct violence, as a kick from a horse or the passage of the wheel of a carriage, in which case it is often of a compound or complicated character; or it may be occasioned indirectly by a fall upon the foot or knee.

Fractures of the Inferior Fourth of the Shaft.—Fracture of the inferior portion of the shaft of this bone derives a special interest from the fact that, when occurring very low down, the inferior end of the upper fragment may, especially if it is very long and sharp, penetrate the joint, and thus seriously complicate a case otherwise easy of management. The fracture, moreover, is liable to be compound, the upper piece piercing the muscles and integuments just above the knee. As in fracture of the other divisions of the shaft, already described, so in this the line of the solution of continuity generally ranges from behind forwards

and from above downwards, a transverse fracture, properly so termed, being extremely uncommon. The degree of obliquity is variable, but generally it is so considerable as to cause great shortening of the limb and angularity of the part; which, together with the everted state of the knee and foot, are characteristic signs of the nature of the accident. The inferior fragment is always drawn backwards and upwards, its superior extremity forming a distinct prominence in the popliteal region, which can easily be effaced by restoring the pieces to their proper position. When the fracture occupies the lower extremity of the shaft, nearly on a level with the joint, the upper fragment may descend so far down as to push the patella away from the trochlea of the femur, over upon the tibia, so as to create an appearance simulative of partial luxation of this little bone. If several hours have elapsed since the receipt of the injury, the diagnosis will sometimes be obscured by the tumefaction of the joint; but, in general, whatever may be the condition of the parts, any existing doubt may be cleared up by a thorough examination of the limb.

The relative position of the fragments in this fracture are well depicted in fig. 445, from a specimen in my cabinet.

Fig. 445.

Fracture of the femur at its inferior fourth.

The causes of fracture in this situation are commonly of a direct nature, a greater amount of force seeming to be necessary to produce it than when it occurs higher up. It may, however, be induced in an indirect manner, as when a person, falling from a considerable height, alights upon his foot or knee, the violence of the shock being concentrated upon the inferior portion of the femur.

Treatment.—The treatment of fractures of the shaft of the thigh-bone may be conducted according to several plans, of which that by extension and counter-extension, the limb being in the straight position, is, as a general rule, the most eligible, fulfilling, as it does, more effectually than any other, the different indications presented by this class of injuries. Before any steps, however, are taken to adjust the broken pieces, it is the duty of the attendant to see that a suitable bed is procured for the comfortable accommodation of his patient, as well as for the secure management of the case. This subject having already been discussed in a previous part of the work, it will be sufficient, for my present purpose, merely to allude to it here, with the hope of enforcing more fully its importance. I am so thoroughly convinced of the utter impossibility of treating fractures of the femur successfully without a good bed, that I should consider any surgeon justifiable in declining to undertake the management of any case unless his efforts were properly seconded in this respect. There must be no compromise upon the subject; for, if the cure turn out badly, no allowance will be made by the patient and his friends for any deficiencies, short-coming, or want of co-operation on their part. The whole blame falls upon the professional attendant, it being very properly assumed that he ought to know better than any one else what the emergency demands, and he should, therefore, spare no pains to meet it. Every fracture-bed should have slats, a good, firm, but elastic mattress, and arrangements for the evacuation of the bowels, so that the patient

may not be compelled to rise when he wishes to relieve himself. These essentials are all admirably combined in the ingenious contrivances of Dr. B. H. Coates, Dr. Addinell Hewson, and others, which my limits, however, will not permit me to describe.

When both thighs are broken, or even when only one is affected, Jenks's fracture-bed, represented in fig. 446, will be found extremely convenient, both for evacuating the bowels and for making up the bed. It is thus described by Dr. Gibson :—

Fig. 446.

Jenks's fracture-bed.

"It is composed of two upright posts about six feet high, supported each by a pedestal; of two horizontal bars, at the top, somewhat longer than a common bedstead; of a windlass of the same length placed six inches below the upper bar; of a cog-wheel and handle; of linen belts, from six to twelve inches wide; of straps secured at one end of the windlass, and at the other having hooks attached to corresponding eyes in the linen belts; of a head-piece made of netting; of a piece of sheet-iron twelve inches long, and hollowed out to fit and surround the thigh; of a bed-pan, box, and cushion to support it, and of some other minor parts."

For the purpose of securing quietude of the limb, and accuracy of apposition of the ends of the fragments, numerous contrivances have been devised, all possessing, apparently, more or less merit, and yet not one of them so perfect as to be wholly unexceptionable. A bare description and delineation of all the fracture apparatus now before the profession would form a stately volume. The surgical cabinets of some of our medical schools contain cart-loads of such material, most of it as effete as the contents of a curiosity-shop. Much of this apparatus has been patented, and extensively distributed by the inventors. The character of most of it is familiar to me, and I do not hesitate to declare that a large proportion of it is most villanous. The great and fundamental principles which every contrivance of the kind must necessarily possess is enjoyed by all, though in different degrees of perfection, and it cannot be doubted that the constant multiplication of such machinery, and the implicit confidence reposed in it by the younger members of the profession, have been a prolific source of the many disastrous results that have so frequently, especially of late years, attended the treatment of fractures of the thigh. I have long been satisfied that the more simple the apparatus is, the more easily it is managed, and the more likely to

prove efficient. With a proper knowledge of what is needed, and a little ingenuity on the part of the surgeon, the requisite means for the successful management of almost every case of fracture of the femur, however bad, may generally be provided upon the spur of the occasion, or, at all events, within a reasonable time after the occurrence of the injury.

The apparatus which is usually employed in this country is that of Desault, as modified and improved by Physick, consisting of one long splint, fig. 447, extending from below the sole of the foot to the axilla, and of a short one extending from the same point to the perineum. They are connected below by a transverse bar, for receiving the extending bands, and along the leg and thigh by strips of bandage. The counter-extension is effected by a suitable thigh belt, the ends of which are passed through the mortise holes near the upper end of the splint. The apparatus is, however, an awkward one, constantly subject to derangement, and the results obtained by its aid are by no means so gratifying as they should be. It has always been found extremely unsatisfactory in my practice, and I have therefore, for many years, never employed it in a single case, having given the preference to the fracture-box, represented in fig. 448. This box, which I used, for the first time, upwards of twenty-

Fig. 447.

Physick's long splint.

Fig. 448.

The author's fracture apparatus.

five years ago, extends from the tuberosity of the ischium to a level with the sole of the foot, which rests against the vertical piece, provided with two slit-like holes for the passage of the extending bands. The posterior surface of the box is hollowed out for the more easy accommodation of the thigh and leg, while the side-pieces, fastened by hinges to the horizontal one, project so as to come to a level with the surface of the limb in front. To the outside of the box is secured a movable splint, about two inches in width, crutch-shaped and well padded above, and long enough to reach into the axilla, while another, similarly arranged and constructed, is attached to the inside, being intended to press against the perineum. The whole apparatus is made as light as possible, and any intervals that may exist between it and the limb, after it has been properly adjusted, may be filled with cotton, tow, or, what is preferable, especially in compound fractures, with wheat bran, the latter answering an admirable purpose, under such circumstances, not only affording an agreeable protection to the broken bone, but absorbing the discharges and preventing the development of maggots, which are so liable to form in such cases in hot weather. In changing the dressings, all that is necessary is to let down the sides of the box, the extension being, in the meantime, kept up, if necessary, by an assistant having hold of the foot. A broad leather splint, or one of binder's board, extending from the groin to the knee, should cover the thigh in front; it should be accurately moulded to the parts, and be firmly secured in its place with pieces of tape encircling the box.

Instead of the fracture-box now described, use may be made of two splints, one of binder's board and the other of wood, the former, which is intended for the inside of the thigh, reaching from the groin to the knee, while the other, placed along the outside of the limb, extends as high up, on the one hand, as the

crest of the ilium, and, on the other, as low down as four inches below the level of the sole of the foot. These splints being well padded, are secured with an ordinary roller, the adhesive strips being attached to the inferior extremity of the long one, in order to keep up the requisite degree of extension.

Within the last few years adhesive plaster has been much employed in this city, both for maintaining extension and counter-extension in fractures of the thigh, chiefly through the influence and writings of Dr. Gilbert and Dr. Neill. The practice, which is rapidly coming into general vogue, is unquestionably, as stated elsewhere, a great improvement upon the ordinary means heretofore in use, as it not only tends to preserve better and closer union of the ends of the fragments, but, what is a matter of great moment to the patient, prevents the pain, chafing, and ulceration which so frequently attend the old methods. The treatment is equally serviceable in simple and compound oblique fractures of the lower extremity.

In a remarkable case of compound fracture of both thigh-bones, in a boy eleven years of age, recently under the care of Dr. Gilbert, a most excellent cure was effected by means of adhesive plaster, aided by the apparatus represented in fig. 449; the dressings being removed on the forty-fifth day. A long splint was stretched along the outside of each limb, from a few inches below the sole of the foot to within a short distance of the axilla; the extending strips, tied under the sole of the foot, and secured to a horizontal block, were controlled by a tourniquet; while the counter-extending strips were carried along the pelvis, both in front and behind, and firmly fastened by transverse bands passed round the hip-bones, the back, and abdomen.

A valuable addition to the long splint, affording increased means for making counter-extension, was suggested, in 1860, by Dr. H. Lenox Hodge. It consists, as will be seen by reference to figs. 450 and 451, of a bar of wrought iron, secured to the outer and upper part of the splint by bolts with movable nuts, and bent to the right or left, in accordance with the side to which it is applied. The splint should be sufficiently wide above to permit the rod, which terminates in a horizontal hook, about six inches in length, to pass clear of the patient's arm and shoulder. A long strip of adhesive plaster, at least two inches and a half in breadth, is extended along the front of the body from the pelvis to the top of the shoulder, and thence down the back to the buttock, leaving, as it crosses the

Fig. 449.

Dr. Gilbert's fracture apparatus.

Fig. 450.

Dr. Hodge's method of counter-extension in fracture of the femur.

shoulder, a short loop, in which is placed a small block of wood, fastened by means of a tape to the hook of the bar. To prevent the long strip from be-

Fig. 451.

Bar of wrought iron for counter-extension.

coming detached, the body is completely encircled, at different heights, by three horizontal bands.

The advantages of this contrivance are that the extension and counter-extension are made in a straight line, that the dressings maintain their place much longer than the ordinary ones, and, lastly, that, as the patient cannot sit up in bed, there is less danger of displacement of the ends of the broken bone. The only objection to it is

that the circular adhesive bands might impede the respiration, but any trouble that might thus arise will generally speedily disappear of its own accord.

Professor N. R. Smith has for a long time treated fractures of the thigh with great ease and success, with what he calls the *anterior splint*. It consists, as seen in fig. 452, of a single piece, made of wire, of the size of a No. 10 bougie,

Fig. 452.

Dr. N. R. Smith's anterior splint.

and bent at each extremity, the whole representing the form of a long parallelogram, three inches wide above, and two inches and three-quarters below. It must be long enough to reach from a point a little above the anterior spinous process of the ilium to an inch beyond the toes, when the thigh, leg, and foot are extended, three feet eight inches being a good average length for adults. The side-pieces are firmly connected by cross-pieces at a distance of about eight inches. Thus constructed, the wire frame is easily bent to suit the case in hand. The angle at the tibio-tarsal joint, six inches from the extremity, is about 120° , to secure an easy posture for the foot; that at the knee and the one at the hip are each about 160° , the latter being seven inches from the upper extremity.

The splint, properly padded or tightly wrapped with a muslin bandage, and secured to the limb by a roller extended from the toes upward, is suspended by means of a pulley, cord, and loops to the ceiling, as represented in fig. 453, a compress being placed upon the instep and another upon the groin, to ward off pressure. The proper position of the hooks is a matter of great consequence. In general the upper one should be attached nearly over the seat of the fracture, and the lower a little above the middle of the leg, the object being the thorough equalization of the pressure of the splint. The roller, confining the apparatus, should be well stitched to prevent it from slipping, and great care taken that it do not make undue constriction. This apparatus, the efficacy of which has been thoroughly tested in numerous cases, is exceedingly light and comfortable, and is equally well adapted to fractures of the thigh and leg, in every portion of their extent.

An excellent mode of treating fractures of the thigh, attended with very gratifying results, and originally suggested by Dr. Gurdon Buck, is pursued at the New York Hospital. The long splints are entirely dispensed with, the extension being made by the action of a weight and pulley, and counter-extension by the usual perineal strap lengthened out and fastened to the head of the bedstead. A piece of adhesive plaster, from two and a half to three inches in width, is stretched along the sides of the limb, to a short distance above the knee, and confined with a roller extended from the toes up, the middle of it forming a loop below the sole

of the foot. A thin block of wood, the width of the plaster, and long enough to prevent pressure over the ankle, is inserted into the loop, and thus serves to receive the extending cord, which is fastened to an elastic rubber band passing round the block, and playing either over the footboard of the bedstead, or, if there

Fig. 453.

Dr. N. E. Smith's apparatus applied to the limb.

is none, a temporary frame, perforated at a height of about five inches above the level of the mattress. The thigh, at the seat of fracture, is surrounded with short splints, the heel is supported upon a thin, wedge-shaped hair cushion, and a bag, filled with sand or bran, is placed along the outside of the leg and foot to prevent rotation. The amount of weight to be employed must be determined by the age of the patient and the other circumstances of the case. A child under eight years of age will seldom require more than five or six pounds, while an adult may require from fifteen to twenty. The most suitable perineal band is a piece of India-rubber tubing, of one inch calibre, two feet in length, with a ring at each end, stuffed with bran or cotton lampwick, and covered with canton flannel, wrapped spirally round it, and renewed whenever it becomes solid. The apparatus of Dr. Buck is represented in fig. 454.

Fig. 454.

Dr. Buck's fracture apparatus.

The treatment of fractures of the thigh, lately introduced by Dr. Swinburne, recommends itself by its simplicity and efficiency, and deserves, in my judgment, the most favorable consideration. It consists, as will be seen by a reference to the annexed sketch, fig. 455, exclusively of extension and counter-extension, without splints, the perineal and crural bands being secured to the bedstead, as in Dr. Buck's apparatus, and composed of similar materials. Free use is

made of adhesive strips at the leg and foot, and also, if necessary, at the thigh. With such an arrangement, the affected limb may be inspected or measured as often as may be desired, all danger of embarrassing the circulation is done away with, perfect cleanliness may be preserved, and any topical applications that may be required may be made and removed with the utmost facility. The advantages

Fig. 456.

Dr. Swinburne's method of treating fractures of the thigh.

of this method are particularly conspicuous in complicated fractures of the thigh. Dr. Swinburne states that he has treated in this manner upwards of forty cases of fractures of the femur and tibia with very little, if any, shortening, except in the intra-capsular form of the accident.

Whatever apparatus be employed, whether those now described, or others of a similar character, there are several circumstances which should claim the special attention of the practitioner, especially in the treatment of fractures of the shaft of the femur.

1st. Care must be taken that the ends of the broken bone are steadily maintained on a line with each other; any tendency to angularity, lateral distortion, or tilting up of the fragments must be promptly counteracted by pressure opposite the point of projection. This disposition manifests itself, more or less, in nearly all fractures of the femur, and should never for a moment be lost sight of, lest it be not discovered until it is too late to remedy it. It is particularly strong when the fracture is seated from two and a half to three inches below the small trochanter, in consequence of the action, on the one hand, of the iliac and psoas muscles, and, on the other, of the external rotators; the former, as before stated, tilting the lower end of the superior fragment forwards, and the latter outwards. For want of attention to this circumstance, wretched deformity of the limb is a frequent result of this lesion.

2d. Proper care must be taken that no *shortening* occurs. To prevent this, constant vigilance must be exercised in regard to the tightening of the extending and counter-extending bands. If any doubt exist, a comparative estimate must be made from time to time of the length of the two limbs, by stretching a piece of tape from the centre of the umbilicus to the inferior and inner border of each patella, the body and limbs lying perfectly straight.

3d. A slightly *everted* condition of the limb being that which is most natural when the body is dorsally recumbent, the surgeon should aim to maintain it in that position during the period necessary to obtain reunion of the ends of the broken bone.

4th. The *heel* must be seen to; if it be neglected it will be sure to inflame and ulcerate, if not slough. Too much care, therefore, cannot be taken to ward off pressure by filling up the hollow on each side of the tendo Achillis with cotton, or by employing, if necessary, a small air-bag, or a bladder partially filled with water.

5th. *Extension* must be maintained with two broad strips of adhesive plaster, stretched along the sides of the leg nearly as high as the knee, secured by cross-pieces, and fastened to the foot-board of the splints or fracture-box; the surface being carefully shaved prior to their application. Or, instead of this, two long, broad strips of muslin are secured to the limb by means of a roller, the upper

extremity of each being turned, loop-like, down upon itself, over the bandage, and then properly fastened. The gaiter and handkerchief should not be used in any case, for reasons previously mentioned.

6th. The *perineal band* must also receive due attention, otherwise it will be sure to gall and fret the parts, and thus greatly distress the patient. Besides, if not properly managed, it will be extremely apt to displace the upper fragment, by pushing it outwards, away from the inferior.

7th. In *compound fractures*, one of the splints may be bracketed, as originally recommended by Dr. Hayes, of Indiana, the method having been adopted by him as early as 1813. The opening which is thus left affords ready access to the wound, and, consequently, great convenience for the application of the necessary dressing.

8th. Much objection has been urged by certain writers against the *bandage* in the treatment of fractures of the thigh, on the ground that it is not only inconvenient, but absolutely useless. My experience does not corroborate this statement. On the contrary, I have always derived the most marked benefit from the bandage, both in controlling spasm, and in counteracting the tendency to shortening, so common in nearly all cases of this kind. To answer the purpose, however, it must be applied with great care; otherwise harm, not benefit, will result.

In simple fractures of the thigh, the ordinary roller is sufficient, but in compound fractures preference is given to the bandage of Scultetus, inasmuch as, being composed of separate strips, it admits of more easy removal and reapplication.

The *starch bandage* may often be employed with great advantage, giving adequate support to the broken limb, and enabling the patient to take exercise in the open air, or about the house, upon crutches, a matter frequently of great importance. My experience, however, is averse to its use in the early stage of the treatment; applied too soon after the accident, before there is pretty complete subsidence of inflammation and swelling, it may do incalculable harm, not only greatly aggravating the local trouble, but endangering the safety of the limb by the induction of gangrene. For these reasons, therefore, I seldom resort to it before the end of a fortnight or the beginning of the third week.

8th. Care must be taken to keep off the bedclothes from the fractured limb, as their weight would not only be oppressive, but tend to derange the ends of the fragments. A good and ready mode of accomplishing this is to cut a stout barrel hoop through at the middle, and to place the two halves, tied firmly together, crosswise, over the injured extremity. Or, instead of this apparatus, the surgeon may use, what is much better, the frame depicted at page 869.

Mr. Pott, of England, conceived the idea that the best mode of treating fractures of the femur was to place the affected limb upon its outside, the body inclining in the same direction, and the knee being in a semi-flexed state. The leg and foot, supported upon smooth pillows, were elevated somewhat above the level of the thigh, which was enveloped by a many-tailed bandage, and covered in by two broad, carved wooden splints. This plan, which Mr. Pott recommended with all the enthusiasm of a man of genius, was founded upon the erroneous notion that it would completely relax the different sets of muscles connected with the broken bone, thus preventing them from acting injuriously upon its fragments; forgetting that, in proportion as he took off the tension from one class, he necessarily increased that of another. It has been found to be altogether impossible to carry out this plan successfully in practice, experience having shown that the patient is utterly unable to remain so long in one position without suffering greatly from bed-sores, and that the apparatus, with all the care that can be taken to keep it in place, is wholly inadequate to answer the purpose of an accurate adjuster.

Another mode of treating fractures of the body of the femur, quite different from any hitherto described, was much in vogue at one time, both in England and in this country, chiefly in consequence of the influence of the late Sir Charles Bell, by whom, if it was not originated by him, it was extensively employed for a long time at the Middlesex Hospital, London. It consists in placing the limb upon two grooved cushions, resting upon two pieces of board, united by hinges

in the form of a double inclined plane, as seen in fig. 456, and long enough to extend from the tuberosity of the ischium to the back part of the heel. A roller

Fig. 456.

Double inclined plane of Sir Charles Bell.

having previously been applied from the toes to the groin, two light, but firm binder's board splints, carefully softened in hot water, are secured to the outer and inner parts of the thigh, meeting nearly in front and reaching from the groin to the knee. The extremity is now laid over the inclined plane, in an easy, comfortable position, the angle of flexion having special reference to this point; the foot is attached to the foot-board, and the limb and plane being tied firmly together by tapes, or, what is better, a bandage, the dressing is completed.

The method of treatment by the double inclined plane ought not to be too lightly condemned, for it cannot be denied that very excellent cures are occasionally effected with it. Much less frequently employed now than formerly, it is more particularly applicable to the treatment of fractures of the condyles of the femur and of the upper extremity of this bone, attended with a constant disposition to displacement of the lower end of the superior fragment. It may also be advantageously employed in compound fractures, attended with severe contusion and laceration of the integuments, where confinement in the extended position would be productive of violent pain and great discomfort. The extension is made mainly by the weight of the leg and foot, while the counter-extension is made by the pressure of the apparatus against the tuberosity of the ischium. The annexed drawing, fig. 457, represents M'Intyre's splint, or double inclined plane, modified by Liston. Fig. 458 exhibits it as it is applied to the limb.

Fig. 457.

M'Intyre's splint, simplified and improved by Liston.

Fig. 458.

M'Intyre's splint applied to the limb.

Finally, when *both thighs* are broken the case may be treated with a double inclined plane, or a fracture-bed, the hinges being arranged in such a manner as to permit the trunk to be raised or lowered at pleasure, without causing any motion of the hips. The limbs should be well protected with side and front splints, and immovably tied together.

The period required for the consolidation of fractures of the shaft of the femur must necessarily be greatly influenced by circumstances, as the age and health of the patient, and the care with which the ends of the fragments are kept together. In children of from five to fifteen years, complete union may usually be looked for in from twenty-four to twenty-eight days. In eighteen cases analyzed by Dr. A. L. Peirson, of Massachusetts, the cure in persons of thirty years of age and under, occupied 35.88 days; while in seventeen, where the age was upwards of thirty, the average period was 36.64 days; thus showing only a very trifling difference in the two series.

It has been asserted by many highly respectable practitioners that it is always extremely difficult, if not impossible, to effect a cure in fractures of the shaft of the thigh-bone without some degree of shortening, and my opinion is that this conclusion is only too well founded. There can be no question at all that in many cases a certain degree of shortening is absolutely and positively unavoidable, not on account of any defect in the treatment, but from the very nature of the fracture itself. How is it possible it should be otherwise, when the ends of the fragments are driven the one into the other? The best skill and the most devoted attention would utterly fail, under such circumstances, to make a good limb. So, also, when a fracture is compound or comminuted, more or less deformity and shortening will almost be inevitable. In the New York Hospital, where fractures of the shaft of the thigh-bone are very common, and where this accident is probably treated with as much adroitness and care as anywhere in the world, from a third to half an inch of shortening is generally looked for, as a natural consequence, by the surgeons of the Institution, and it is questionable whether the statistics of similar establishments, if they could be ascertained, would exhibit a more favorable result.

2. FRACTURES OF THE INFERIOR EXTREMITY.

Fracture of the condyles of the femur is, in comparison with that of the humerus, an extremely infrequent occurrence. Indeed, it is very uncommon, not only relatively, but absolutely, speaking. Sir Astley Cooper mentions only two instances of the kind in his work on Dislocations and Fractures; the Dupuytren Museum at Paris, so rich in osteological preparations, contains but five specimens of the lesion; and in the Mütter collection, not a single bone, illustrative of the occurrence, is to be seen. The cabinet of Professor William Gibson, now at Richmond, has, however, several beautiful specimens of fracture of the condyles; and among my own preparations is a very rare one, in which these eminences are broken off vertically, leaving the trochlea attached to the lower end of the shaft which exhibits a remarkably comminuted appearance, consisting of not less than five distinct fragments.

The fracture may be limited to one of the condyles, which, however, is extremely rare, or it may implicate both, the fissure in the latter case extending between the two prominences, and terminating above in an oblique fracture of the shaft, so as to give rise to three distinct fragments. From the amount of force required to produce this fracture, it is generally attended with a great deal of injury to the soft parts, and, for the same reason, it is not infrequently of a compound and comminuted character, the ends of the fragments protruding either externally or projecting into the cavity of the knee-joint. A partial fracture of one of the condyles occasionally occurs. In rare cases, the fracture presents the character of impaction, the lower end of the shaft being forcibly impelled into the cancellous structure of the condyles, which are completely severed in their entire length. Fig. 459 conveys an excellent idea of a fracture of the external condyle from a drawing of Sir Astley Cooper.

Whatever form the fracture may assume, it is nearly always the result of direct violence; generally of a fall upon the knee, the passage of the wheel of a carriage, or the kick of a horse. In one of the three cases that have fallen under my observation, it was occasioned by a fall from a high scaffolding, the individual, a man upwards of fifty years of age, alighting upon his feet, but striking, before he could recover himself, his knee against a large stone. The subjects of these fractures are usually old persons, in whom the condyles of the femur have become atrophied and brittle from the effects of interstitial absorption and fatty degeneration.

Fig. 459.

Fracture of the external condyle.

The symptoms of fracture of the condyles are not always well characterized, owing to the fact that the fragments are generally held in place by the ligaments of the knee, thus preventing marked deformity, and rendering the production of crepitus difficult. The joint appears to be wider and flatter in front than usual, and if the patella be pressed backwards, the condyles may be considerably separated, so as to increase the transverse diameter of the limb. The joint is much swollen and bruised, the member is completely powerless, and, when the fracture affects both prominences, there is nearly always marked shortening, often amounting to from one to two inches, the lower fragment being drawn up behind the superior by the action of the hamstring muscles.

When only one condyle is broken, the deformity, other things being equal, will be less than when both suffer, and there will also, of course, be less shortening.

In the specimen of vertical fracture of the condyles in my cabinet, previously alluded to, the short fragment is drawn upwards against the posterior surface of the shaft of the femur, to the distance of at least two inches, its upper surface looking towards the trochlea, with which it forms an obtuse angle, thus greatly increasing the antero-posterior diameter of the joint. The various appearances of this rare specimen are well represented in fig. 460.

Fig. 460.

Comminuted fracture of the lower extremity of the femur.

Fracture of both condyles occasionally simulates a partial luxation of the head of the tibia backwards. In a case reported by Professor Neill, the symptoms resembled much more those of an accident of this kind than of a fracture of the condyles. The leg being thrown backwards, rendered the patella remarkably prominent in front, but there was no increased breadth of the knee, no crepitus, and no contortion of the foot, at the same time that it was easy to flex and extend the joint. The best diagnostic consists in taking hold of the condyles, and attempting to press them in opposite directions, which cannot be done, if there is no fracture. The same proceeding can hardly fail to elicit crepitation, although

this may be rather slight, especially if the fragments are held pretty firmly together by the ligaments.

The *prognosis* of this fracture is especially grave, on account both of the injury done to the soft parts, and of its connection with the joint, which may be involved in an alarming degree. The fracture may, as already stated, be compound or comminuted, and when this is the case the danger will, of course, be greatly increased, perhaps to such an extent as to require amputation, or, when this is not deemed advisable, in such a manner as to jeopard life by mortification, pyemia, erysipelas, or congestive pneumonia.

The *treatment* will usually require, in the first instance, to be strictly antiphlogistic, leeches and evaporating lotions being necessary, on account of the injury done to the soft parts. The limb, enveloped in a bandage, is laid in an easy position, and free use is made of anodynes in order to prevent spasm, so common and annoying after these accidents. As soon as the inflammation has been sufficiently subdued, the fragments are restored to their proper position, and maintained by appropriate apparatus, the limb being extended, if the fracture is transverse, or nearly so, or placed over a double inclined plane, if it is very oblique, with a strong tendency to displacement of the broken ends. Passive motion is instituted at the expiration of a month, but, despite the attention of the surgeon, a good and unexceptionable cure will be extremely difficult, if not impossible, especially when both condyles are implicated.

Complicated fractures of the condyles are occasionally met with, principally as the result of direct violence, such as the passage of the wheel of a carriage, or of gunshot injury, and are among the most dangerous of accidents, bringing life in jeopardy by tetanus, erysipelas, pyemia, profuse suppuration, and hectic irritation. The danger is proportionately increased when the lesion is attended with extensive wound of the knee-joint, or a comminuted condition of the bone. An attempt may be made to preserve the limb when the patient is young and in good health at the time of the fracture, when the weather is not too hot and exhausting, and when the injury in the soft parts is comparatively slight; under opposite circumstances the best plan will be to amputate on the spot, immediately after the occurrence of reaction. To hesitate, in such a case, would only be to trifle with the patient's life, which could hardly fail to be the forfeit of the surgeon's timidity.

3. FRACTURES OF THE SUPERIOR EXTREMITY OF THE FEMUR.

The superior extremity of the femur comprises the head and neck of that bone, together with the two trochanters, so that in an individual of ordinary stature it is from three inches and a quarter to three inches and a half in length, there being, however, no distinct boundary line between it and the shaft. The head composes nearly two-thirds of a sphere, and rests upon the neck, which is inclined obliquely upwards and inwards, so as to form an obtuse angle with it; they are surrounded by the capsular ligament, the strongest membrane of the kind in the body, and consist of a large amount of spongy tissue, inclosed by a thin lamella of compact substance. Both these structures undergo important changes in consequence of advancing age, the former becoming greatly rarefied, light, and porous, while the latter is so attenuated as to be, in some places, hardly as thick as common letter paper. These changes, the necessary effect of which is to render the bony texture frail and brittle, are particularly conspicuous after the fiftieth year, and are a principal cause of the frequency of fracture of the neck of the femur at and after this period of life. There is another circumstance, also, which doubtless materially contributes to this occurrence, namely, the alteration which this portion of the femur undergoes in its direction in the old, causing it, in many cases, to stand off almost at a right angle with the shaft of the bone, or even to sink slightly below this level. This alteration in the obliquity of the bone is, as a general rule, more common, as well as more marked, in women than in men, and hence it is that the former are always more liable to this fracture than the latter. These various appearances are well illustrated in the *adjoint*

Fig. 461 represents the ordinary normal shape of the head and neck, together with its spongy and compact structures. Fig. 462, from a preparation in my

Fig. 461.

Natural appearance of the head and neck of the femur.

Fig. 462.

Alterations of the head and neck of the femur from the effects of old age.

collection, affords a good idea of the changes which these parts experience in consequence of the effects of age.

A thorough knowledge of the disposition and strength of the two ligaments of

Fig. 463.

Head and neck of the femur with the capsular ligament laid open.

the hip-joint is of great consequence in the study of fractures of the superior extremity of the femur, both as it respects their symptoms and mode of repair. The capsular ligament, fig. 463, represents a kind of shut sac, which is attached, on the one hand, to the periphery of the cotyloid cavity, and, on the other, to the prominent lines which extend, in front and behind, from one trochanter to the other, thus including both the head and neck of the bone. It descends further down on the anterior than on the posterior surface of the neck, and is thicker and stronger above and behind than in any other portion of its extent. Anteriorly, it is strengthened by the psoas, iliac, and femoral muscles, together with a band of ligamentous fibres; posteriorly, by the geminal, pyriform, and inner obturator muscles; internally, by the pectineal and outer obturator muscles; and superiorly, by the small gluteal.

The inter-articular ligament—the round ligament of anatomists—is a dense, triangular bundle of fibres, which arises from the depression upon the head of the femur, just below

its centre, and is inserted by two divergent processes into the margins of the cotyloid notch of the acetabulum.

These two ligaments, maintaining the head and neck of the femur in their proper position, generally sustain serious injury in fracture of the superior extre-

mity of the bone. When the lesion is intra-capsular, the capsular ligament is usually completely torn across so as frequently to admit of the escape of the upper end of the inferior fragment through the rent, either on the spot, or soon afterwards, thus accounting, in some degree, for the shortening experienced by the limb. The upper fragment, on the contrary, hangs on, as it were, to the round ligament, which thus supports and nourishes it, its vascular and nervous supplies being cut off in every other direction.

There is another point of great practical interest in the anatomy of the neck of the femur, which, from the influence it exercises over the repair of the fractures, deserves brief mention. I allude to the fact that this portion of the bone is nearly destitute of periosteum, thereby disqualifying it, in great degree, for the formation of callus, an occurrence which is still further opposed by the circumstance that this part is invested by a synovial membrane, which, in case of accident, always pours out a large quantity of fluid, the interposition of which between the ends of the fragments becomes thus a powerful obstacle to their reunion.

Fractures of the neck of the femur are divisible into two classes, those, namely, which occur within the capsular ligament, and those which take place exterior to it; the former being now usually termed intra-capsular, the latter extra-capsular. The distinction is one of great pathological as well as practical importance, and is, therefore, worthy of profound consideration.

INTRA-CAPSULAR FRACTURES.

Fracture of the neck of the femur within the capsular ligament may occur at any portion of this part of the bone, as exhibited in the accompanying figs., 464, 465, and 466; but, in general, it is met with at a short distance below the

Fig. 464.

Fig. 465.

Illustrations of intra-capsular fracture.

head, or between the head and centre of the neck, where the compact structure is unusually weak, and where, consequently, the slightest force frequently produces the accident. Sometimes the line of fracture is on a level with the globular head, which, therefore, alone constitutes the upper fragment; and, on the other hand, cases are observed where the bone yields just above the attachment of the capsular ligament. Finally, the fracture is sometimes partly within and partly without the ligament, forming an interesting variety, especially in reference to the question of the process of consolidation. The direction of the fracture is usually oblique; but it may be perfectly perpendicular, especially when the neck, in consequence of age or disease, forms nearly a right angle with the shaft of the bone.

An incomplete variety of intra-capsular fracture has been from time to time recognized by surgical observers, but much doubt has always been entertained by many in relation to the possibility of such an occurrence. I have myself never met with an example in the numerous dried specimens that I have examined in different collections, and I, therefore, assume that the accident must be extremely uncommon. A well-marked instance of the kind occurred in 1856 to Dr. J. B. S. Jackson, of Boston, in a man aged forty-two years, in consequence of a fall through two stories of a building upon a hard floor, breaking his spine and the femur at several points. The fracture of the neck, commencing at its junction with the head, reached, as is seen in fig. 467, nearly in a perpendicu-

Fig. 466.

Intra-capsular fracture of the femur.

Fig. 467.

Vertical fracture of the neck of the femur.

lar direction, to within about a quarter of an inch of the inferior and internal wall of the bone, the fissure being so extensive that, if the man had been able to walk, the unbroken part could probably not have supported the weight of his body.

The *cause* of intra-capsular fractures is generally some trivial accident ; most commonly a fall upon the great trochanter, or a blow upon the hip when the thigh is fixed and separated from its fellow, thus increasing the strain upon the upper portion of the bone. I have known the injury to be produced by the great toe catching in the fold of the carpet, while the person, an old lady of seventy-six, was walking across the floor. In London, according to Sir Astley Cooper, it most frequently occurs from the foot suddenly slipping off the edge of the sidewalk over the curb-stone, upon the carriage pavement, the weight of the body being thus thrown forcibly upon the neck of the bone in a perpendicular direction, when it is unprepared for such an event. The fracture may also happen in turning awkwardly in bed, or in stepping carelessly out of the bed upon the floor, the individual in either case powerfully twisting the thigh-bone. The fact that so serious a lesion may arise from so trivial a cause, while it is of great value in a diagnostic point of view, affords the clearest possible proof that a bone, liable to be so affected, cannot be very sound, but that, on the contrary, its structure must have undergone serious changes to render it capable of an accident, which, in other pieces of the skeleton, requires an extraordinary degree of force. That this is true, as a general principle, has already been shown, the immediate cause being the fatty, atrophied, and rarefied condition of the compact and spongy tissues of the neck of the bone, the animal matter being absorbed, and the earthy alone left, the result of the whole being a weakened condition of the affected parts, and, consequently, a predisposition to fracture. Although the lesion is

usually occasioned by slight accidents, instances are observed where the reverse is the case, but then it is worthy of remark that it is ordinarily of a complicated character.

The *age* at which this variety of fracture occurs is, diagnostically considered, a matter of great importance. A fracture in other bones, or parts of a bone, may take place at any period of life, even in infancy and early childhood. Thus, I have seen the shaft of the femur itself broken in an infant of four weeks. But it is very different with the neck of this bone within the capsular ligament, experience having shown that it is subject to fracture only, as a general rule, after the age of fifty, when, as already stated, its spongy and compact tissues suffer from atrophy and fatty degeneration, thus rendering it more or less brittle, and incapable of withstanding injury. The youngest subject in whom this fracture has been observed was a lady of eighteen, whose case has been reported by Mr. Stanley, of London. Sir Astley Cooper saw an instance at thirty-eight. Doubtless other examples have happened, without, however, disproving the rule that this variety of fracture is generally an occurrence of advanced life.

Sex also exerts a considerable influence upon the production of intra-capsular fracture. Of its precise relative frequency in males and females, no reliable statistics, at least none upon a large scale, have been placed before the profession; but a sufficient amount of information has been obtained to justify the assertion that it is much more common in the latter than in the former. In the tables of Mr. R. W. Smith, in his *Treatise on Fractures*, the sex is given in 28 cases, of which 17 were women and 11 were men. The cause of this difference appears to be twofold, the more horizontal position of the neck of the femur and the greater amount of atrophy and fatty degeneration of this portion of bone in old females than in old males.

The intra-capsular fracture may be *complicated* with fracture of the neck on the outside of the capsular ligament, the lines of disjunction running into each other. Such an occurrence, indeed, is not infrequent. Again, an intra-capsular fracture may be associated with a fracture of the great trochanter; but this is extremely rare. In twenty-three specimens of this lesion in the Dupuytren Museum at Paris, there is not a solitary example of such a coincidence.

The *symptoms* of intra-capsular fracture are deserving of particular attention. They are: 1. Shortening of the thigh. 2. Eversion of the foot. 3. Preternatural mobility. 4. Crepitation. 5. Change of situation in the great trochanter. 6. Pain at the site of injury. 7. Peculiarity of the patient's body in the erect position.

The *shortening of the thigh*, or of the limb through the thigh, is one of the most striking phenomena of this variety of fracture, and is the more valuable because of its almost universal occurrence. It is usually the first circumstance that attracts the attention of the surgeon, whether the patient is lying on his back, or standing up. As might be expected, it varies in different cases and in different conditions of the same patient, its extent being greatly influenced by the state of the capsular ligament, being generally less in proportion to the integrity of this membrane, and conversely. It is always less immediately after the occurrence of the injury than it is after the lapse of several days, and also in impacted fracture than in the ordinary form of the accident. The amount of immediate shortening ranges from half an inch to an inch; it may, however, be considerably less than this, not, perhaps, exceeding three lines; and, on the other hand, it may reach an inch and a quarter, and even an inch and a half, especially if there is extensive laceration of the capsular ligament. During the progress of the case, the shortening will not infrequently amount to upwards of two inches, and in rare instances it has been known even to exceed three.

The diminution in the length of the limb, although generally immediate, is not always so, depending, perhaps, not so much, as has usually been supposed, upon the integrity of the capsular ligament, as upon the want of separation of the ends of the fragments, in consequence of the peculiar arrangement of their surfaces favoring their temporary contact. It is hardly reasonable to imagine that, if the integrity of the capsular ligament were the only cause of it, this

would become so stretched or torn within so short a time as to admit of the amount of shortening above mentioned. Under such circumstances, the shortening will, of course, be immediately permanent, unless the broken pieces are pulled together in the examination of the limb, or by the patient turning about in bed.

Eversion of the foot, or, rather, of the whole limb, is seldom absent in any case. When the patient causes the heel of the affected side to point towards the tendo Achillis of the sound limb; while, when the limb inclines outwards almost horizontally, dropping in contact with the floor. It is usually an immediate effect of the accident, does not last until some time after, depending upon the manner in which the fragments are held together. When the fracture is incomplete, or the foot and knee, instead of being everted in the opposite direction.

The cause of the eversion of the limb, in this case, is explained. Most writers ascribe it to the action of the thigh outwards when it has lost its support above, upon the fracture being an additional incentive to whom I include myself, on the contrary, attribute it to the limb, which has a natural tendency to eversion when they are thrown off their guard, as is observed during sleep. In a perfectly passive, the foot invariably inclines outwards.

Præternatural mobility, common to all fractures, is a variety, and, therefore, serves as a sign of the accident. There are cases, however, in which it is entirely absent, as in the impacted fracture, and in others it is increased, as when the ends of the bone are held partially together by the incompleteness of the solution of their fibres, by the incompleteness of the solution of their fibres. Its existence, as well as its degree, is determined by taking hold of the limb and rotating it upon its axis, extending it behind the line of the sound limb, and moving it outwards; movements which cannot be executed with the head of the femur. Extension and counter-extension, restoring the limb promptly to its proper length, and discontinuing the original shortening is reproduced.

Crepitation, the most valuable sign of all in fracture of the femur. Indeed, it can only be absent in the impacted fracture, in those cases where the ends of the fragments remain in contact with each other. It is usually discoverable immediately, and may, of course, be produced as long as the fragments are in contact. In order to determine its existence, it is necessary to bring the bone fully in contact by extension and counter-extension. When the limb, it will at once declare itself.

Change of position in the great trochanter is always present in intra-capsular fracture. This bony prominence is directed towards the ilium, in this accident, but it is brought to the border of the acetabulum, and is, therefore, much nearer to the normal state, in which it is always so conspicuous. When the thigh is rotated upon its axis by taking hold of the limb, it will be found to turn, as it were, upon a pivot, or to move

circle than natural. From the circumstance of the limb being generally strongly everted, the portion of the broken neck attached to the trochanter is directed inwards and upwards, and is thus placed in closer proximity with the anterior superior spinous process of the ilium than the trochanter itself.

Pain at the site of injury, being common to all fractures, is of special value only in connection with the other symptoms already described. It derives its chief importance from the fact that it is located at the upper and inner part of the thigh, in the direction of the small trochanter, and that it is always greatly increased whenever an attempt is made to rotate the limb, to bend it upon the pelvis, or to carry it inwards over the sound one. When the patient is perfectly quiet, the limb being placed in a relaxed position, the suffering is usually very trivial, except when the bone, in addition to the fracture, has been severely concussed, when the pain will frequently be excessive. It is generally worse, too, at night than in the day, and in wet weather than in dry.

There is a peculiarity in the *patient's attitude* as he stands up, which cannot fail to strike the most careless observer. The body, in this position, is inclined forwards in such a manner as to throw its weight upon the sound limb, which is firmly planted upon the floor, while the other hangs off in a constrained, unseemly, and awkward manner; the foot and knee are strongly everted; the leg is supported upon the ball of the toes, while the heel, resting in the interval between the ankle and tendo Achillis, is elevated from two to three inches from the surface; the natural prominence of the hip is destroyed; and the least attempt to walk or to raise the limb not only proves abortive, but is productive of exquisite pain.

Finally, there is seldom much *swelling* in this variety of fracture; it is only when the hip has been struck a severe blow that the superficial parts are likely to be the seat of any considerable effusion, ecchymosis, discoloration, or contusion, and even then the symptoms are usually very evanescent.

The *pathological changes* in intra-capsular fracture vary very much according to the period of the examination, as well as the character of the original injury. In recent cases there is usually some sanguineous effusion, although the quantity of blood is generally very small, unless, as occasionally happens, there is extensive rupture of the capsular ligament, when it may be considerable. Most commonly the ligament preserves its integrity, but if the accident has been unusually severe it may be torn at one or more points, so as to admit of the partial escape of the inferior fragment, the soft covering of which is often partially detached, hanging off in loose, irregular shreds. If several days have elapsed since the receipt of the injury, the changes will be such as evince inflammation. The synovial membrane will be observed to be unnaturally vascular, and slightly coated with plastic matter, a small quantity of which is also sometimes found upon the ends of the fragments. There is likewise, at this stage, a marked increase of synovial fluid, and the structures around the joint frequently exhibit a contused appearance, with more or less infiltration of blood and serum.

If the dissection be made after the lapse of some months, the capsular ligament will be found to be much thickened by interstitial deposits, as well as by the addition of plastic matter to its synovial lining; the head and neck of the bone are also incrustated with lymph; and the ends of the fragments are softened, unnaturally vascular, and rounded off, or partially connected by fibro-ligamentous bands. The inter-articular ligament retains its normal structure, except in rare cases, in which it is inflamed and changed into fibrous tissue.

In old cases, or such as have lasted for some years, there are not only great thickening and induration of the capsular ligament, but extraordinary alterations in the broken bone, the neck of which is often completely annihilated, the shaft terminating abruptly on a line with the two trochanters. At other times the neck is converted into a short, conical knob, partially incrustated with cartilage, or scooped out, as it were, into a sort of cup-like depression. The trochanters themselves are occasionally a good deal changed in their appearance, especially the great, which is liable to be diminished in size and altered in configuration. The head of the bone generally retains its position in the acetabulum,

but that portion of the neck which remained attached after the accident is usually totally absorbed; and cases occur, where the entire fragment is destroyed, or where it is represented by a small remnant held in place by the round ligament. The lower surface is occasionally hollowed out into a kind of the rounded conical end of the lower fragment; the head being rounded off, and the lower fragment scooped out at the two extremities, continually moving upon each other with a smooth, polished, eburnized character, the better qualified to perform their various functions.

The changes now described are sometimes closely imitated in the head and neck of the femur by a fall or blow causing absorption of the osseous tissue, and shortening of the bone, and shortening of the articular cartilage and eburnization of the surface, as in arthritic rheumatism. There is reason to believe that this is not infrequently mistaken, both during life and after death, for a fracture of the neck of this bone. The appearances here alluded to are those of Fig. 468 and 469.

Fig. 468.

Scalloping of the neck of the femur

Atrophy which might be mistaken for a fracture

The mode of repair of intra-capsular fractures is peculiar. The fragments generally unite by osseous matter, which passes through a considerable period in the completion of the process; but in this variety of injury the union is of a fibro-ligamentous nature, as in similar lesions of the patella, and skull. But it is not always that the fragments unite, imperfect as it is; in many cases the ends of the bone refuse to unite, being gradually rounded off, and the articular cartilage, or, as not infrequently happens, especially in old subjects, becoming, in time, completely absorbed, the head of the bone sinking as far down as the two trochanters, and the upper surface of the acetabulum. In rare cases, indeed, even the entire head of the bone, with the greater portion both of the round and the capular ligament, is absorbed.

A very excellent idea of the fibro-ligamentous union of the fragments is afforded in fig. 470, from Sir Astley Cooper. It was the result of an accident, from a patient between thirty and forty years of age.

The causes of this want of union are of easy recognition. The parts have to encounter the prejudicial influence of the surrounding soft parts, and the pressure of the surrounding muscles, which tend to separate the fragments.

difficulty of maintaining accurate apposition of the broken ends of the bone; a circumstance which is so essential to the successful repair of fractures in other pieces of the skeleton, but which it is almost impossible to effect here, in consequence of the want of proper leverage in the upper fragment. All the apparatus that has yet been devised for the purpose has utterly failed to accomplish the object; whatever may be done, more or less motion is inevitable. Secondly, the accident is always followed by a considerable degree of synovitis, and, as a necessary result, by an increased quantity of synovial fluid, which, bathing the ends of the bone, acts inimically to the consolidating process. Thirdly, the most important reason, however, of all, is the want of power in the parts to furnish the requisite amount of plastic matter from the injury sustained by their vessels and nerves at the time of the accident. The superior and smaller fragment, represented by the globular head of the bone, or the head and a little remnant of the neck, is solely dependent for its vascular and nervous supplies upon the round ligament, and every one who knows how small this ligament is, and how insignificant its vessels are in the natural state, must be aware how utterly inadequate it must be for the nourishment of the bone to which it is attached. It need not then be wondered at that there never is any osseous matter effused by this fragment. Nor does the inferior fragment fare much, if any, better in this respect. Destitute, in great measure, of periosteum, with many of its vessels in a hopelessly lacerated condition, its powers are too feeble to afford any substantial aid in the process of repair. Hence the result must necessarily always be as above stated; that is, there will either be no union at all, or, if an attempt is made at establishing a connection between the two fragments, that attempt will go no further than the formation of a fibro-ligamentous substance.

When no effort whatever at repair occurs, it is highly probable that the ends of the fragments speedily undergo the fatty degeneration, and that they then become an easy prey to the action of the absorbent vessels, eventuating in their final annihilation.

It would, perhaps, be going too far to deny altogether the possibility of bony union in intra-capsular fracture of the thigh-bone, and yet I have no hesitation in asserting that I have never seen what I could regard as an unequivocal example of the kind. I have examined most of the specimens in this country, purporting to be cases of osseous consolidation, and in no instance have the appearances been such as, in my opinion, to justify such a conclusion. In general, the history of these cases has either been so exceedingly defective, or the necroscopic characters have so closely resembled those witnessed in the changes which the head and neck of the femur undergo in consequence of old age or disease, as to destroy all confidence in their authenticity as genuine examples of intra-capsular fracture. I need not insist here upon the great difficulty which the practitioner frequently encounters in establishing a correct diagnosis in injuries about the hip; what skill and care it generally requires to discriminate accurately between a mere sprain and a fracture, or a fracture and a dislocation; or how frequently even slight lesions of the ileo-femoral articulation, and of the head and neck of the femur, are followed by changes in the structure and conformation of these portions of bone which might so closely simulate those produced by fracture as to deceive the most enlightened and cautious observer.

The question, then, in regard to the repair of intra-capsular fracture, resolves itself into four groups of facts, which may thus be stated: 1. Under favorable

Fig. 470.

Fracture of the neck of the thigh-bone, united by fibroid matter.

circumstances, both as it respects the patient and the fibro-ligamentous union, answering the purpose of admit of tolerable progression after recovery from the accident. 2. Under adverse circumstances, that is, decrepit, or worn out by disease, and cannot, in consequence of treatment, or when, although the system is sufficiently robust, but the neck of the bone, or both neck and limb remaining, of course, permanently shortened union, although perhaps not wholly impossible, is yet that it cannot reasonably be looked for in any circumstances attending it, both as it respects the attention of his attendant. The event, other things being equal, is likely to happen in the impacted form of the injury, in comparatively young and robust persons. 4. In a mixed character, that is, partly within and partly without the mode of repair will be similar to that of ordinary fractures, but will require more time and care for its successful issue.

The *prognosis* in this variety of fracture is embarrassed respecting its repair, and need not, therefore, engage much regard to life, the danger is generally inconsiderable, the result of very trivial accidents, involving no serious comminution of the bone. In respect, however, to the function of the fracture is always more or less imperfectly be impaired in a degree proportionate to the nature of the connecting medium. For a long time, the patient is obliged to use a crutch, but eventually he will be able to walk with the high-heeled shoe, the parts strengthening by exercise, and a strong tendency to atrophy of the muscles.

Treatment.—Fractures of the neck of the femur are not, I think, generally as well managed as they are, not wholly, to the influence of the writings of Sir Astley Cooper, inasmuch as there never is any osseous union in this variety, and, therefore, proper to torture the patient with a protracted recumbent posture, and the application of an extensive cast. In such a proceeding the more necessary because the subjects of this fracture are old and decrepit persons, who are confined very badly, soon becoming affected with fever, and perishing from hectic irritation or congestive pneumonia. In this view, he was in the habit of placing the limb upon a high position, for about a fortnight, or until the pain arising from the accident, had in great measure subsided. He then allowed the patient to leave his bed, and sit in a high chair, or exercise taken to bear, at first, very gently upon the foot for the ends of the fragments. Subsequently, as the high-heeled shoe was ordered, and a stick was substituted.

If this treatment were the exception, and not the rule, common sense and experience would concur in its propriety; but his desire to generalize it, has carried it much further than patients justify. It is unquestionably true that metatarsal fractures do not bear confinement well; but the same is not true of the femur, and soon become bedridden. Such cases are managed, and are not likely to be benefited by the mechanical contrivances calculated to compress the limb, and constrain it to a position. To this class, the treatment is peculiarly applicable; indeed, no other can be employed, but to make the patient comfortable, and let the limb rest. There is another class of subjects, who, though perhaps old, are, nevertheless, quite stout and robust, and

time of the injury, whose constitution has never been impaired by intemperance or excess of any kind, and who can bear the long confinement incident to such an accident with the most perfect impunity. The persons composing this class are, for the most part, residents of the country, and not the poor, broken-down inhabitants of crowded cities, without any bodily vigor, and, therefore, without any recuperative power. Hence, an exclusive plan of treatment should not be adopted; on the contrary, it should be varied according to the exigencies of each particular case. Such a course is the more necessary because it is utterly impossible always to determine positively, by the most careful examination, whether the injury is one purely of intra-capsular or extra-capsular fracture, or whether it partakes, as, indeed, it not infrequently does, of the character of both, the two being conjoined.

Acting upon the above principles, I have, for many years, treated most of the cases of intra-capsular fracture that have come under my notice as any other fracture of the femur, by permanent extension and counter-extension, not with the hope, as already stated, of obtaining bony consolidation, but with the view simply of keeping the ends of the fragments more accurately in contact, and thus affording them an opportunity of becoming united by fibro-ligamentous tissue. It is obvious that such a result can only reasonably be anticipated when this condition is fully complied with. When the broken pieces are permitted to overlap each other constantly, hardly any union will be possible, certainly none of a useful kind; and there is, moreover, under such circumstances, always great risk that at least the neck, if not also the greater portion of the head, of the bone, will be absorbed, and the patient, in consequence, never regain the functions of his limb. Should the treatment fail, the surgeon has the consolation to know that he has discharged his duty, by having kept the parts in the only position in which it is ever possible for them to become united in any way. The thigh may be maintained in the extended position, and the apparatus which best fulfils this indication is that depicted at page 954; or, instead of this, the limb may be placed over a double inclined plane; or, what is better, when it can be procured, the patient may be put upon a Daniel's fracture-bed, represented in fig. 471. The latter contrivance, which, unfortunately, however, is too expensive for general

Fig. 471.

Daniel's fracture-bed.

private use, is particularly adapted to cases of old persons likely to require protracted confinement. The bed is so arranged that, while the patient can sit up, or vary his position, efficient extension and counter-extension may be maintained with adhesive strips. An elaborate description of the apparatus may be found in the tenth volume of the Transactions of the American Medical Association.

Whatever plan of treatment be adopted, its effect must be watched, so that it may not prove irksome, much less time during which the patient should be confined must be avoided. It may last from ten weeks to three months and a half. During all this time the patient must be on a full allowance of meat and porter; at all times in order to sustain the system and promote reparative action. All other depressing means should be used as sparingly as possible, and must be freely given in the evening to allay pain and

EXTRA-CAPSULAR FRACTURE

The extra-capsular fracture is situated at the base of the neck of the femur, extending from above downwards and from behind forwards, passing above the intertrochanteric line. It is not always, however, strictly exterior to the capsular ligament; on the contrary, it may pass above the attachment of the ligament, so as to involve both of an inner and an outer fracture of the neck of the femur. It is always associated with fracture of the trochanters, sometimes with both, thus leaving in the former case three fragments. Again, the fracture is often comminuted and involves the trochanters; and in the great majority of cases there is more or less penetration of the superior piece into the shaft of the bone, however, induces me to believe that, generally speaking, it is trivial, hardly ever exceeding three lines, and often

Fig. 472.

Extra-capsular fracture of the femur.

Comminuted

that. Figs. 472 and 473 afford a good idea of the nature of an extra-capsular fracture.

The extra-capsular fracture is not as common as the intra-capsular, however, is trivial. Men are somewhat more liable to it than women, and, while it may take place at any period of life, it is most commonly met with almost exclusively after the age of fifty, the cases occurring after the sixtieth year. It is generally caused by violence, and is more common in the male sex. It is generally correctly, that a much greater amount of violence is required to produce an extra-capsular fracture than the intra-capsular, but the rule admits of exceptions. The most common exciting cause is a fall or blow upon

a fall upon the foot or knee and the passage of the wheel of a carriage across the pelvis or upper part of the limb. Finally, cases occur where it happens from the body being crushed by a heavy load descending upon the back, the lower extremities being in a fixed state at the moment of the accident. In not a few instances, however, the fracture is occasioned by very slight causes, while in most there is reason to believe that the bone where the lesion occurs is in a remarkably brittle condition, predisposing it to the disruption of its fibres. In some of the preparations that I have examined in different osteological collections the compact structure, although not very seriously diminished in thickness, was almost of a vitreous consistence, while the spongy was extremely rarefied and expanded, thus occasioning great weakness of the part. The cervical portion of the bone, under such circumstances, frequently retains a remarkably healthy appearance. When the osseous tissue is so very fragile at this point, it is not improbable that it may occasionally give way under mere muscular contraction, as has happened in at least one well authenticated case, the patient, a woman, aged eighty-three, having met with the accident in an effort to preserve her equilibrium when in the act of falling.

The *symptoms* of this variety of fracture bear a strong resemblance to those of the intra-capsular, some existing in a less, others in a greater, degree, but none, considered separately, possessing any diagnostic value. In describing these symptoms it will be most satisfactory if they be presented in the same order as in the preceding case.

The *shortening*, which is a constant occurrence, varies from half an inch to an inch, as its minimum, to an inch and a half, as its maximum. In exceptional cases it may, however, amount to two inches and upwards. It is usually most distinct when there is a badly comminuted state of the bone, or when the great trochanter, forming a part of the upper fragment, is drawn uncommonly far outwards, so as to permit the lower fragment to ride considerably over the upper. Moreover, it possesses the peculiarity of being generally as great immediately after the fracture as at any period subsequently.

The knee and foot are generally *everted*, the limb lying as if it were perfectly powerless, the muscles having apparently lost all influence over it. This symptom is even more striking than in the intra-capsular fracture. Eversion, however, is not so constant an occurrence as in the latter accident; in a considerable number of cases the limb is strongly rotated inwards, and in both varieties, but especially in the former, the displacement is occasionally so obstinate as to require an unusual degree of force to rectify it, depending, doubtless, upon the interlocking of the fragments.

The extra-capsular fracture is characterized by complete *mobility* of its fragments, except when they are impacted, an occurrence which, as already stated, is more common here than in fracture within the capsule. The loss of function is also complete, the patient being unable to lift the limb by the effort of his muscles, or to execute any of its natural functions.

The *crepitation* is generally very distinct, being often loud and cracking, and is readily perceived by the hand and ear, applied to the hip when the limb is rotated upon its axis. It is usually more marked than in intra-capsular fracture, and does not, as in the latter, require extension and counter-extension for its production. When the fracture is badly comminuted, the fragments may often be readily detected with the fingers, and be made to move upon each other so as to emit a grating sound not unlike that caused by rubbing together several pieces of broken china.

The position of the great *trochanter* may be the same as in the intra-capsular fracture, obeying the movements of the limb, and turning, as it were, upon a pivot, instead of describing the segment of a lesser circle, as it does in the natural state. In many cases, however, it is completely detached, and then, of course, it either remains stationary on rotating the foot, or it follows the inferior fragment as a separate body. In general, it will be found to be somewhat farther off from the spine of the ilium than in the intra-capsular fracture, depending upon the smaller amount of retraction of the limb.

The *pain* is always unusually severe, and is greatly increased by every attempt at motion and manipulation; it is more superficial than in intra-capsular fracture, and is concentrated, as it were, upon the two trochanters.

The *swelling* is also uncommonly extensive, and there is nearly always considerable discoloration of the surface, owing to the contused and ecchymosed condition of the skin and subcutaneous cellular tissue, the latter of which is often extensively infiltrated with blood.

The *attitude* of the patient possesses nothing peculiar; it partakes of the same general character as that which is met with in intra-capsular fracture, and, in fact, so closely simulates it as to be with difficulty distinguished from it.

Finally, along with the symptoms now described, there is generally, in extra-capsular fracture, evidence of severe shock immediately after the occurrence of the accident, and the resulting reaction is not infrequently followed by high fever, lasting often for a number of days, and requiring great attention on the part of the professional attendant. In intra-capsular fracture the patient may feel very faint, but he soon recovers, and has afterwards seldom much constitutional disturbance.

Repair of the extra-capsular fracture is effected precisely in the same manner as in fracture of any other piece of the skeleton provided with periosteum. It differs, therefore, wholly, in this respect, from that of the intra-capsular form of the lesion. Here osseous union is the rule, the want of it the exception, the reverse being the case in intra-capsular fracture. The period at which the consolidation is completed will, of course, depend, as a general rule, upon the age and health of the patient, the presence or absence of complications, and, above all, upon the care which is observed in keeping the ends of the fragments in accurate apposition.

Although the extra-capsular fracture invariably unites by osseous matter, the *prognosis* is very far from being always favorable either as it respects the possibility of avoiding deformity and lameness, or our ability to save the patient. When the fracture is comminuted, or the bone is broken into a number of pieces, including the two trochanters, a good result is hardly to be anticipated under the most judicious management that the case can receive. Under such circumstances the neck of the bone, having lost its support, is pushed downwards and inwards below its natural level, and the consequence is that a certain degree of shortening with deformity of the upper part of the thigh will be inevitable. The same result must necessarily follow when the fracture is impacted. These facts should be well studied and appreciated, and should always be promptly communicated to the patient, lest, when the cure is completed, he should blame his attendant for making him a bad limb when it was impossible to make a good one.

From the great violence that is so frequently inflicted upon the parts, both soft and hard, the extra-capsular fracture often proves hazardous both to limb and life. Occasionally, though rarely, the patient dies from shock: in some instances he suffers greatly from the effects of excessive reaction. Most generally, however, when there is danger, life is put in jeopardy by the supervention of erysipelas, or pyemia, the former commonly setting in within the first forty-eight hours from the occurrence of the fracture, and the latter towards the end of the first week or the beginning of the second. Some idea of the danger of extra-capsular fracture may be formed when it is stated that, of eighteen cases treated in the Richmond Hospital at Dublin, nine proved fatal, the period of death ranging from the fifth to the fifteenth day. In some cases the patient sinks from the exhaustion consequent upon extensive suppuration or the formation of large sloughs over the sacrum and buttocks from protracted confinement in one position.

The *treatment* of extra-capsular fracture differs in no wise from that which is necessary in fracture of the shaft of the bone. The limb, placed in the straight position, is kept perfectly at rest by means of splints, stretched along its outer and inner surfaces, and connected below in such a manner as to admit of the requisite extension and counter-extension until a cure is effected. The foot should incline slightly outwards to favor relaxation of the external rotator muscles, and special care should be taken to prevent overlapping of the fragments, or

angular deformity, by the use of a gutta-percha splint, accurately moulded to the outer and anterior part of the thigh, and well secured by the bandage. The dressing should be continued for at least five weeks.

IMPACTED FRACTURES OF THE NECK OF THE FEMUR.

Fracture of the neck of the femur occasionally presents itself as an impacted lesion, the lower extremity of the upper fragment being forcibly impelled into the cancellated structure of the upper end of the lower fragment, the great trochanter being usually carried along with the descending portion. The accident, which is sufficiently rare, and of which fig. 474, from a specimen in the Mütter collection, affords a beautiful illustration, is nearly always associated with extra-capsular fracture, and occurs under two varieties of form, the complete and incomplete, of which the latter is by far the more frequent. Old persons only are subject to it, and it is most common in those in whom the neck of the femur is of inordinate volume in consequence of the expansion of its spongy structure. The line of

fracture is generally at the base of the neck, or at the junction of the neck with the shaft, the penetration occurring in the direction of the anterior surface of the bone, with which the neck is more intimately continuous, being separated from it behind by a well-marked depression, and by the large ridge connecting the two trochanters. The fracture usually

Fig. 474.

Impacted fracture of the neck of the femur.

Fig. 475.

Impacted fracture through the trochanters, the upper fragment being wedged into the lower.

happens from the body being crushed by the falling of a heavy substance upon the trunk, while the chest is inclined forwards, and the knee rests upon a solid surface, the hip at the same time receiving a severe blow, as when a person is buried by the caving in of a coal bank; or, it may be produced by a fall from a height upon the knee, in which the weight of the body is violently impelled in the opposite direction, the two forces continuing to act after the bony tissues have given way. The direction of the fracture is generally oblique, extending from above downwards, from the great to the small trochanter, both of which are not infrequently included in the injury, as in fig. 475.

The distance at which the upper fragment is buried in the lower varies from a few lines to half an inch, three-quarters of an inch, or even an inch, depending upon the degree of the impelling force and the amount of expansion of the cancellated structure at the base of the cervix. The compact substance of both fragments is often extensively comminuted, and the fragments themselves are usually interlocked in such a manner as to give the thigh-bone the appearance

of being twisted upon its axis, the limb after the accident as in fracture without impaction, though in a less manner.

There is a variety of impacted fracture of the neck of the femur. The lower fragment is impelled into the cancellated structure of the upper. This occurrence is very rare, and the amount of shortening is considerable. It is the more common form of the injury.

The *symptoms* of impacted fracture of the neck of the femur are quite characteristic, though a good deal of care is required in order to make a correct diagnosis. The most valuable signs are the shortening of the thigh, the eversion of the foot, the inability to walk, or to bear the weight of the body upon the limb. The resistance which the fragments offer to extension is very intense, generally much more so than in ordinary fracture. There is not infrequently extensive ecchymosis over the point of fracture, with a wondrous swelling and discoloration.

The degree of shortening varies, as already stated, from a quarter of an inch to more, the average ranging from a quarter of an inch to an inch. The eversion of the foot, although it is in a slighter degree than in fracture of the neck of the femur, whether the injury is seated on the outside or on the inside. The occurrence is the more valuable as a diagnostic sign if ever, entirely absent. As the continuity of the femur is generally able to walk after the accident, although the limb is shortened, or, at all events, he can bear the weight of his body upon it. For the same reason, the limb is easily rotated at the hip, the pelvis, extended, abducted, or adducted; and when it is brought to its normal length, the effort, unless very powerful, is sufficient to overcome the resistance of the fragments retaining their interlocked position. Finally, there is generally, in a fracture of the neck of the femur, a more or less deformity, although this can be corrected on account of the excessive swelling, and, when permanent, is characteristic.

What, then, are the most important phenomena in a fracture of the neck of the femur? Beyond all doubt the shortening of the thigh, the existence of deformity at the hip, in the situation of the fracture, the absence of crepitation. When these signs are present, there is no dislocation of the ileo-femoral joint, nor fracture of the neck of the femur, but fracture of this portion of the femur.

The *prognosis* of this variety of fracture is much more favorable than in ordinary fracture of the cervix; for, inasmuch as the fragments are in contact, it usually requires but little callus to effect union. A very little retentive apparatus is usually necessary, and the patient can use his own splints. On the other hand, however, there is a certain degree of deformity, consisting of slight shortening and incurvated state of the thigh just below the hip. So that, in a fracture of the neck of the femur, it can therefore, reasonably be looked for after the accident, and in favorable circumstances. I have seen several specimens of the neck of the femur where great and irremediable deformity had been produced, the osseous matter being extended, in the form of bridge, over the innominate bone, immediately around the accident, together in a solid mass.

These protective means are displayed in a remounting of the bone above depicted, of impacted fracture of the neck of the femur. The head and neck of the bone, being a quarter of an inch in length, occupy a horizontal position in the center of the bone, being driven into the cancellated structure of the lower fragment. The superior third, or more, of the shaft of the bone is

and outwards, and is surrounded by a casing of new osseous matter, more than half an inch in thickness at the concavity of the curve, or weakest portion of the femur, and at a point, consequently, where, after such an accident, the greatest amount of support is required. A large ledge of bone, two inches long, and very broad, thick, and firm, projects from the anterior and inner aspect of the superior extremity over towards the hip-joint, being connected by a strong, round ligament, upwards of two inches in length, with the anterior inferior spinous process of the ilium, which juts out as a remarkably long, slender prominence, more than twice the normal size. An idea of the amount of shortening of the femur may be formed, when it is stated that the summit of the great trochanter projected fully one inch above the upper border of the acetabulum. Nothing is known of the history of the case; but, judging from the completeness of the reparation, the accident must have occurred many years before death. Some degree of motion, certainly very slight, must have existed both in the acetabulum and at the junction of the two fragments, the upper end of the lower of which was converted into a socket into which the lower end of the upper was received, a kind of adventitious membrane having been interposed between the contiguous surfaces.

In the *treatment* of this fracture, one important point is not to pull the ends of the broken bone asunder in our attempts to examine the case. Hence, whenever impaction is suspected, the rule is to refrain from all rotation and extension. The nature of the accident being properly diagnosticated, the limb is to be placed in an easy position in bed, a pillow lying under the ham, and gentle, but steady pressure being made, by means of a compress and bandage, in the direction of the great trochanter, with a view of rectifying any deformity that may exist in that situation. Generally, no splint will be required, and in ordinary cases the patient will be able to move about on crutches in three or four weeks.

General Diagnosis.—Fractures of the neck of the thigh-bone are liable to be mistaken for other lesions, and it is, therefore, a matter of great importance to have accurate conceptions of their real nature, errors of diagnosis here being always particularly prejudicial both to the patient and to the practitioner. The affections with which they are most apt to be confounded are sprains and dislocations of the hip-joint, and, in many cases, great difficulty is also experienced in deciding whether the injury is one of fracture within the capsular ligament, or of fracture exterior to it.

The symptoms of fracture of the neck of the femur, especially the intra-capsular, are sometimes closely simulated by sprains and contusions of the hip, causing involuntary obliquity of the pelvis with apparent shortening of the limb, and eversion of the knee and foot, along with excessive pain and difficulty of motion. The resemblance is occasionally so perplexing as to create doubt in the mind of the most skilful diagnostician, and, among the less informed, has often led to the most serious errors of practice, by the employment of harsh means when the most mild and soothing alone were necessary. The signs of distinction are the following: 1. In fracture the shortening is real, and can be effaced only by extension and counter-extension; in sprains and contusions, on the contrary, it is not real, but apparent, as may be proved by placing the limbs parallel with each other, and bringing the two iliac crests on the same level. 2. In fracture the eversion of the foot is complete, the extremity presenting an appearance characteristic of total loss of power; in ordinary injuries of the hip and upper part of the thigh, the eversion is comparatively slight, and the patient can, in general, rectify it by his own efforts, although they may be productive of severe distress. 3. In fracture there is usually complete abolition of muscular action; so that the thigh can neither be flexed, extended, nor rotated, however determined the attempt. It is only in the impacted fracture that the individual has still some control over the limb, and then the best guide for avoiding mistake is the existence of actual shortening. In sprains and contusions motion is diminished, perhaps very greatly, but not abolished.

A very unpleasant consequence of sprains and contusions of the hip-joint is shortening of the thigh from interstitial absorption of the neck of the femur. Hence the patient, on recovering from the immediate effects of the injury, finding

that the limb is permanently disabled, might accuse him in order to guard against such a charge, it is well for the surgeon at an early period of the treatment, of the possibility of a dislocation of its head upon the dorsal surface.

It might be supposed, at first sight, that it would be an inexperienced practitioner, to mistake a fracture of the femur for a dislocation of its head upon the dorsal surface. Cases are upon record testifying not only to the possibility but to its actual occurrence in the hands of the surgeon. The only way to avoid error is to remember clearly each lesion. The subjoined tabular arrangement will, in its proper light, at the same time that it renders the diagnosis an easy task:—

INTRA-CAPSULAR FRACTURE.

1. Occurs nearly always in old persons.	1. Is most common in old persons.
2. Is most common in women.	2. Occurs in both sexes.
3. Usually the result of slight causes.	3. Always occurs after a fall.
4. The foot is strongly everted.	4. The foot is strongly everted.
5. There is great shortening, readily effaceable by extension and counter-extension, but recurring the moment the force is discontinued.	5. The shortening is readily effaced only in the neutral position.
6. Marked crepitation exists.	6. There is no crepitation.
7. There is preternatural mobility, the ends of the fragments being movable upon each other.	7. The bone is rigidly fixed in position.

But the greatest difficulty in the diagnosis of the hip arises from the embarrassment which the surgeon meets with in determining whether the case is one of intra-capsular fracture, or of dislocation of the femur. As the subject is one of great practical importance, to be studied with unusual care, and I shall, therefore, present the points in tabular form:—

INTRA-CAPSULAR FRACTURE.

1. The result commonly of slight injury, often indirect.	1. Usually the result of a severe injury.
2. The shortening, slight at first, generally not exceeding a third or half an inch, gradually increases to two inches and upwards.	2. The shortening is considerable after the accident, and increases in the intra-capsular fracture.
3. The crepitation is indistinct, and can only be fully elicited by extension and counter-extension.	3. Crepitation is often perceived on rotation and rotation.
4. Function is much impaired, but not wholly abolished.	4. The joint is usually lying in a healthy position.
5. The great trochanter, on rotating the limb, moves, as it were, upon a pivot.	5. The great trochanter is separated from the limb, and then but in the intra-capsular fracture.
6. The pain is unreliable, both as it respects site and intensity, being generally most severe at the upper and inner part of the thigh, in the direction of the small trochanter.	6. Pain is severe, especially at the great trochanter.
7. There is generally little or no contusion, swelling, or discoloration.	7. Usually there is considerable swelling and discoloration.

Nothing of any diagnostic value can be deduced from the age at which these two fractures occur, since, as we have seen, they are met with almost exclusively after the fiftieth year. The authenticated cases on record of its occurrence prior to the age of thirty is true in relation to sex, experience having shown that the influence upon the production of these two varieties of fracture is almost entirely imaginary. I am inclined, from a careful study of the

ance, in this respect, upon the existence of severe external injury, as contusion, swelling, and ecchymosis, and upon the presence of shortening, than upon any other phenomena. In the intra-capsular fracture, the external signs of injury are certainly, as a general rule, exceedingly slight, while the reverse is usually the case in the extra-capsular, the parts being nearly always much bruised and discolored. In regard to shortening, it possesses, I think, great value as a diagnostic of the two lesions; for it may be assumed, on the one hand, that when it is very slight immediately after the receipt of the injury, and gradually increases afterwards, it depends upon intra-capsular fracture; and, on the other, that when it is very considerable immediately after the accident, it is caused by extra-capsular fracture. Rodet, who studied the subject with much attention, arrived at the conclusion that every fracture of the neck of the femur, produced by a fall or blow upon the great trochanter, was of an extra-capsular nature; whereas, every one occasioned by a fall upon the feet, or by muscular action, must be seated within the ligament. This conclusion, however, is altogether unfounded; in adopting it we should be compelled to assume that all intra-capsular fractures are the result of falls upon the feet, when all experience teaches that they are almost invariably produced by force applied directly to the hip.

The most important diagnostic characters of the *impacted* fracture of the neck of the femur, whether within or without the capsule, are, as has already been stated, shortening of the limb, the absence of crepitation, and the comparative or complete immobility of the fragments. The shortening is always immediate, and remains permanent in its original degree, unless the ends of the bone are rudely drawn asunder; hence it is a sign of an unequivocal character; the absence of crepitus is also very significant, and the trivial mobility, or complete absence of motion, is another circumstance of importance. The great danger in such a case is that the fracture may be mistaken for a dislocation; but from this it may usually be readily distinguished by a careful study of its history, and a thorough examination and comparison of the symptoms characteristic of the two lesions.

FRACTURES OF THE GREAT TROCHANTER.

Fracture of this bony apophysis may take place as an independent lesion, or as a concomitant of fracture of the neck of the femur, outside of the capsular ligament, as mentioned previously, and as exhibited in fig. 476, from a specimen in my collection. As an independent fracture, it is very infrequent in comparison with the other variety. It may occur at any period of life, but is chiefly observed in elderly subjects, as a consequence of direct violence, as a fall, blow, or kick, breaking off the trochanter in an oblique direction from above downwards. The fracture is sometimes comminuted, the trochanter being broken into several pieces, of irregular size and shape, the fragments grating under the fingers like a number of pieces of china. It may also be compound, although, in general, it is unaccompanied by any wound of the soft parts.

The *symptoms* of fracture of the great trochanter are generally well marked, the most important consisting of eversion of the limb, with separation of the fragments, inability on the part of the patient to sit down, and difficulty of obtaining crepitation. The eversion is unusually distinct, and is probably due, at least in great degree, to the loss of power in the external rotator muscles; the limb lies in a helpless condition, and no effort that the patient can make can change its position. The broken trochanter is commonly widely separated from the shaft of the bone, and hence the difficulty which is generally

Fig. 476.

Fracture of the great trochanter.

extension of the limb contraindicated, this being only practicable by placing the parts in a position of flexion and extension. The displacement is either upwards towards the ilium, or downwards towards the tuberosity of the ischium, the former being the more frequent. When the patient attempts to sit down he is completely foiled, and immediately experiences great increase of pain, compelling him to desist. It is not unfrequently accompanied by swelling of the limb as a symptom of this fracture, but the swelling being slight, it can only be in a very slight degree. More or less effusion of blood and extravasation of the soft parts are usually present.

The principal signs are the eversion of the limb, the loss of prominence at the trochanter major, the elevation, the fixed position of the small fragment on the greater, the heat and rigidity, and rigidity in approximation of the broken ends.

The treatment of this fracture is by assuasive matter, and, unless the bone is comminuted, the patient may be expected without any deformity of the hip to be able to perform the functions of the limb. Considerable difficulty, however, is experienced in maintaining apposition of the fragments, and hence every remedy which requires more than ordinary vigilance on the part of the physician.

The patient is confined to maintaining the limb in a perfect state of quietude by means of the following solution, the foot being supported in a perpendicular direction with a slight tendency to eversion, which is the most natural position for a person when he lies on his back, and therefore the most eligible for relaxing the muscular and ligamentous system when there is a fracture of the trochanter. The broken trochanter being drawn into its natural situation, is confined there by a soft bandage extending from the thigh to the pelvis, and furnished with a sort of pillow and a roller of four inches in diameter, for the purpose of embracing more effectually the prominence of the hip. Hardly any extension will be necessary. If the soft parts are much contused, leeches and fomentations should be applied to the part, and in the permanent dressings. After the patient has been confined for a month, he may be permitted to exercise on crutches. The

Fig. 477.

FIG. 477. — Treatment of fractures of the great trochanter.

annexed cut, fig. 477, represents the mode of treating fractures of the great trochanter recommended by Sir Astley Cooper.

The great trochanter is occasionally detached from the neck and shaft of the femur, by the forcible laceration of the fibro-cartilage by which it is connected to these parts during its *epiphyseal* state. The accident, which is one of uncommon occurrence, and which is usually produced by a severe fall upon the hip, is always extremely difficult of diagnosis, owing to the fact that there is seldom much, if any, appreciable displacement. In most of the recorded cases there was much diversity in the symptoms: in some, the patient was able to walk immediately after the accident, while in others he had lost all control over the muscles of his limb; in some, the foot was everted, while in others it preserved its natural position, or was even inverted: in all there was severe pain, with considerable swelling, either alone or conjoined with ecchymosis, at the site of injury, and, during their progress, more or less constitutional disturbance.

The best manner of determining the diagnosis, in this accident, is to make the patient lie on his back and incline the pelvis over the injured side, while the

affected limb is thoroughly abducted, or carried away from the sound one. The gluteo-femoral muscles being thus completely relaxed, the trochanter, if detached, may easily be pushed into its natural position, and crepitation elicited by rubbing it against the neck and shaft of the femur.

The occurrence of this accident is not without danger, several cases having been recorded in which it proved fatal from extensive suppuration and constitutional disturbance. When recovery takes place, the limb remains long weak and painful. The union, under such circumstances, is fibro-cartilaginous, or partly cartilaginous and partly osseous. The treatment must be conducted upon the same principles as in ordinary fracture of the trochanter.

FRACTURES OF THE THIGH IN CHILDREN.

Fractures of the femur sometimes occur in very young children, and are always peculiarly troublesome. The bone generally gives way at its shaft, as the result of external violence, and the symptoms are characteristic. Diastasis of the femur is extremely uncommon. Fractures are much more frequent in children than is generally supposed. Coulon states that in one year 140 cases were admitted into the St. Eugenia Hospital at Paris. Of these 26 affected the femur. This bone is occasionally broken during delivery. The youngest case that I have ever met with was an infant four weeks old, in whom the accident was caused by a child rolling over its thigh as it lay in bed.

In infants at the breast the treatment of this class of injuries is always attended with peculiar embarrassment and annoyance, owing, first, to the remarkable tendency to displacement of the fragments, and, secondly, to the constant liability of the dressings to be soiled by the discharges. To meet the first of these contingencies, the limb, after the subsidence of the inflammation and swelling, should be enveloped in a plaster of Paris bandage, and incased in two very light splints, either of wood, gutta-percha, or binder's board, the outer one reaching from a short distance below the level of the foot to the crest of the ilium or even to the chest. Layers of wadding should be applied to ward off pressure, when the splints should be secured with adhesive plaster, and covered with a roller. A little additional support is generally necessary in front of the thigh. Soiling of the dressings is best obviated by a thick coating of gum-shellac, or coachmaker's varnish, frequently renewed. The object of the long splint is to keep up a certain degree of extension, and to prevent the child from flexing the pelvis upon the thigh. It is very important that the limb should be frequently examined, otherwise it may become shortened and crooked. The consolidation will be completed in from fifteen to eighteen days.

In children from five to ten years old I have usually found the most convenient and suitable apparatus to be a case made of stout, unoled sole-leather, long enough to extend from the groin to an inch and a half below the heel, and sufficiently wide to come well round the limb, especially the thigh. It is supplied with a foot-piece of the same material, and is well padded at its upper extremity, to prevent undue pressure upon the perineum. The outside portion of the trough is continued for some distance over the hip, to which it is secured by a spica, or common roller, carried round the thighs and pelvis. A splint, also of leather, or of binder's board, gutta-percha, or thin wood, is stretched along the forepart of the limb from the groin to the patella, wadding being suitably interposed to ward off pressure; the apparatus is held in place by means of an ordinary bandage, adhesive strips having previously been secured to the leg and attached to the foot-piece. The dressing is completed by placing the limb, with its apparatus, in an easy position upon a hair or cotton bolster, gradually tapering upwards, its thickness below not exceeding four inches. By this simple contrivance I have always found it easy to obtain the requisite extension and counter-extension, the perineum affording a *point d'appui* which effectually prevents the ascent of the apparatus, while the foot-piece serves to keep the foot in place, at the same time that it receives the extending bands.

CHAPTER IX.

DISEASES AND INJURIES OF THE JOINTS.

SECT. I.—WOUNDS.

THE joints are liable to be laid open in various ways—by cuts, stabs, punctures, balls, machinery, and other means—and hence such lesions are said to be incised, punctured, gunshot, contused or lacerated, according to the nature of the vulnerating body. In extent they may be small or large; in character, simple or complicated; in effect, trivial or severe.

The *symptoms* are generally sufficiently distinct. When any of the large joints are opened, whether by a cut, laceration, or bullet, the nature of the accident is ordinarily denoted by an immediate escape of synovial fluid, rapidly followed by great pain, tension, and swelling of the part, with severe constitutional disturbance. When the wound is very large, especially if it is of a gunshot nature, there will generally be, along with the symptoms just mentioned violent shock, the patient being deadly pale, faint, and sick at the stomach; and some hours may elapse before reaction comes on. In from twelve to twenty-four hours after the accident, fever commonly sets in, often preceded by rigors, and soon succeeded by delirium, great gastric distress, intense thirst, and excessive restlessness, with a strong, full, and bounding pulse. The local phenomena assume a more aggravated character. The heat, pain, redness, and swelling increase in intensity, and the surface of the limb, at the seat of the injury, often assumes an erysipelatous aspect, sometimes as early as the first thirty-six hours after the accident, and seldom later than the third or fourth day. Meanwhile, the discharge of synovial fluid augments in quantity, as well as in consistence, exhibiting a thick, ropy, turbid appearance; or, if the wound is closed, and the fluid is retained, the joint becomes distended in every direction, but particularly in its more dilatable parts, the integuments pit on pressure, and distinct fluctuation is perceived. The secretion now takes on a puriform character; the patient has frequent rigors, alternating with flushes of heat, and followed by copious sweats; the joint is exceedingly tense; the synovial membrane is universally involved; perforative ulcers form at different points; matter is freely discharged, often of a highly fetid nature; the bones are rendered carious; and the ligaments softened and thickened, yield at various points of their extent. In some cases matter forms exterior to the joint, and is extensively diffused among the muscles and through the subcutaneous cellular tissue.

But it is not always that matters progress in this wise. The case here described is an extreme one. In many instances, depending mainly upon the nature and extent of the lesion, and the character of the treatment, the inflammation, after having persisted for a few days, gradually disappears, and the patient recovers with hardly an untoward symptom, the joint, it is true, remaining temporarily stiff, but ultimately completely regaining its functions.

All lesions of this kind, however, should be regarded with suspicion; for, if they are not dangerous in the first instance, they are exceedingly liable to become so during their progress, and this is true of the most trivial wound as well as the most extensive. Sometimes a fortunate recovery occurs in cases, apparently, of the most desperate character. Thus, I attended, many years ago, a lad of fourteen, who, while bathing, struck his knee against the sharp point of a rock causing a severe penetrating wound, which got well without any serious local or

Constitutional symptoms, although it was in all respects, at first, most unpromising. In another instance the knee-joint was opened by a pistol-ball, entering the side of the patella, and permanently lodging in one of the condyles of the femur, with no other effect than that of a moderate synovitis, and slight tenderness.

Simple incised wounds are less to be dreaded, as a general rule, than lacerated or gunshot, although undoubtedly many cases occur where the symptoms are extremely severe, and where the risk to limb and life is very great. It may also be assumed that wounds of a small joint are less dangerous than similar injuries to a large joint, incised than lacerated, small than large, and simple than complicated; the lesions, in these respects, being governed by the same laws as wounds in other parts of the body. There are several circumstances, however, which render wounds of the joints, especially the more important ones, as those of the knee, ankle, and elbow, peculiarly perilous, and which are the more to be dreaded because they are of frequent occurrence. These are erysipelas, pyemia, and tetanus.

Erysipelas, as a consequence of articular wounds, usually sets in within the first thirty-six hours, beginning at the site of injury, and spreading thence gradually over the neighboring surface. Its precise type will depend materially upon the state of the system at the time of the accident; its symptoms exhibit nothing peculiar, but its progress is often very rapid, and its presence is always denotive of a bad state of the constitution, which it is frequently difficult to counteract by remedies.

Pyemia is a frequent result of wounds of the larger joints, especially when of a lacerated, contused, or gunshot nature. Abscess of the internal organs, as a consequence of such lesions, was occasionally noticed by some of the older surgeons. The viscera which are most liable to suffer are the lungs, liver, spleen, and kidneys, the disease usually appearing within the first five or six days, and speedily undermining the constitution. As a concomitant of this occurrence important changes take place in the local symptoms. The pain becomes extremely intense, the swelling rapidly increases, and the wound discharges an abundant fluid, of a thin, sanious, and highly fetid character, denotive of the bad nature of the inflammation. The general phenomena are typhoid, the patient is delirious, and death soon closes the scene.

Tetanus is an occasional occurrence after injuries of this kind, but not as frequently, perhaps, as is generally supposed. I have seen only a few cases of it. The last which I had under my charge was a young man of twenty-four, who received a large wound in his knee, involving the patella, from the fall of his horse, the animal rolling upon his leg. For some days he was progressing favorably, when delirium tremens and tetanus set in, and he died shortly afterwards. Such an occurrence is much more common in military than in civil practice.

The *hemorrhage* which follows wounds of the joints, although generally trivial, is occasionally quite profuse, not always so much from lesion of the articular vessels themselves as from injury of those in the immediate vicinity. When the blood accumulates in the cavity of the articulation, whether from internal effusion, or in consequence of outward introduction, it may act as an extraneous substance, undergoing decomposition, and thus greatly aggravating the case.

Treatment.—The treatment of these wounds is sufficiently simple, inasmuch as it involves no principles different from those which guide us in the management of similar lesions in other regions of the body. It consists, mainly, in removing extraneous matter, approximating the edges of the incision, excluding the admission of air, forbidding all motion of the joint, and employing antiphlogistics to their fullest extent.

When the wound is simply an incised one, a few strips of adhesive plaster will generally suffice to effect approximation, and the risk of admitting air will be greatly diminished, if the part be covered with a compress wet with blood, and bound down by a roller, extending from the distal portion of the limb. Collodion often makes an excellent dressing, applied upon strips of patent lint. If the wound is large, a few sutures may be necessary, carried simply through the com-

mon integuments; and, when so used, they will be just as innocent as in any other class of injuries. When the wound is very ragged, it will generally be advantageous to pare its edges, as this will place them in a better condition for immediate reunion. Great care should always be taken to exclude the air, for, although it is in itself perfectly innocuous, it is extremely liable to prove prejudicial by causing rapid decomposition of the inflammatory products.

When the wound is large, the synovial membrane may be covered with extraneous matter, as dirt, sand, or other substance, which may not only prove difficult of removal, but will be sure to enhance the danger of erysipelas, pyemia, and tetanus. Clearance must be thorough, and the finger and forceps will be the best instruments for effecting it. Any clotted blood that may exist must be dealt with in a similar manner. If the foreign matter is deeply imbedded in the joint, and the wound is disproportionately small, rendering a search for it difficult and uncertain, the safest plan will be to let it alone. Balls ought certainly always to be treated in this manner. If, on the contrary, the projectile lie loose in the articulation, it should unquestionably be extracted at once, and so with every other movable or floating body, provided it is readily accessible, or that it can be taken away without the risk of inflicting serious additional injury. All officious interference, by finger, probe, or other instruments, must be scrupulously avoided, as the synovial membrane is exceedingly intolerant and resentful of manipulation, however gently conducted.

When there is no prospect of union by the first intention, or when the condition of the wounded joint is such as to render suppuration inevitable, the proper course to be pursued is to draw the edges of the wound lightly together with adhesive strips, and to resort, without delay, to medicated applications, either in the form of water-dressing, or of emollient cataplasms. To do otherwise would only enhance the danger of inflammation and of other bad consequences, without any compensating advantages.

The joint is maintained in an elevated and quiet position, all motion being guarded against by the use of splints and other suitable means. If the inflammation run high, liberal use must be made of leeches, scattered over the affected surface, in such numbers as the exigencies of the case may seem to require. If the patient is young and plethoric, blood is promptly taken from the arm, the bowels are thoroughly moved, and the saline and antimonial mixture is freely employed, a few drops of tincture of aconite being conjoined with each dose, in order to lessen more effectually the heart's action. Opium, in large quantity, will be required to relieve pain and spasm; and there is hardly a case, certainly none of a severe character, where it will not be proper to combine calomel with the anodyne, with a view to its speedy effects upon the system. The acknowledged efficacy of mercury in all inflammations of the serous textures clearly points to its administration as a matter of paramount importance here. It not only exerts a most happy influence upon the capillary vessels of the diseased membrane, modifying and changing their action, but it is a powerful sorbefacient, and thus proves beneficial in the removal of effused fluids. Its effects, however, must be carefully watched, lest they exceed our intention, which is only to cause tenderness of the gums, not positive ptyalism.

During the progress of the treatment, matter may form within the joint, and become pent up for the want of an adequate outlet. Under such circumstances relief must be afforded by a valve-like aperture, the puncture being immediately closed by collodion, and afterwards reopened as occasion may seem to demand. When the quantity of pus is very great, pressing upon the joint in every direction, a free, direct incision should be made, to admit of full drainage. It has always appeared to me that surgeons are too timid in these cases, and that they do not sufficiently co-operate with nature in her efforts at relief. It is not necessary here to describe the pernicious consequences which purulent accumulations, especially if long retained, must inevitably exert upon the component elements of the articulation. They can be nothing short of utter ruin of the synovial membrane, cartilage, and bone. Early evacuation must also be effected, if mat

ter form immediately around the joint, beneath the integuments and among the muscles.

When the discharge is profuse and offensive, injections of infusion of linseed, slightly medicated with the chlorides, will be of service; they should be thrown in tepid, several times in the twenty-four hours, and may sometimes be advantageously followed by the introduction of very weak solutions of iodine, or nitrate of silver, with a view of modifying the action of the synovial membrane. Too much caution, however, cannot be used in the application of these remedies, as the inflamed membrane is often exquisitely sensitive, and intolerant of such contact.

Whenever there is extensive suppuration, the parts will either recover by ankylosis, or the cartilage and bone will become so involved in the disease as to require removal. In the former case, the joint should be placed in the best position for future convenience and usefulness; while in the latter the affected structures should either be excised, or the limb be amputated. The choice of the proceeding must be regulated by circumstances. If the inflammation has measurably subsided, and the patient's strength is not too much exhausted, the joint may possibly bear excision; in all cases of an opposite character removal of the limb will be the safer operation.

In the milder forms of wounds, where there is no risk either of limb or life, the great point of interest is to guard against ankylosis, which is so liable to occur even in the most trivial affections of the articulations. Passive motion, sorbefacient embrocations, and the gradual use of the limb will be the surest means of preventing this.

Primary amputation will be required when the joint is severely shattered, whether by gunshot or otherwise, and the external opening is unusually large, or complicated with lesion of the principal vessels and nerves of the limb. As a general rule, it may be assumed that gunshot wounds of the large articulations of the extremities are nearly always followed by fatal consequences, if amputation is not speedily employed. The same is true, though in a more limited sense, of gunshot injuries of the joints of the toes and fingers, in which tetanus and other bad effects are prone to ensue.

SECT. II.—SPRAINS.

A sprain is the wrenching of a joint in which its ligaments are severely stretched, if not partially torn, and more or less injury is done to the parts around. Falls, blows, and twists, attended with rotation of the articulating surfaces, or a movement of these surfaces in opposite directions, are the most common causes of the accident.

The joints which are most obnoxious to sprains are the ginglymoid, or those which admit of motion principally in two directions, as the knee, ankle, and elbow. The articulations of the toes, thumb, and fingers frequently suffer for the same reason, their functions and exposed situation rendering them especially prone to such accidents. The reason why the orbicular joints are so seldom affected in this way is their greater latitude and freedom of motion, their surfaces being thus enabled to undergo extensive rotation without putting their ligaments or the surrounding parts materially upon the stretch, whereas in the hinge-like joints the most trivial twist, by opposing a sudden check to their extremities, must necessarily cause a severe wrench. Moreover, it must not be forgotten that there is an essential difference in the structure of the ligaments themselves in the two classes of joints, which cannot fail to exert a powerful influence upon the production of the accident in question. In the orbicular joints the connecting media are of a fibrous texture, comparatively thin, yielding, and extensible, and therefore able, to a considerable extent, to get out of the way of injury; in the ginglymoid, on the contrary, the ligaments are exceedingly firm, short, and indisposed to stretch, or, when stretched, incapable of withstanding rupture of their fibres. The orbicular joints are, however, notwithstanding their greater latitude of motion and the more yielding nature of their ligaments, occasionally severely sprained in consequence of the extreme abduction of the limbs. Thus the ilio-

femoral articulation is sometimes violently sprained by the sudden slipping of the foot outwards, far beyond the line of the body, so as to put both the capsular and round ligaments strongly upon the stretch, inducing symptoms extremely simulative of dislocation of the head of the bone into the thyroid notch.

It is probable that there is, in every case of severe sprain, more or less injury inflicted upon the parts in immediate relation with the affected joint. The muscles and tendons must necessarily participate in the wrench, suffering partial displacement, and sometimes even slight laceration; the nerves and vessels are stretched, and the integuments are often bruised and discolored, especially when the accident has been the result of external violence. In the latter case, the articulating surfaces, being violently brought together, not only experience a severe shock, but a considerable degree of contusion, thus greatly aggravating the case.

Symptoms.—The symptoms denotive of sprain are the instantaneous occurrence of pain, referred to the affected joint, impairment, if not total loss, of motion, and a sense of faintness or sickness, caused by the shock of the system, which is sometimes extremely severe, even when no external injury has been sustained, the accident having been induced merely by a wrench or twist of the limb. If some time has elapsed since the accident, there will be swelling and tenderness of the integuments, as well as of the deeper structures, and probably also an indistinct perception of crepitation, depending upon the deposit of plastic matter. Discoloration of the surface, from extravasation of blood, is also a not uncommon phenomenon. The pain is often at first excessive, and quite overpowering in its effects upon the system.

The only accident with which a sprain is liable to be confounded is dislocation; but from this it may generally be readily distinguished by a careful manual examination, by the form of the joint, by a comparison of the length of the affected limb with that of the sound one, by the history of the cause of the lesion, and, lastly, by the fact that the patient is usually able to use the parts, at least to some extent, immediately after the receipt of the injury. The examination should always be most thorough, lest a luxation be ultimately found, perhaps when too late to effect reduction, where originally only a sprain was suspected.

When the sprain is slight, the pain gradually subsides, the swelling is resolved, and the joint soon regains its accustomed functions. It is far otherwise, however, when the injury is of an opposite character or attended with severe wrenching of the ligaments, violent contusion of the articular surfaces, and considerable lesion of the surrounding parts. The suffering will then be proportionately great, inflammation will be apt to run high, convalescence will be tedious, and the joint may remain weak and tender for many months, if not for several years. A severe sprain, in fact, is often a much more serious accident, as it respects its secondary effects, than a dislocation or a fracture near a joint. In neglected or ill-treated cases, and sometimes even when every possible precaution has been adopted, it will be found that the articulation not only continues to be weak and uncomfortable for a long time, but that the corresponding limb becomes cold, wasted, flabby, and exquisitely sensitive; perhaps also the seat of neuralgic pain, subject to severe exacerbation whenever exercise is attempted, or there is a change in the weather. Occasionally, indeed, the movements of the joint are never regained. Conjoined with this local trouble there is generally grave disorder of the general health, the patient being extremely nervous, irritable, and dyspeptic, fancying himself helpless and disqualified for all useful exertion, both of mind and body. The probable cause of all this suffering is the shock or concussion sustained by the nerves of the affected joint at the moment of the accident, the effect thus produced exercising a pernicious influence upon the nutritive functions of the whole limb, and indirectly upon the well-being of the general system, especially the great nervous and ganglionic centres.

Treatment.—Two leading indications present themselves in every case of sprain, whether light or severe; the first is to limit and combat inflammation, the second to restore the joint, if possible, to its wonted functions. The former is fulfilled by the judicious use of antiphlogistics; the latter, by sorbefacients, passive motion, and exercise in the open air.

As soon as the joint has been subjected to the requisite examination for determining the diagnosis, the limb connected with it is to be carefully bandaged, and placed perfectly at rest in an easy, elevated position, splints, a tin-case, or a wooden box being used, if necessary, to insure more certain quietude. Sometimes the object is readily attained by laying the limb simply upon a pillow, though in warm weather this will be objectionable, as tending to keep up too much heat. Fomentations will usually be found to be more agreeable and soothing than cold applications, especially during the first few days, in nervous, irritable subjects; and the one which I generally prefer is a strong solution of acetate of lead and opium in hot water, applied by means of a piece of flannel, arranged in four, six, or eight thicknesses, and covered with oiled silk, to confine the heat and moisture. Instead of removing the cloth whenever it becomes dry, the best plan is to squeeze the lotion upon it from a sponge, as this will obviate injurious motion and exposure to the atmosphere. Solutions of hydrochlorate of ammonia and opium, a mixture of warm water, laudanum, and alcohol, and thin bags of hops will also be found extremely soothing. In sprains of the ankle-joint, the happiest effects frequently follow the protracted immersion of the limb in hot salt water. When the pain and swelling are unusually severe, leeches will be necessary. Anodynes will be required to allay muscular spasm, and should be given in liberal doses, either alone or in union with diaphoretics. Purgatives must not be neglected; and, if there is any constitutional excitement, the saline and antimonial mixture will come in play. In short, the whole antiphlogistic system must be carried out in its full extent.

When warm applications prove disagreeable, or are unproductive of relief, they should be replaced by cold, consisting either simply of water or of some refrigerating mixture. The proper rule, in all cases, is to continue no remedy longer than it is found to be soothing and beneficial.

The bandage must be carefully watched; judiciously employed, its effects are usually highly advantageous, affording support to the injured joint and limb, preventing swelling and spasm, and promoting the absorption of effused fluids.

In the milder forms of sprains, more simple means will of course answer, such, for instance, as applications of the tincture of arnica, laudanum, or laudanum and spirits of camphor, aided by perfect quietude of the affected parts.

The urgent inflammatory symptoms having thus been dissipated, embrocations, liniments, or lotions will be of use, the object now being the removal of effused fluids and the gradual restoration of the functions of the joint. These should be applied at first once, and afterwards twice, a day with the bare hand, the friction being regularly increased as the pain and tenderness diminish, and it will be well generally to keep the parts constantly wet with the medicine by means of a piece of flannel. Whatever local remedies are used, the bandage must on no account be neglected; for, beneficial as it may have been in the first instance, its effects will now be incomparably more so. The limb, weakened by the previous suffering, requires tone and support, and there is nothing so well calculated to afford these as the careful and judicious employment of the roller. It should be renewed at least once a day. Sometimes the bandage may be advantageously replaced by adhesive strips, applied as in dressing indolent ulcers.

At a still later stage of the treatment, great benefit will accrue from the cold douche, the water being pumped upon the part, or poured upon it from a considerable height, and the surface well rubbed afterwards with the bare hand, or a piece of coarse flannel. In some cases, where a more powerful impression is necessary, it will be found highly advantageous to use the hot and cold douche, in immediate succession. Along with these means the use of the bandage is still steadily continued, and it may even be necessary to persist in the employment of stimulating embrocations. In very obstinate cases I have derived marked benefit from the daily application of fish-brine, which seems to possess other properties than those simply dependent upon the presence of saline matter, though it is impossible to define their character. Occasionally a blister affords more relief than any other remedy, and now and then electricity is advantageous.

Finally, as soon as the disease has reached the chronic stage, the joint must

be gently exercised, and the patient made to walk about upon crutches in the open air. As great care should always be taken, in the acute stage, not to move the parts too soon, so in this we must not too long postpone its employment. Motion is the proper stimulus of a joint, as air is of the lungs, or food of the stomach, and when, after any injury, it is long neglected, serious consequences will be sure to arise. By and by the crutch must be laid aside for the cane, and this in turn for the limb, the joint and muscles being gradually forced into action. In nervous hysterical persons this will often be a sore trial, requiring no ordinary effort of the will; nevertheless, it must be done; there is no alternative; the parts must be used, or they will inevitably remain stiff and tender, and ultimately become worthless.

When there is much constitutional suffering, as there often is in the more severe forms of sprains, alteratives and tonics will be needful, and the best of these will be found to be blue mass, quinine, iron, iodide of potassium, and bichloride of mercury. Exercise in the open air must not be neglected.

SECT. III.—SYNOVITIS.

Inflammation of the joints, technically called synovitis, is liable to occur in all articulations, but more especially in such as are of large size, and of great importance as it respects their functional activity; it may be induced by various causes, both local and constitutional, as exposure to cold, the presence of interarticular bodies, and mechanical violence, as sprains, blows, falls, and contusions. In the great majority of cases, however, it arises from the effects of rheumatism, gout, eruptive fevers, syphilis, scrofula, and the inordinate use of mercury.

Symptoms.—The symptoms characterizing inflammation of a synovial membrane may be stated, in general terms, to be stiffness of the corresponding joint, which is usually greatest in the morning immediately after rising, but gradually diminishes upon exercise; pain and tenderness on moving and percussing the limb; swelling and fluctuation of the affected part; a pale, glossy appearance of the skin; inability to maintain the extended position; and a sense of heat within the articulation. As the malady progresses the symptoms increase in severity and the system, sympathizing with the local disorder, is thrown into violent commotion, there being high fever, a full, bounding pulse, and an arid state of the skin,

with excessive thirst and all the other phenomena of inflammatory excitement. Under such circumstances the pain is generally very excruciating, especially at some particular spot, depriving the patient completely of appetite and sleep, and requiring opiates in large doses for its relief.

The disease, however induced, frequently comes on in a slow gradual, and insidious manner, even when caused by external injury, being characterized, perhaps, merely by a trifling enlargement of the joint, arising from an increase of synovial fluid within its cavity or partly from this and partly from inflammatory deposits in the surrounding structures, attended with some degree of tenderness on pressure, and more or less suffering on motion of the affected parts. Eventually, however, yet it may

Fig. 478.

Acute synovitis of the right knee, the other being healthy

not be under several weeks, or even months, the joint assumes a soft and really

swollen appearance, as in fig. 478, the limb becomes wasted, the functions of the articulation are materially impaired, and all the symptoms are aggravated.

In *rheumatic* synovitis the symptoms are usually bold and well-marked from the start. The attack often comes on in this way: The patient, having been exposed to cold, or been guilty of some excess in eating or drinking, retires at night, with some degree of soreness in his joints, commonly attended with a general feeling of *malaise*, and wakes up in the morning with excessive pain, great tenderness on pressure of the affected parts, with considerable discoloration of the integuments, and probably utter inability to use his limb. He is feverish and uncomfortable; his pulse is strong and full; the skin is hot and dry; the bowels are costive; and the urine is scanty, high-colored, and loaded with urates. The joints become gradually more deeply involved; all the local symptoms increase in violence; an abundance of synovial fluid is effused; and, if the inflammation is not speedily arrested, suppuration will probably take place, the event being preceded and accompanied by rigors and high constitutional excitement. The joints most liable to suffer from rheumatic synovitis are the knee, ankle, wrist, and elbow, those of the hip and shoulder being seldom involved. The articulations of the fingers also frequently suffer, and that of the great toe rarely escapes when the disease in the other joints is at all severe. The inflammation often begins simultaneously in several joints; or, if it commences in one only, it is extremely prone to involve others in its progress, especially its fellow of the opposite side. Thus, articular gout, or rheumatism of one knee, nearly always attacks the other knee before it finally ceases.

In chronic articular rheumatism, calculous concretions are liable to form, especially in the joints of the fingers, where they always prove a source of great inconvenience and suffering. Their character will be specially considered under the head of interarticular bodies.

Syphilitic synovitis belongs to the tertiary form of syphilitic disease, and seldom makes its appearance until several years after the primary affection. It is most frequently met with in persons whose health has become exhausted by profuse courses of mercury and habitual intemperance. The larger articulations, especially the tibio-femoral and humero-ulnar, are its most common seat; but the smaller ones, particularly those of the fingers, are by no means exempt from it. A good deal of effusion of synovial fluid usually attends; the joint, in consequence, is swollen and fluctuating, motion is impeded, the parts are tender on pressure, and the patient is harassed by excessive pain, which is always worse at night, after he becomes warm in bed. This latter circumstance, together with the history of the case, and the coexistence of syphilis in other structures, will always suffice to determine the diagnosis.

Of *strumous* synovitis particular mention will be made under a separate head; meanwhile, it is only necessary to state that the disease is almost peculiar to childhood, that it most commonly attacks the hip, knee, and elbow, and that it occurs only in persons of a strumous predisposition.

Suppuration, as a consequence of ordinary synovitis, is unusual. Arthritic inflammation of the joints also rarely terminates in the formation of pus; in articular syphilis it is occasionally witnessed, but still it is infrequent; in scrofulous affections of the joints, on the contrary, it is extremely common, and constitutes one of the great dangers of the disease.

The phenomena which announce the occurrence of suppuration are such as denote its presence in other parts of the body. After the disease has continued for some time, violent rigors set in, followed by high constitutional reaction and copious sweats, the patient being delirious, excessively restless, and tormented with thirst. The local symptoms are all materially aggravated, as is shown by the severity of the pain, the rapid increase of the swelling, the extraordinary heat, and the deep discoloration of the surface. If the pus is not speedily evacuated, hectic irritation supervenes, the appetite declines, the sleep is interrupted, the surface is drenched with perspiration, colliquative diarrhoea comes on, and death gradually closes the scene. Such, however, is not constantly the course pursued by the disease. In many cases ulceration takes place, and the

matter, thus finding a vent, ceases to commit further ravages. In general, however, this does not occur until after the cartilaginous and osseous tissues have been deeply involved in the mischief, and the patient, consequently, is doomed to carry out a miserable existence, with a stiff joint and a deformed limb, or to perish from the remote effects of the malady, after many months, if, indeed, not several years, of great suffering.

When a joint has once been inflamed, from any cause, it remains weak, and predisposed to disease, for a long time afterwards. The most trivial circumstance will then be able to induce a relapse, and re-awaken the symptoms with all their primitive severity. A frequent repetition of the morbid action is sure ultimately to lead to disorganization of the component structures of the joint, and to complete loss of function. In any event, in fact, synovitis is a dangerous malady; plastic matter is generally poured out in considerable quantity, and there are few cases, however slight, in which there is not a strong tendency to adhesion of the opposite surfaces. In this respect, there is the greatest resemblance between the serous membranes of the articulations and those of the viscera; in neither can inflammation go on to any extent, or for any length of time, without a flow of plasma, and the danger of adhesion.

Morbid Anatomy.—The pathological changes which characterize this affection must necessarily vary a good deal, according to the nature of the exciting cause, and the duration of the morbid action. Ordinarily, in the earlier stages of the malady, there is merely some degree of vascularity, along with slight opacity of the affected membrane, and some increase of the natural secretion. Here and there a little plastic matter is perceptible, either adherent to the inflamed surface, or floating about in the midst of the synovial fluid, which is usually, at the same time, more or less turbid, and abnormally thick and viscid. At a subsequent period, and especially in the more severe forms of the disease, the morbid appearances here enumerated exist in a still higher degree. There is a greater amount of lymph, the vascularity is more intense, as well as more diffused, and the synovial secretion is of a dirty, glutinous nature. In some instances the inflammation produces results still more disastrous; pus is freely poured out, and lining membrane, cartilage, and bone, are all involved in the ruinous consequences. In the worst cases the purulent fluid excites perforative ulceration, and escapes from the joint, the passages afterwards remaining fistulous. The surrounding structures are thickened by plastic deposits, softened, and unnaturally red and congested.

Treatment.—In discussing the treatment of an affection so various in its origin as synovitis, it is impossible to do more than to lay down a few broad general principles for the guidance of the surgeon. When the case is one of ordinary character, depending upon traumatic causes, or ordinary constitutional derangement, as a depraved condition of the secretions, or, finally, upon a suppression of the cutaneous perspiration, it will generally yield to the judicious application of the more common antiphlogistic measures, such as would be indicated in common inflammation of other parts of the body. If the symptoms are at all urgent, and the patient is young and robust, blood must be freely taken from the arm, and the bowels opened with an active cathartic, followed by the antimonial and saline mixture, with the addition of a sufficiency of morphia to promote perspiration, allay pain, and induce sleep. Mercury is administered if there is danger of structural lesion, or evidence of plastic effusion, and is carried to the extent of rapid but gentle ptyalism, with the hope of saving texture, and preventing adhesion. The diet is light and spare; the drink cooling and acidulated.

As it respects the local means, the joint is placed in an easy, elevated and relaxed position, over a pillow, or bolster, the limb being put up, if necessary, in splints, or other suitable apparatus, for the purpose of more certainly insuring quietude. The rest must be absolute and unconditional. If the affected surfaces are permitted to rub against each other, even in the slightest degree, the effect must inevitably be to aggravate and protract the morbid action.

Of direct topical applications the most important are leeches and fomentations.

Leeches, however, are, as a general rule, necessary only in the more urgent cases, attended with great pain, heat, and swelling, and then they should be employed freely, in such numbers and in such a manner as the violence of the disease and the condition of the system may seem to indicate. Cupping is not to be thought of in inflamed joints, as the percussion attending the operation would cause more injury than benefit, to say nothing of the pain it would produce. In young and otherwise healthy subjects, especially during the hot weather of summer, cold applications, simple or medicated, will sometimes be exceedingly grateful and beneficial, promoting evaporation, allaying pain, and opposing swelling; but in general warmth combined with moisture will be found to be most soothing and agreeable, and should therefore have the preference. The best plan, however, always is to consult the feelings of the patient, or to change the applications whenever they cease to be beneficial. My constant practice is to medicate the dressing largely with opium or laudanum, and it is difficult to conceive of a case of synovitis where these articles can properly be dispensed with. When these means fail, or when the disease is making rapid progress, there is no remedy so capable of affording relief as a blister, large enough to cover in the whole joint, well sprinkled with morphia, and retained until it has produced thorough vesication, the parts being dressed afterwards with a light emollient poultice or with cloths wrung out of tepid water, with a piece of oiled silk over its surface to confine heat and moisture.

If matter form, it is to be dealt with in the same manner as when it occurs in other parts of the body. It is folly to look upon it in any other light. It is pent up; it is not amenable to the action of the absorbents, and must therefore be evacuated as early as possible, before it has had time to cause serious structural evil. The incision need not, nay, must not, be direct or large, but subcutaneous, and small, and when this precaution is observed, and the orifice is immediately closed to prevent the admission of air, nothing but good can result from it. A timid, cautious course will not answer here; as long as the pus is confined it must keep up pain, and injure the structures with which it lies in contact; impairing and ultimately destroying their vitality, and thus putting both limb and life in imminent peril. The opening is of course made at a dependent part, and is repeated from time to time until the matter ceases to accumulate, the joint being well supported in the interval by the bandage, or by a roller and adhesive strips. In some cases, the joint may be so completely distended with pus as to demand imperatively a free incision for its relief.

The surgeon need not always despair of effecting a good cure even after supuration has taken place, if the above measures are cautiously carried out; the probability will certainly be that the joint will be stiff, but it should be recollected that an ankylosed joint is always better than no joint at all, provided of course that it is put in a proper position for future usefulness.

When the disease has passed into the *chronic stage*, our main reliance must be upon the steady, persistent use of the bandage, the douche, stimulating lotions, and friction. The joint is showered twice a day, first with hot, and immediately after with cold water, when, being dried, it is thoroughly rubbed with some embrocation, or painted with a weak solution of iodine, and put up in a roller, extending from the distal portion of the limb. Passive motion is instituted, and steadily continued so as to afford gentle and equable compression to every part, until we succeed in restoring the functions of the joint. Exercise must be taken upon crutches in the open air without being carried to fatigue; and for a good while the limb must not be permitted to sustain the full weight of the body. In some cases the joint may be advantageously strapped with ammoniac and mercurial plaster, or a plaster composed of opium and galbanum, to promote the absorption of effused fluids, and lend support to the weakened structures. If the case prove obstinate, the remaining symptoms may be scattered by the use of iodide of potassium with a minute quantity of bichloride of mercury, given three times a day, and pushed to gentle ptyalism. When ankylosis is found to be unavoidable, all motion of the joint should be prohibited, and the limb placed in the position in which it is most desirable it should be in that event.

I have said nothing here of counter-irritation by tartar emetic pustulation, vesication with croton oil, and the use of issues, the seton, and the moxa ; because, although sometimes serviceable, these means seldom afford the relief that has been so generally ascribed to them. I have certainly not, in my own practice, found them of much advantage, while occasionally I have thought they had acted decidedly prejudicially. Pustulation with tartar emetic is not only extremely painful, but it not infrequently, in delicate persons, creates nausea and other disagreeable effects, rendering its continuance improper. The use of croton oil is hardly less objectionable. An issue may sometimes be established beneficially directly over the affected joint with the actual cautery, or the hot iron may be drawn linearly over its surface at several points, in a vertical direction. The latter operation, however, is always extremely painful, and seldom affords any compensating advantage. The seton should never be used in any articular disease.

In *rheumatic and gouty* affections of the joints, our reliance must mainly be upon the use of colchicum, whose virtues here are unrivalled. It is not to be understood, however, that colchicum is infallible ; there are, undoubtedly, cases wherein it either entirely fails, or in which its effects are but little apparent ; but in general it will answer an admirable purpose, promptly relieving pain, depurating the blood, and expelling or neutralizing the arthritic poison. A little preliminary treatment by way of purgation, if not also by venesection, will usually be proper, and then the colchicum, given in drachm doses, with a grain of morphia, at bedtime, and followed by a gentle laxative late in the morning, will seldom disappoint our highest expectations. The pain will speedily vanish, fever, swelling, and stiffness will subside, the lithates will disappear from the urine, and health will soon resume its wonted sway. When there is much arterial action, as evinced by a full, bounding, and frequent pulse, the tincture of aconite will come in play, in doses of from three to four drops every three hours, or the saturated tincture of veratrum in from four to eight drops, either alone, or, as I generally prefer, in union with a minute quantity of antimony, and the eighth of a grain of morphia, so as to produce a more powerful diaphoretic impression. In the use of these several articles, great caution is needful that the dose is not carried too far, or the remedy continued longer than is necessary. Their agency is potent, and demands vigilance to keep it in proper check.

Along with these means, with a view of neutralizing the acid state of the blood, free use should be made of alkalies, of which the bicarbonates of soda and potassa, in the proportion of twenty grains of the former to ten of the latter, are the most eligible. The medicine should be repeated at least every six hours, in two ounces of soft water.

When the disease is rebellious, calomel and opium will be found serviceable, but the former of these articles should be used with great caution. As a local application, nothing will be more beneficial than soap liniment and laudanum, well rubbed in twice a day, and retained constantly upon the affected joint with a piece of flannel, covered with oiled silk. This may be succeeded, if the disease is inclined to linger, by a fly-blister.

In *sypilitic* synovitis, the great remedy, as stated elsewhere, is iodide of potassium, aided, in obstinate cases, by mercury, carried to gentle ptyalism. Other means, both general and local, and such as have already been adverted to, are not to be neglected.

SECT. IV.—DROPSY OF THE JOINTS.

Dropsy is an accumulation of fluid in the interior of an articulation, generally as a result of chronic disease of the synovial membrane. It is most common in the ginglymoid joints, as the knee, elbow, and ankle, especially the first, which suffers more frequently in this way than any other.

The *causes* are both local and constitutional. Among the former may be classed different kinds of accidents, as sprains, blows, concussion, dislocation, and the presence of interarticular concretions, irritating the synovial membrane, and inducing an inordinate secretory action in its vessels. Severe and long con-

tinued exercise, attended with excessive fatigue in the joints, may also excite the disease.

The constitutional causes are not always very obvious. Very often the disease is associated with, or directly dependent upon, a rheumatic state of the system, as is clearly evinced by the consentaneous existence of rheumatic suffering in other parts of the body. Gout occasionally produces a similar effect. In tertiary syphilis, it is not uncommon to meet with dropsy in several of the joints simultaneously, especially in the knee and elbow, and I believe that such an effect will be more certainly brought about if the individual has been subjected to severe courses of mercury for the cure of the primary affection. When a strong predisposition to the disease exists the slightest causes are generally sufficient to call it into action. In weak, strumous subjects, it is occasionally a sequel of typhoid fever, scarlatina, measles, and smallpox. Suppression of the cutaneous perspiration may also induce it; and in many cases it comes on without any assignable reason.

The *symptoms* are generally well marked, the most prominent and reliable, in a diagnostic point of view, being a loss of the natural contour of the joint, and the existence of a soft, elastic, and irregularly circumscribed swelling. The skin ordinarily retains its normal color, and the motion of the articulation, although considerably impeded, is rarely attended with much pain or inconvenience. The tumor affords distinct fluctuation, and is most conspicuous where the ligaments of the joint are loose and superficial. In the wrist, for example, it is most apparent at the anterior and posterior aspects of the joint; in the ankle, in front of the malleolar processes, a short distance above the instep; in the shoulder, in the space between the deltoid and pectoral muscles; in the knee, at the sides of the patella. In the latter, where the swelling is often double, its shape and consistence are materially influenced by the movements of the limb, being softer and more decidedly fluctuating in extension than in flexion. Pressure upon the tumor is seldom productive of much pain; generally, indeed, it causes merely a little uneasiness, or a sense of tenderness. In cases of long standing there is sometimes considerable enlargement of the subcutaneous veins, but this is uncommon.

The progress of these dropsical affections is commonly very chronic, many months often elapsing before the tumor attains any considerable bulk. Sometimes, however, the reverse is true; in the knee, in particular, frequently large collections occur within a few weeks. Their march is usually most rapid in rheumatic and gouty subjects, and after attacks of the exanthematous fevers.

In regard to the *diagnosis*, the history of the disease, the change in the contour of the joint, the fluctuating and indolent character of the swelling, and the comparative freedom of motion of the affected structures, will generally serve to prevent error. Should there, however, be any doubt after the swelling has been thoroughly scrutinized, the difficulty may at once be decided by the insertion of a very delicate needle, the nature of the escaping fluid being characteristic.

The *pathological anatomy* of these collections is not well determined, owing to the fact that an opportunity is seldom afforded of inspecting the affected joint. Enough, however, is known to show that there is generally, especially in cases of long standing, considerable opacity and thickening of the synovial membrane, with some degree of vascularity, the vessels being spread over the surface of the membrane in delicate, arborescent lines, widely separated from each other. Occasionally slight deposits or patches of lymph exist, giving the part a rough, uneven appearance, but this is infrequent. The cartilages and bones present no perceptible changes, nor do the muscles and other parts around the joint, except that they are more or less displaced by the dropsical distension. When the accumulation is very great the capsular ligaments, pressed upon in every direction, become very much stretched and attenuated. Indeed, in the worst forms of the disease they may be so much distended as to give way, thus allowing the fluid to diffuse itself among the surrounding structures.

The dropsical fluid is generally of a pale, yellowish, straw or amber color, and

of a ropy, unctuous, or sero-oleaginous consistence ; sometimes it is turbid, whey-like, or sanguinolent, and intermixed with flakes, shreds, or masses of lymph. Its quantity is variable, depending upon the size of the joint, the duration of the case, and other circumstances. In the knee it frequently amounts to from sixteen to twenty ounces.

The *prognosis* is always more favorable, other things being equal, when the swelling is recent and small than when it is of long standing, large, and attended with serious lesion of the synovial membrane. In the latter case the disease is often extremely obstinate, and may become dangerous, as it is liable to be followed by disorganization of the articular cartilages and bones. Anchylosis is not uncommon.

Treatment.—In the treatment of dropsy of a joint it must be borne in mind that it is not a disease, but, like dropsy everywhere else, merely a symptom of disease. Hence, one of the very first and most important objects is to endeavor to remove the lesion upon which the presence of the fluid depends. The question will, therefore, necessarily arise, in every instance, what has been the origin of the affection? Has it been local or constitutional? Upon the success with which this question is answered will mainly depend the success of our remedies.

When the affection is of a local nature, caused by a sprain, contusion, or other injury, local remedies alone will generally suffice to effect a cure, especially if assisted by an occasional purge and a properly regulated diet. The means to be chiefly relied upon are, perfect quietude of the affected joint, embrocations and vesicants. Without rest, absolute and unconditional, little progress can be made in any case ; it should of course be conjoined with proper elevation and an easy, relaxed position of the parts. In the milder varieties of dropsy, friction with iodinized lotions, soap liniment, camphorated spirits, and mercurial unguent seldom fail to make a rapid and decided impression upon the absorbent vessels of the joint, as is shown by the speedy diminution of the size and tension of the swelling. They should be applied at least twice a day, being rubbed upon the whole of the affected surface with the bare hand until a decided glow is produced, when the friction should be discontinued, to be repeated in the same careful, but efficient, manner at the next operation. In the meanwhile, the part should be well supported with the bandage, extending from the distal extremity of the limb, the compression thus derived powerfully aiding the reduction of the effused fluid. When it is evident, from the gradually decreasing volume of the sac, that the absorbents have been fairly roused, the inunctions may be advantageously preceded by the cold douche, or by the hot and cold, applied in immediate succession ; a plan which I have often seen productive of the most salutary effects.

When there are evidences of incited action, as when the surface is hot and tender, refrigerating lotions, consisting simply of cold water, or of water impregnated with acetate of lead and opium, must be employed ; for as long as the capillary vessels are over-active little benefit can be hoped for from sorbefacients properly so called. Even leeching and brisk purgation may then be necessary.

In obstinate cases, there is no topical remedy at all comparable to a blister well sprinkled with morphia, and left on until the epidermis is thoroughly raised. The discharge is promoted by emollient dressings, and the blister is reapplied as soon as the surface is partly cicatrized. This method is much more salutary than that of keeping open the sore by means of irritating salves ; it seems to exert a more direct effect upon the absorbent vessels, and is at the same time much less painful, an object of great importance in the treatment of all chronic maladies.

Pustulation with tartar emetic ointment and croton oil, so much vaunted by some practitioners, is generally hurtful ; and, as to issues and setons, their employment is never indicated, as the object may always be attained by milder means.

When the affection is of a rheumatic, gouty, syphilitic, or strumous origin, remedies calculated to meet these several contingencies are clearly indicated.

and nothing short of their exhibition will be likely to be of any permanent benefit. Colchicum, mercury, iodide of potassium, and other kindred articles, are then the means chiefly to be relied upon. When the dropsy is symptomatic of fever, or some of the eruptive diseases, it often disappears spontaneously, as the patient improves in health and vigor, or readily yields to mild measures, particularly tonics, and change of air. Ordinary hydragogue medicines afford little, if any relief, in this affection in any of its forms.

As the joint will necessarily remain weak for a long time after the removal of the fluid, it should be well supported with a laced-cap, fig. 479, or a suitable bandage, and kept cool by frequent ablutions with alcohol and water. Fatigue must of course be avoided.

Finally, should the disease resist the means now suggested, or continue to increase, so as gradually to impede the motions of the joint, accompanied with wasting and coldness of the limb, relief should be attempted by *evacuation* of the fluid by subcutaneous puncture. The operation may be performed either with a delicate trocar or bistoury, inserted in such a manner as to make a valve-like opening, which should be closed, the moment the fluid has been drawn off, with collodion, a compress, and bandage, to prevent the entrance of air. The instrument should be introduced at the most dependent and superficial portion of the swelling, at least two inches beyond its boundaries, its point being carried along the cellular tissue until it reaches the sac, which is then pierced in the usual manner. Thus performed, no possible injury can result from the operation, while, by removing the fluid, over which the absorbents have no longer any control, it affords the only chance of relief. For some days after the operation the limb is kept perfectly quiet, light diet is enjoined, and every precaution is taken to prevent inflammation. Re-accumulation is guarded against by the means already indicated.

Fig. 479.

I have not been so bold as to use *injections* for the permanent cure of this affection, convinced that the practice must be fraught with danger. The article which has been used for this purpose, by Velpeau, Bonnet, and others, is tincture of iodine, diluted with two, three, or four parts of water, introduced subcutaneously with a syringe, to the amount of several ounces, and retained for a few minutes, the joint being pressed slightly during its sojourn, in order to bring the solution fully in contact with the diseased sac. It is then permitted to flow off spontaneously, when the opening is carefully closed, and the case treated upon general antiphlogistic principles.

Of the safety, and, consequently, the propriety of this operation, great doubt is entertained by many practitioners, and, I think, justly so; for, although it has unquestionably succeeded in some cases, yet it is equally certain that in others it has been followed by such a degree of inflammation as to imperil both limb and life.

SECT. V.—MOVABLE BODIES WITHIN THE JOINTS.

Various kinds of bodies, mostly movable, but sometimes adherent, are liable to form in the cavity of the joints, where, interfering with the functions of the opposing surfaces, they become a source of much annoyance, and sometimes even of intense suffering. Ambrose Paré, in 1558, seems to have been the first to call attention to them. They are divisible into several classes, differing materially in their structure.

1. Those bodies, usually known under the name of *interarticular cartilages*, or osseous concretions, have been met with in various joints, particularly in those of the knee, elbow, wrist, and jaw, the first, however, being apparently their favorite seat, for it is there that they occur most frequently, and that they attain their greatest bulk. The orbicular joints rarely suffer from them; a circumstance which does not admit of easy explanation, although it may be assumed that it depends mainly upon the conformation of the articular surfaces opposing their development in the one case, and favoring it in the other. It is difficult to determine why the tibio-femoral articulation should suffer so much more frequently

in this way than any other joints of its class, unless of larger size and its greater liability to all kinds of inflammation in its lining membrane.

The size, number, form, color, consistence, and liability to much diversity. In the knee, where they sometimes acquire the dimensions of the patella, mostly they are much smaller. Their number is great in proportion to their volume. When very large there is often only one in each joint. In some circumstances there may be as many as a dozen. In one case, as many as sixty were found. The largest known to be removed from one joint was thirty-eight in size, as large as a pea to that of a pullet's egg. They are, for the most part, of a pale straw color; while their consistence, like that of fibro-cartilage to that of bone, with every part of the joint. Their shape is generally very much modified by the circumstances in which they are developed. Thus, in the knee they are often of an irregularly flattened figure, not unlike that of a disk, convex on one side, and concave on the other. In the line of the condyles of the femur and the head of the tibia, even in the knee, they are of a lenticular shape. Consisting usually of a single mass, they are sometimes of several lobules, connected together by a kind of condensed surface may be perfectly smooth, or partly smooth and partly rough. I have seen specimens which presented numerous hollows giving them a porous aspect. Their weight depends upon their size and consistence.

The structure of these bodies varies. In their early stage they are fibrous, but as they advance in age they assume the structure ultimately that of osseous matter. The process of ossification is generally very gradual, and almost always gradual, though occasionally it displays itself in a more rapid manner, and at the periphery, or first at the surface and afterwards in the interior. Several such bodies coexist in the same joint in their development; some being comparatively soft and gelatinous nature, and others very hard and osseous.

The immediate cause of these structures is the deposit of plasma. This matter no doubt soon becomes constantly compressed by the opposing surfaces of the joint into the peculiar shape which is found to distinguish them when they have attained their maturity. When the friction of the joint is generally proportionately smooth, if not assisted by the presence of these bodies, the consistence will also be more dense than when the joint is rough. They are susceptible of various transformations according to the nature of the circulation, and also that this circulation closes their attachment to the synovial membrane, and it is evident that they are originally developed, not as a separate tissue, as has sometimes been alleged, the excessive accumulation of this substance being altogether incompatible with its attachment. At a certain period they become loose, or floating, and it is not doubtless depends very much upon the amount of friction in the joint. The detachment of these bodies is doubtless contributes to their detachment is the experience after their development has reached the point. Their primitive connection is usually effected by a short, narrow pedicle.

The size and shape of these bodies are well illustrated by the drawing of several in a collection of thirty-eight, from John T. Berry, of Kentucky, who removed them from the left knee of a colored man upwards.

When quite young, he received a slight injury upon the joint, which, though not painful, was soon followed by considerable enlargement. Two years prior to the operation performed for his relief, he perceived a small, round, movable tumor, immediately above the external condyle, which was followed in about twelve months

Fig. 480.

Loose articular concretions.

Fig. 481.

Attached articular concretions.

by two others just above the inner part of the knee. These swellings gave him but little trouble, with the exception of some stiffness in the articulation. Occasionally, however, the external one changed its position, slipping round to the anterior surface of the thigh, above the patella, where it interfered so much with his progression that the man was immediately obliged to sit down, and push it back to its original position. An incision being made into the external tumor, the concretions were readily extracted, having all been contained in one sac, of a dense, firm consistence, which occupied the lower part of the front of the thigh, and communicated with the cavity of the joint. There were thirty-eight altogether, from the volume of a pea to that of a pullet's egg, of a whitish, glistening appearance, rough or pitted on the surface, and of various configurations, as spherical, oval, lobulated, or angular. Fig. 481 exhibits several bodies of this kind as they lie in the joint attached to the synovial membrane. The specimen is in my collection.

The symptoms which announce the presence of interarticular bodies are often so well marked as to render it impossible to be deceived by them. This is particularly true when they occur in the knee. There are, however, on the other hand, cases where the nature of the disorder is so obscure as to elude, at all events for a time, the most careful examination. In general, it will be found that the intruder, if large, will cause but little pain, whereas if it is small, and susceptible of slipping about, or of becoming wedged in between the articular surfaces, it will occasion severe suffering, followed, if the accident is frequently repeated, by violent synovitis. When, for example, the interarticular substance gets behind the patella, as the patient is standing or walking, he is often seized with a sudden pain, and is instantly compelled to sit down, in order to save himself from falling. In the night, his sleep is liable to be disturbed by any inadvertent movement of the limb that may favor displacement of the concretion; and when the disease has existed for a long time, and is attended with much relaxation of the ligaments, any accident of the kind, however trivial, is almost sure to produce excruciating agony, often attended with syncope.

When the extraneous substance gets in the habit of slipping about, it is sure not only to create pain, keeping the joint constantly tender and uncomfortable, but also enlargement, both by interstitial deposits in the surrounding structures and increase of synovial fluid. The intumescence, however, is rarely so great as to prevent the surgeon from feeling the concretion, or pushing it about from one

point to another. In the knee, it generally forms a r of the patella, more frequently on the external than 1 distinguishable both by the sight and touch. Cases a particular part of the joint, it becomes compara being so comfortable as to imagine he has got rid of ever, usually very brief, it leaves its lurking place 1 causing a renewal of all the former trouble.

As the affection progresses, the joint becomes mo and feeble; the synovial membrane, constantly frett eration, pours out an additional quantity of its app ments become greatly relaxed, and the patient, at fir rendered permanently lame and helpless.

The most important *diagnostic* signs are the sud is deprived of its use, the severity of the concomit surgeon to feel, see, and push about the concretion the patient can generally relieve himself by his own of the disease, the absence of external injury, and t symptoms from the most trivial circumstances, afford of the character of the affection.

Although the complaint under consideration is r as it often materially interferes with the moveme occurs, and does not admit of permanent relief, ex which is itself always hazardous, we cannot be too c nosis. The removal of the concretion, by the ab impossible.

Treatment.—The treatment is palliative and re is moderately large, or if, whatever its size may be, i and not to occasion any material inconvenience, o1 barrassment in the functions of the joint, the most j alone, care being taken to support the parts with a l able contrivance, calculated to prevent the substance doing harm. The relief thus afforded, however, is we are, therefore, compelled to adopt other and mo

Great objection has been urged against the use of these interarticular bodies, and not without just r all interference of the kind is eminently dangerous remark, however, is more particularly applicable to the joints; that is, by direct incision, an operation 1 the most serious consequences, and which should, th discarded. We have no elaborate statistics to show t but enough is known to satisfy any unprejudiced min fearful, judging from the number of fatal cases and have appeared in the journals of this and other count precaution was observed in regard to the preparat the operation was performed with the greatest possi result was often most disastrous; or, if the patient the most anxious attendance that his safety was f true, occasionally got well without a solitary untow ample, communicated to me by Dr. Berry, above ref such a case cannot be used as an argument in favor

None of these objections lie against the operat neously by Goyrand and Syme, in which, the knife taneously, there is no admission of air, and consequ Nevertheless, it is of great importance, even here, to rigid preliminary course of treatment. With this vi the house for at least a fortnight, with the affected j dition; the bowels and secretions should receive ca should be perfectly plain and simple, all animal fo dicted.

The subcutaneous section of the knee will serve as a type of the operation upon the other joints. The limb being extended upon a table, the foreign body is brought to the upper and outer side of the patella, beneath the large external muscle, where it is to be securely held by an assistant, either with the fingers or with an acupuncture needle, while the surgeon introduces a long, narrow bistoury, from above downwards, into the synovial pouch, which is then freely divided, so as to permit the concretion to be pushed through the opening into the subcutaneous cellular tissue, or among the structures exterior to the joint, entirely beyond the serous lining. The puncture is covered with collodion, and a compress is gently bound upon the knee, between it and the concretion, the object being to promote speedy union of the edges of the articular wound. The limb is kept perfectly at rest, free use being made of cold water-dressing and other antiphlogistics. When the inner wound is healed, the extraneous substance may be removed by simple incision; or, if not in a condition to cause inconvenience, it may be allowed to remain in its new position, where it will soon become imbedded in plastic material, and so prove comparatively harmless. In some cases, indeed, it is speedily absorbed.

The *statistics* collected by Hippolyte Larrey show that the subcutaneous operation for the removal of these bodies is by no means so safe as has been generally supposed. The total number of cases was 167, of which 129 were by direct incision, and 38 by indirect, or subcutaneous. Of the former, 96 were cured, 5 failed, and 28 died; of the latter, 19 recovered, 14 were unsuccessful, and 5 perished.

2. The movable joints are occasionally the seat of *gouty concretions*, which, from their color and consistence, have received the name of chalk-stones. They are composed of urate of soda, a peculiar fatty matter, phosphate and carbonate of lime, and a minute quantity of carbonate of magnesia. In an old man, whom I examined some years ago, I found these concretions in nearly all the principal joints of the body, in small amorphous masses, of a whitish color, and of a soft, unctuous consistence. Sometimes they are perfectly smooth and round; more commonly, however, they are rough and irregular, grooved or nodulated. They are generally small, but have been observed of the volume of an egg. Their origin is always connected with a gouty diathesis.

The *treatment* of this form of concretion is chiefly constitutional, directed to the removal of the gouty diathesis, with which its origin is so intimately associated. Colchicum and aconite, with an occasional mercurial purge, and free use of lemon-juice, constitute the chief remedies. For a long time, means should be employed to depurate the blood, and to keep up a healthy state of the digestive organs, with an active condition of the renal secretion. If the joint ulcerate, or threaten to do so, extrusion should be effected; in the former case, by direct incision, in the latter by the subcutaneous method.

3. The synovial membrane is occasionally the seat of *fibrous tumors*. They occur in different joints, but principally in that of the knee, where several sometimes exist together, varying from the volume of a bean to that of a large almond. On one occasion, several years ago, I removed a growth of this description, which was fully as large as a pullet's egg. It was of an elongated, flattened, pyriform shape, and was attached, by a short, narrow pedicle, to the upper and anterior part of the inner condyle. The patient, a man of twenty-seven, had labored under synovial irritation for many years, attended with partial ankylosis, and much pain and tenderness, which were always aggravated upon the slightest exertion. A subcutaneous incision being made into the articulation, the tumor was detached by a few turns of the point of the knife, and immediately extracted with a very delicate, slender pair of forceps. The wound, closed with collodion, healed by the first intention, no untoward symptom occurring, as far as the joint was concerned. Some erysipelas, however, appeared upon the skin, and a week afterwards a large abscess formed at the inner and middle part of the thigh, which somewhat retarded recovery. Another tumor, doubtless of a similar nature, was found occupying the deeper portion of the joint, but, dreading farther interference, it was thought best not to meddle with it. The functions of the knee were much improved by the operation.

The tumor, after ablation, was found to be of a pale firm and tough in ing, and somewhat of a distinct

Fig. 482.

Fimbriated growth of the synovial membrane.

Fig. 483.

The synovial membrane of the knee-joint studded with numerous melon-seed shaped bodies, the patella being turned down.

4. There is a membrane, to which its appearance, then applied. It is common to joints, as in those which consists of innumerable sizes, from that of a pea, of a palm, and bearing a variety of epiploic appendages. Of a smooth, glistening the free surface in every direction, by a broad base, or, in some cases, by a narrow structure is evident, originating from the joint, which assumes in question in the joint in which it is exerted upon it. The accompanying illustration is indebted to the excellent illustration of growth.

The symptoms of synovial membrane are mechanical character, stiffness, and of exercise, along with and around the joint. There is no treatment and the treatment is based upon general principles.

5. *Fibroid* bodies of cucumber, occasionally form in the same manner, as the larger concave fig. 483, from the contraction of a remnant of growths.

SECT. VI.—TUMORS

1. GENICULAR

Tuberculosis of the knee-joint is called white swelling, this name by some authors, an extremely common either in the articular extremities of the limbs, or the

perhaps not infrequently happens, simultaneously,

all these structures, it is almost peculiar to children under ten years of age, and generally pursues a chronic course, although occasionally it proceeds with so much rapidity as to entitle it to the distinction of an acute malady. However this may be, it seldom stops until it has produced the most extensive textural ravages, consisting in the destruction, either partial or complete, of the affected articulation. Constitutional involvement is usually well-marked, especially in the latter stages of the complaint, when it is also not uncommon to find serious lesion of some of the internal viscera, as the lungs, spleen, and mesenteric ganglions. The disease, as the name imports, is essentially of a strumous nature, and can therefore occur only in persons of a strumous diathesis.

The joints which are most prone to suffer from tuberculosis are the movable ones, particularly the hip, knee, ankle, elbow, and wrist. Those of the tarsus are also remarkably liable to it. Sometimes several joints suffer simultaneously, and instances occur in which the disease is, apparently, hereditary.

Etiology.—The exciting causes of this affection are, in general, exceedingly obscure. Indeed, in the great majority of instances they are utterly inscrutable. The surgeon, it is true, is often told that the patient, perhaps weeks or months before the appearance of the characteristic phenomena, received some injury, as a blow, fall, or kick, or that the affected joint had been sprained, bruised, or twisted; but my experience is that such information is usually little reliable, or that, if such an occurrence really did happen, it exerted little, if any, influence in developing the complaint. Unless very severe, such accidents would no more provoke tuberculosis of a joint than a similar injury of the chest tuberculosis of the lungs, or of the head tuberculosis of the arachnoid membrane.

Exposure to cold, intense or protracted, is a powerful cause of this disease, and is particularly apt to prove pernicious in persons of feeble constitution, with an impoverished state of the blood. The influence of this agency in exciting pulmonary phthisis has long been recognized by practitioners. Living in damp, under-ground, ill-lighted, and ill-ventilated apartments operates in a similar manner. Simple suppression of the cutaneous perspiration, suddenly induced, as when an individual is exposed to a strong current of air, is also liable to produce the disease, especially in one predisposed to its occurrence.

In many cases tuberculosis of the joints appears to be caused by the use of unwholesome food, chronic disorder of the digestive apparatus, imperfect assimilation, or inadequate nutrition, however occasioned. Protracted courses of mercury, establishing a severe drain upon the system, followed by the abstraction of the plastic elements of the blood, may lead to similar results. The same is true, though the circumstance does not always readily admit of proof, of the exhaustion consequent upon copious and protracted hemorrhages, infantile cholera, chronic diarrhoea, scarlatina, measles, smallpox, and of typhoid, intermittent, and other fevers; in short, of everything that has a tendency to enfeeble the system and degrade the blood.

It has frequently been asserted that rheumatism is a common cause of this disease, but of the truth of this statement I have myself never had any evidence. The fact is it is not at all probable that this affection ever exerts such an influence; for, in the first place, it is well known that tuberculosis is exceedingly rare in rheumatic subjects, and, in the second, that, when disease of the joints shows itself in persons of this description, it is very different from the strumous disorder under consideration.

Persons of fair complexion, light hair and eyes, a delicate skin, and a languid circulation, with a tendency to eruptions of the scalp and enlargement of the lymphatic ganglions, are most prone to tuberculosis of the joints. In many cases the strumous diathesis exists in a marked degree, the tumid lip and belly, the long eyelashes, the cold extremities, the flattened shape of the fingers, and the disordered condition of the digestive organs, affording unmistakable evidence of its presence.

No one who is in the habit of meeting with this disease can fail to notice the different temperaments of those who are most prone to its attacks. These are, according to my observation, the sanguine and the lymphatic, or a combination

of these. In the former, the characteristics are, a well-developed muscular system, with a tendency to a state of *embonpoint*, a vigorous circulation of the skin, and an active state of the intellect. In the latter everything is the reverse. The face is pale, often swollen and pasty, the muscles are habitually cold, the cutaneous circulation is sluggish, and the mind is sluggish. In both, but more particularly in the former, the belly and upper lip are often remarkably tumid, and a peculiar diathesis. These two varieties of temperament deserve careful consideration, as they form the basis of the indications in the disease in question.

Morbid Anatomy and Pathology.—The morbid changes vary according to the different stages of its progress. In its incipency, all that we know of these changes is learned accidentally, by examining the bodies of the dead. Enough, however, has been ascertained to show that it differs materially, if any, from those of ordinary inflammation. The membrane, which is commonly first implicated in the disease, is of a pale, or slightly grayish aspect, and is of a soft, or slightly vascular, a few delicate, straggling vessels being observable upon its surface, and, in most cases, it is softened, not uniformly, but at certain points. An effusion is often imparted to it, from the deposit of lymph, which, quite freely, soon assumes a pulpy consistence and a greenish color. Sometimes it becomes filamentous. The articular cartilage, if seriously involved, is of a dull whitish, or slightly grayish aspect, and is partially separated from its osseous connections. The surface of the bones is abnormally vascular, light, porous, and easily broken and cut. Not infrequently its cells are filled with a tubercular matter, of a semi-solid, caseous consistence. It presents itself in the form of distinct masses, free or adherent, larger than a millet-seed. The ligaments usually are red, tumefied, and softened. The synovial fluid is increased in quantity, but rarely to any considerable extent.

As the malady advances, the alterations above

Fig. 484.

Section of a strumous ulcer of a cartilage, magnified 500 diameters.

Section exhibiting dark granules in the lamellae.

tinctly defined; the disorganizing process being now in full play, its devastating effects are plainly visible in every portion of the joint. The lymph gradually increases in quantity, and is often intermixed with a little sero-purulent matter, or thick greenish-looking pus. The synovial membrane is partially destroyed, and what remains is of an opaque, muddy, and ragged appearance. The cartilage is ulcerated, pulpified, discolored, perforated, and almost completely detached. The bony structure is very red, soft, carious, rough, and easily crumbled. The ligaments exhibit well-marked signs of inflammation, being loose and spongy at one point, attenuated at another, and perhaps thickened or hypertrophied at a third.

The microscopical appearances of ulcerated cartilage and carious bone, the result of changes wrought during the progress of strumous disease of the joints, are well shown in figs. 484 and 485, from Barwell.

The disease having reached its acme, the structures of the joint are completely subverted, with hardly any trace of their original appearances. Pus is now usually seen, often, indeed, in large quantity, with all the qualities of strumous matter. This, however, is not always the case; for, at times, it is thick and pultaceous, caseous, ichorous, or sero-sanguinolent. In some instances it is very thin, and almost black, evidently from the effects of the necrosed condition of the bones.

If death takes place after a process of recovery has been set up, the joint will be found to be filled by a white, fibrous, organized substance, the extremities of the bones being ankylosed, or firmly attached by new matter to the surrounding structures. It is very rare for a new socket to be formed, and yet this is not impossible. In time, the artificial joint may admit of considerable motion, but, in general, this is extremely restricted. Occasionally an imperfect ligament is formed round the bony remnants, and the surface of these bony remnants may even become slightly tipped with cartilage. Finally, osseous growths—short, irregular, and friable—sometimes make their appearance upon the bones, in the vicinity of the former disease.

The bodies of those who die of strumous disease of the joints usually exhibit serious pathological changes in some of the internal organs. These changes are the direct result of the tubercular cachexy, which is generally so well marked in the latter stages of the local malady, and they exist in various forms and degrees in different structures. The most common are tubercular deposits and dropsical effusions, which are rarely entirely absent in any case, especially if of long standing.

Tubercles of the lungs are very common; they often exist in great numbers, especially in the summits of these organs, and they always exhibit the same characters as in ordinary phthisis. Cavities sometimes form, but death usually occurs before they attain any considerable magnitude. The bronchial ganglions generally participate in the pulmonary disease, being enlarged and tuberculized. Occasionally extensive adhesions are found between the lung and costal pleura, with or without serous and other effusions. The heart is seldom affected.

The peritoneum is sometimes extensively tuberculized, and considerable quantities of water are often found in its cavity. In children, the lymphatic ganglions of the pelvis and mesentery are liable to suffer from strumous deposits, and similar changes are occasionally witnessed in the spleen. The liver is often cirrhotic and hypertrophied. Now and then the glands of Peyer suffer. The pancreas, stomach, and genito-urinary organs are usually sound. The blood is very thin, and deficient in fibrin and coloring matter. The lower extremities, and even the hands, face, and genital organs are, at times, anasarctous, especially when the system has been worn out by tubercular disease of different parts of the body.

Tuberculosis of a joint, as the name correctly implies, is essentially a scrofulous disease; but, like phthisis, it is a mere local expression of a constitutional vice. Take away this vice, this strumous dyscrasia, and in either case no local disorder can arise.

The existence of tubercular disease in an organ does not necessarily imply in

that organ the existence of tubercular deposits. For example, there is nothing of the kind, and yet no one of the character of that malady, would deny it such a parent. In the skin there is undoubtedly scrofulous action, determined, any secretion of tubercular matter. When the synovial membrane of the joints it probably deposits as when it invades the tunics of the eye; and occurs when it takes its rise in the cartilaginous tissue it commences in the osseous structures, there is often a kind, similar to that which is so frequently met with in the spine and foot, and also in the articular extremities, independently of articular implication.

Symptomatology.—In regard to the symptoms of the disease, for the sake of more definite description, be divided into three stages.

In the first stage, the patient's suffering is generally referred to the effects of cold, rheumatism, or some slight complaint consists in some trivial pain, either fixed or steady, but wandering and intermittent, and sometimes exacerbations. If swelling is present, it is also very insignificant, somewhat stiff, and the patient is easily fatigued by exertion, but is unimpaired, or only slightly implicated.

By degrees these symptoms assume a more threatening character, the disease has now attained its second stage, as is indicated in the affected structures. The pain is now more severe and deep-seated, and commonly requires active means to be resorted to. The patient is annoyed with spasmodic twitches, especially at night, and the joint becomes sensibly wasted and flabby. The joint is swollen, attended with marked deformity and fluctuation, the presence of an undue quantity of synovial fluid, or effusion. The parts feel abnormally hot, and there is commonly a redness of the skin, which induced the older authors to call it "white swelling." There is also, in this stage, usual enlargement of the subcutaneous veins. The constitutional symptoms are in keeping with the local affection. The appetite and sleep are irregular, and there are occasional paroxysms of fever, with general discomfort.

In the third stage of the disease, the symptoms, both local and constitutional, are strongly denotive of the horrible ravages of the morbid process. The surrounding structures are swollen and enlarged to a considerable extent, colored, immovable, exquisitely tender and painful, distended with synovial fluid, and freely fluctuating under pressure. A suppuration of the articulating surfaces generally exists, adding to the deformity. The pent-up matter, gradually approaches the surface, and is spontaneously evacuated, much to the relief of the patient. The resulting sinuses, always slow in healing, often continue to discharge, and there is much diseased or dead bone.

The constitutional symptoms which accompany this stage are of a severe character. The patient, at least for a time, has regular fever, the face is flushed, the pulse is excited, the sleep is disturbed, during the night, is drenched with copious sweats. The strength declines, and the bowels are harassed. Thus life may be gradually worn out by exhaustion, or a reaction may take place, followed, sometimes even in the end, by ultimate recovery.

Suppuration, however, does not always take place. Sometimes, if it does, there is either very little matter, or it is absorbed, as not to produce any characteristic symptoms. Occasionally even when the greatest ravages have been done, the patient recovers.

Sometimes the pus is situated altogether externally.

other cases, again, also infrequent, it is formed both externally and internally. However this may be, the structures over and around the affected joint always participate in the morbid action, becoming hard, condensed, and enlarged from interstitial deposits.

The matter in scrofulous disease of the joints is generally more fluid than ordinary pus, and also of a more greenish tinge. In fact, it very closely resembles the contents of a cold abscess, or the pus of a pulmonary cavern. It is often intermixed with small whitish particles, not unlike grains of soft boiled rice, with flakes of lymph, or even with small clots of blood, especially when the antecedent inflammation has been unusually severe, or the parts have been roughly handled. Now and then it contains the debris of articular cartilage, ligamentous tissue, or osseous matter. The pus, when long confined, is sometimes very fetid. In general, however, it is entirely free from odor. Received into a vessel, and permitted to stand for a while, it generally separates into two parts, one at the bottom, solid and granular; the other at the top, fluid, and of a pale whey-like or oleaginous aspect. When an abscess of this kind has once fully emptied itself, the subsequent discharge is often of a gleet character, ichorous, or thin and bloody.

The quantity of matter may be very small, or so abundant as gradually but surely to exhaust the system. At times the suppuration is almost entirely suspended, perhaps, indeed, for several months, when, either suddenly or gradually, it reappears, and becomes as profuse as before. Once established, it has no special limit as to its duration, but may last, with hardly any interruption, for years. Whenever the discharge is unusually protracted, it may be assumed that there is serious and obstinate caries of the bony structure of the joint, especially if it is attended with the occasional escape of gritty substance.

Prognosis.—Tuberculosis of the joints is essentially a chronic disease, which, after having persisted for an indefinite period, terminates either in recovery or in death. The recovery may be complete, both as it regards the part and system, or, the local action disappearing, the joint may be left weak and ankylosed, and the general health regain its original vigor; or, as not infrequently happens, particularly after the process of disorganization has commenced, both the articulation and the constitution may remain for a long time, if not permanently, in a degraded and crippled condition.

Many circumstances, mostly of an individual nature, conspire to influence the prognosis in this disease. So much, in truth, is this the case, that it is impossible to lay down any definite rules for the guidance of the practitioner. Much will, doubtless, depend, in every instance, upon the state of the constitution, the presence or absence of complications, and, above all, the duration of the malady. Age also exercises an important influence. It is well known that, other things being equal, children will live longer, and also stand a much better chance of recovery, than young adults and middle-aged subjects, in whom, especially the latter, the disease often proceeds with extraordinary rapidity, sometimes ending fatally in a few months. When the constitution is naturally feeble, or when it has been rendered so by the intensity of the local suffering, the probability of an unfavorable termination will be much increased. Imperfect alimentation, however induced, is another source of mischief, both as it respects the part and system. Intercurrent maladies, such as typhoid, intermittent, and eruptive fevers, diarrhoea, dysentery, and erysipelas, often retard recovery, or hasten the fatal crisis. These and other diseases, by establishing a drain upon the system, already exhausted by the local suffering, are the principal causes of the mortality in strumous affections of the joints. When the disorder proves fatal without such intervention, it will generally be found that death is directly due to the depressing effects of tuberculosis of the lungs, lymphatic ganglions, spleen, or peritoneum, which is so liable to show itself under such circumstances.

Much of the mortality of this disease, as well as most of the bad effects, both temporary and permanent, which it entails upon the affected articulation, results from neglect of appropriate management, prior to the commencement of the disorganizing process. Properly treated at its beginning, it is, generally, as

remediable as any ordinary chronic inflammation, although not, perhaps, so promptly. The morbid action receding, the effused materials are gradually absorbed, and the parts restored to their normal functions. Arrived at its second stage, hardly any course of medication, however judiciously applied, will completely avert permanent rigidity, although life may not be at all in jeopardy. The morbid impression has already advanced too far to admit of easy recession; a certain amount of structural lesion is present, and the patient will be fortunate if he ever completely regains the use of his joint. In the third stage, when the osseous, cartilaginous, and other textures are disintegrated and broken down; when, perhaps, the interior of the joint is converted into a large chronic abscess; when the limb is stiffened or immovable, and, finally, when the constitution is worn out by pain and hectic irritation, there will not only inevitably be loss of function, but also great danger of loss of life. If, under such circumstances, the patient survive, his recovery will be effected at the expense of much suffering, too often eventuating in premature decay and dissolution.

Treatment.—In the treatment of this affection, it must be remembered that, as it is generally, if not invariably, merely a local manifestation of a constitutional vice, topical remedies alone will not avail; to prove efficient and truly useful they must be combined with, and aided by, means addressed to the general system, with a view to the improvement both of the solids and fluids. It would be idle, in the present state of the science, to insist upon a course so palpably proper in itself and so long sanctioned by experience. We might as well expect to be able to cure consumption, or to ameliorate the condition of a person thus affected, by the exclusive employment of counter-irritation and other external measures, as to cure tuberculosis of the joints without the aid of constitutional remedies. Again, in treating this disease it should not be forgotten that it consists of different stages, which, although they run imperceptibly into each other, are, nevertheless, of vast importance in a practical point of view.

Whatever may have been the duration of the malady when the treatment is commenced, the first and most essential element in its management is repose not merely of the joint, but also of the body, repose absolute, unconditional, and persistent. Upon this subject there must be no compromise between the patient and his attendant. The contract entered into at their first interview must be observed with the most scrupulous fidelity; it must be both binding and permanent. The slightest departure from this injunction would at any period of the complaint be of great detriment to the patient's limb, while in its more advanced stages, when the bones and cartilages are destroyed and matter exists in the joint, it might seriously jeopard his life. When the disease is seated in the inferior extremity, recumbency must be observed, not for days or weeks, but months. Too much stress cannot be placed upon this point, when it is remembered how important it is to keep parts, comparatively insignificant, perfectly at rest when in a state of suffering. In inflammation of the fingers and toes repose and elevation of the affected structures are instinctively sought, and, if possible, maintained until the morbid action has been in great degree subdued and function restored. Now, if this be necessary in ordinary inflammation and in textures which have no important uses and sympathies, how much more necessary is it when the malady is of a specific nature and the organ involved is so important as that of a large joint? These facts are well known to practitioners, but the common people are ignorant of them, and they should therefore always be thoroughly explained to the patient and his friends at the very threshold of the treatment.

The *local remedies* must be regulated by the progress of the malady and the constitution of the patient. If the disease is in its first stage, if the pain is violent and frequent in its recurrence, and if the general health remains unimpaired, we can scarcely fail to derive special benefit from the application of leeches, or, in their absence, from the use of a large blister. The leeches should be scattered over the affected joint, and, after they drop off, the flow of blood should be encouraged for some time with cloths wrung out of warm water. Their number must depend upon circumstances, but, in general, from six to eight will be

sufficient for a child from three to six years of age. Sometimes a blister may be applied advantageously within a few days after the leeching, and I much prefer this mode of counter-irritation to the employment of liniments, embrocations, croton oil, tartar emetic ointment, and iodized lotions, which is always attended with friction, and for that reason is often prejudicial to the inflamed structures. By these means, aided by a plain, simple diet, consisting mainly of farinaceous articles, with milk, weak tea, or milk and water, at breakfast and supper, and an occasional purgative of blue mass and jalap, almost any case may be radically cured in a few months. If fever is present, or if decided plethora exists, as denoted by the state of the pulse, face, and skin, the antimonial and saline mixture may be given. To relieve pain and secure sleep, opiates must be used with warm anodyne poultices or fomentations, or, what I have found to be of greater benefit, a lotion composed of soap liniment, laudanum, and tincture of aconite, applied by means of a fold of flannel, kept constantly wet, and covered with oiled silk. Cold applications are generally inadmissible both in this and in the other stages of the disease. When the skin is unusually dry, or the system more than commonly irritable, the warm bath, carefully administered for half an hour at a time, with a Dover's powder at night, is sometimes highly beneficial, but great care must be used in its administration lest the affected joint sustain injury.

As permanent *anchylosis* cannot always be avoided, great care should be taken to place the affected joint in the best position for future usefulness. Thus, in tuberculosis of the wrist the hand should be extended, while in disease of the elbow the forearm should be flexed at a right angle with the arm. When the shoulder is involved, the elbow should be confined to the antero-lateral part of the chest, a tolerably thick pad being fastened in the axilla. In hip-joint disease the thigh is inclined a little forwards, and somewhat separated from its fellow; the leg is slightly flexed when the knee is affected, and the foot is bent at a right angle with the leg in tuberculosis of the ankle.

Such is an outline of the treatment which will usually be found to be most serviceable in the earlier stages of the complaint. There is, however, not a little diversity in regard to the nature of the internal remedies required in different cases. As already stated, there are two distinct classes of patients, the plethoric and the anemic, those with an apparently rich blood and those with an impoverished blood; and therefore two very opposite courses of treatment are frequently necessary, the former demanding perhaps a certain amount of depletion, while the latter will be most benefited by tonics. I have not met with any cases where I thought the use of the lancet was indicated, and yet I am not prepared to say whether, when the inflammation and pain are very great, in a strong, robust child, soon after the commencement of the malady, venesection, to a small extent, might not be highly beneficial, as tending to prevent suppuration, and to save structure; in general, however, the remedy would be too harsh, and I am satisfied that the morbid action may be sufficiently repressed by the antimonial and saline mixture, in union with a minute quantity of tincture of *veratrum viride*, assisted, perhaps, by the application of a few leeches to the seat of the disease. In the anemic, a not uncommon class of cases, tonics and stimulants are often required at the very commencement of the disease, consisting either of quinine and iron, or, what is peculiarly valuable, cod-liver oil, in such doses as shall not prove offensive to the stomach. The diet should of course be of a corresponding character, and the patient should, if possible, be induced to use milk punch, wine, ale, or porter, in order to rebuild the system, and thus enable the affected parts the more effectually to resist the encroachments of the morbid action.

As a general rule, I am not an advocate for confining the affected limb in *splints*, in the incipient stage of the disorder, with a view of securing more perfect rest of the joint. The patient himself will usually instinctively take care of this. It is only, or chiefly, when the limb is much out of shape, or in a position in which, if permanently retained, its usefulness might be seriously impaired, that such a proceeding is either necessary or desirable. The restraint occasioned by all such contrivances is generally exceedingly irksome, if not positively hurt-

ful. When the malposition of the extremity is considerable, the first thing to be done, provided there is as yet no great structural lesion, is to rectify this by extension and counter-extension, aided, if necessary, by rotation and abduction, the patient being under the influence of chloroform, and then to apply a suitable apparatus for maintaining the limb in its new relations. The best material is gutta-percha, undressed sole-leather, or trunk-maker's board, soaked in hot water, carefully adapted to the parts, and kept in place by a common roller. When dry, these articles form an admirable case, which may afterwards be padded with cotton to ward off pressure, and which will thus effectually prevent motion of the affected joint.

The attempts at rectifying the malposition of the limb are occasionally annoyingly counteracted by the contraction of the muscles. When this is the case, the most expeditious plan is to divide them subcutaneously; the effect of such an operation upon the future welfare of the part and system is often most striking, the pain and spasm being relieved as if by magic, and the limb becoming perfectly docile and manageable.

In the *second stage* of the affection, the most reliable local remedy is a large *issue*, to secure a free and permanent discharge of matter. If the case has not been seen before it has reached this crisis, some of the means already mentioned, as leeching and blistering, may be tried; but, unless they are promptly beneficial, no time should be wasted in their employment. The disease is now thoroughly aroused, and must therefore be met in the most decisive manner, to prevent its disorganizing and destructive effects. The best place, by far, for the issue is the most prominent part of the swelling, which is usually either directly over the joint or in its immediate vicinity. The nearer, in fact, the discharge is established to the diseased structures, the more likely will it be to be useful. The place of election, then, is a circumstance of great importance, and should not be overlooked.

The most eligible form of issue is that made with the actual cautery. The patient being thoroughly anæsthetized, the iron, heated white, is gently pressed upon the part until a suitable eschar has been formed; one about the size of a twenty-five cent piece, if the patient is very young, or twice that size, if he is twelve or fifteen years old, being a good average. The slough, which should not extend beyond the subcutaneous cellular tissue, will generally drop off within the week; and, during this period, as well as afterwards, the parts should be kept constantly covered with a linseed poultice, renewed several times in the twenty-four hours. The discharge, if flagging, may be promoted by savine ointment, by simple cerate containing a few drops of nitric acid to the ounce, or, what I prefer, the occasional application, for a few hours, of a small blister. In this manner I have repeatedly maintained an abundant pyogenic discharge for the greater part of a year. The cautery may, if necessary, be reapplied at any time during the progress of the treatment.

The hot iron deserves a decided preference, for making an issue in this disease, over all other modes of cauterization, as affording not only a more copious and persistent flow of pus, but, what is of no little importance, making a much stronger, as well as a more permanent, impression upon the part and system. Although it is impossible always to determine how long the suppurative action should be kept up, it will be found to be a good rule to let it continue until there is reason to believe that the morbid process, for the relief of which it was instituted, has completely subsided. I have never, in any instance, experienced any bad effects from its protracted continuance; indeed, quite the contrary has been the case. If the discharge becomes offensive, as it often does in warm weather, or when proper attention to cleanliness is not observed, the chlorides will come in play, with a more frequent change of dressings. Occasionally the linseed poultice oppresses by its weight, or it causes painful and itchy eruptions around the sore; when this happens it must be temporarily suspended, or be replaced by some more suitable application.

Besides these advantages, the raw surface left by this kind of issue affords an excellent opportunity for the local application of morphia, for combating the

excessive pain and spasmodic twitchings of the muscles, so common in this complaint, and which are much more promptly subdued in this way than when this medicine is administered by the mouth. The quantity necessary to produce the desired effect will, of course, depend upon circumstances; but, in general, from half a grain to a grain will be required for a child three or four years old. Sometimes an injection of laudanum, or an opiate suppository, will allay the pain and quiet the system more effectually than anything else.

In regard to the patient's *diet*, in this stage of the disease, the same rules should govern as in the preceding stage; it should, however, if possible, be somewhat more restricted, especially if there is much pain, with occasional fever.

The *bowels* should also be maintained in an active condition, the best general purgative being a few grains of blue mass, with a suitable quantity of jalap, or the compound calomel pill. Salines and nauseants will rarely be required. If the patient labors under symptoms of debility, as denoted by the pallor of the countenance, the coldness of the extremities, and the disorder of the digestive organs, tonics, especially quinine and iron, should be employed, along with a more generous diet and nutritious drinks.

In the *third stage*, characterized by serious structural lesion, and the formation of matter, the treatment will require to be essentially modified, to meet the local and constitutional contingencies. Prior to this period, it was, if not decidedly antiphlogistic, at all events rather of a depressing character, intended to subjugate inflammation and establish resolution; now that the morbid action has gained the ascendancy, and exhausted both the part and system, a widely different course is demanded.

Two most important indications are presented, in almost every instance, at this stage of the complaint. The first is to limit the suppurative process; the second, to promote the speedy absorption of the effused fluid. To fulfil either is generally no easy task; for experience has proved that there are few cases in which our efforts, however skilfully conducted, are crowned with success. When the suppurative process declares itself by well-marked symptoms, as rigors, alternating with flushes of heat, and followed by copious sweats, something may be done to moderate its violence by the steady and energetic use of antiphlogistics; but, in general, it will be found that the patient is either too feeble to justify their employment, or that the disease has been so insidious in its approaches as to defy recognition before the mischief has been completed. It has been seen, however, that matter does not always attend this stage, and that, when it does, it often exists only in small quantity. Now it is in the latter class of cases, more particularly, and in those where the suppurative process can be carefully watched from its very inception, that strenuous and persistent efforts should be made to prevent its accumulation, with its concomitant mischief. For this purpose the affected joint should be painted at least twice a day with some sorbefacient lotion, such as equal parts of tincture of iodine and alcohol, or a weak solution of iodine and iodide of potassium, care being taken that, while applying it efficiently, it is not put on so freely as to cause pain or irritation. The object should be merely to excite the absorbents, the capillaries being fully kept in abeyance; otherwise injury, not benefit, will be likely to result. Sometimes a large blister answers a good purpose; retained just sufficiently long to produce slight vesication, and repeated every six or eight days for several successive weeks. Thorough or protracted vesication is to be avoided, as likely to prove detrimental, from its irritating effects, both upon the part and system. If the disease has not yet advanced too far, if the abscess is still small, and, above all, if the suppurative process is attended with great pain and constitutional disturbance, there is no remedy so well calculated to fulfil the present indication as the actual canter, applied in such a manner as to produce a broad but superficial eschar. Experience has taught me that, even in this stage of the malady, when everything is apparently most unpromising, more benefit will generally accrue from this mode of counter-irritation than from any other. It not only promotes the absorption of the pus that is already effused, but materially curtails the suppurative process, at the same time that it greatly ameliorates the local distress. If the

accumulation is very large, the remedy must, of artificial evacuation encouraged.

General treatment is not neglected. The most mercury, especially the iodide and bichloride, for solution. Ptyalism is carefully avoided, and the a generous diet, and nutritious drinks.

If these means fail, or if the *abscess* is already to the case, the matter should be evacuated artificially. On this subject, there is generally a great deal of repugnance on the supposition that any interference of this kind is the local disease, and cause hectic irritation. As no just reason why the general rules of surgery apply to a disease any more than in others. It is well known that a large quantity, invariably does harm; for, not only does it exert upon the surrounding parts, but it exerts upon the inflamed surfaces with which it comes in contact, and effectually prevent the restorative process in regard to copious purulent collections general as to require no argument in its support, and the objections respecting such accumulations in the joints. Physicians, influenced by the dogmas of the schools, and the experience and the dictates of common sense, have not been so much in the habit of treating the abscess of the articulations, as a local disease, but as a general one, and the result has been, in the production of much mischief. In the treatment of this disease, they have too frequently allowed them to run their course, and neglected to make any open incision, attempting to steer clear of Scylla, they have run into Charybdis. The proper plan, undoubtedly, is, in all cases where the disease is not a probable event, to promote its escape by an incision, which I have invariably pursued in all joint diseases, and in no instance have I had any reason to regret that a vast suffering is avoided, as well as much stricture, abundantly shown by the numerous and tortuous sinuuses in the hip when the disease is left to pursue its course. An opening, however, is not to be made heedlessly, or without the permanent exclusion of the air, which, although it is a pernicious, from its tendency, when brought in contact with the matter, to favor decomposition, and, consequently, the disease. These effects may generally be prevented by giving issue to the matter as in evacuating chronic abscesses in other situations, rather than an incision, and by closing the orifice of the abscess, with adhesive strips, supported by a light compress. A quantity of matter is unusually large, a portion of which is evacuated in the time, the process being repeated in a few days, until the matter is ordinarily the sac may be emptied advantageously.

As soon as the fluid has been evacuated, whether opiate should be administered, in order to prevent joint becomes painful, warm anodyne fomentation afforded. Afterwards, with a view of moderate painted regularly once a day with some sorbefacient the warm water-dressing being used as the permu

Sometimes this mode of opening an articular violent hectic, perhaps imperilling both limb and parts should be laid freely open, as in an ordinary soft parts.

If *sinusæ* form, whether as a result of spontaneity, the best plan is not to interfere with them, as the result is more frequent upon the employment of the knife would

good effects from the operation. If loose fragments of bone, or pieces of cartilage, present themselves, they should, of course, be promptly extracted.

The violence of the suppurative action having been subdued, the plastic deposits are best dealt with by sorbefacient plasters, applied so as to embrace the whole of the affected surface, and steadily worn for many weeks. Of these plasters, the most useful, for this purpose, is the ammoniac and mercurial, under the influence of which the induration and swelling often disappear with astonishing rapidity. If much pain is present, a suitable quantity of morphia, opium, or cicuta may be incorporated with its ingredients.

During the latter part of this stage *tonics* and stimulants are usually indicated, and often imperatively demanded, by the exhausted state of the system. The patient, emaciated and anemic, must be supported with quinine and iron, cod-liver oil, a generous diet, and nutritious drinks, as milk punch, wine-whey, ale, or porter. If night-sweats be present, the most suitable remedy will be aromatic sulphuric acid, either alone or in union with Huxham's tincture of bark. Diarrhœa and pain must be checked with opiates. The patient's apartment should be frequently ventilated, and the surface of the body should be daily washed with tepid salt-water, followed by dry frictions. Exercise in the open air is now generally of paramount importance, and must on no account be neglected.

In the event of a cure, whether spontaneous or artificial, the surgeon must be careful, when the proper time arrives, to institute *passive motion* with a view of preventing permanent ankylosis. The principles upon which it should be conducted are the same as in dislocations and fractures of the joints. Much judgment, however, is necessary, otherwise the operation may readily re-provoke disease. The best plan is to repeat it, at first, only about every fourth day, until the parts have become somewhat accustomed to it, when it may be employed more frequently. As the proceeding is always very painful, especially for some time, it is highly important that the patient should be well anæsthetized. Indeed, without this precaution, it will be quite impossible to overcome the action of the rigid and contracted muscles, or to break up the morbid adhesions in and around the joint.

When the extremity of the bones is necrosed, or so completely carious as to forbid all hope of recovery by time and ordinary means, the soft parts being riddled with sinuses and the discharge copious and exhausting, excision of the diseased parts will be demanded, and should, if life is not too far exhausted, be promptly executed, as most likely to rescue the patient from impending death. The object of the undertaking, of course, is to remove all the ulcerated structures, and the surgeon should, therefore, endeavor to execute his task in the most thorough and effectual manner. The disease being thus arrested, the part and system will be placed in a much better condition for gradual and permanent recovery, provided the shock of the operation is not so severe as to destroy life, either immediately or consecutively. With proper care after the excision, it may even be possible to preserve a certain degree of motion between the contiguous bones.

Excision is more particularly applicable to strumous disease of the hip and shoulder joints. Good cures, however, occasionally result when the operation is performed upon some of the other joints, though I believe that amputation is always preferable when there is extensive organic lesion, and life is rapidly ebbing away from protracted suffering.

2. TUBERCULOSIS OF PARTICULAR JOINTS.

1. TEMPORO-MAXILLARY JOINT.

It is not often that this articulation is invaded by this disease, and then almost exclusively in young persons of broken down constitution, from the effects of cold, mercury, or irritation of the teeth. It is distinguished by a puffy swelling in front of the ear, or in the temporo-maxillary region, by tension and discoloration

of the skin, and by a dull, heavy pain in the joint, increased by pressure and motion of the jaw. During the progress of the disease, the auditory canal becomes greatly diminished, if not entirely closed, and the seat of a very fetid, purulent discharge, attended with loss of hearing, especially when there is much involvement of the temporal bone. Finally, abscesses and fistulous openings form, exposing this bone and the condyle of the jaw in a carious or necrosed condition.

In the *treatment* of this affection special care must be taken to guard against ankylosis, otherwise, when recovery occurs, the functions of the joint may be permanently lost. Dead bone must be extracted as soon as it is sufficiently detached, and the condyle of the jaw may, if necessary, be resected. When there is much involvement of the temporal bone, the patient may die from an extension of the disease to the brain.

2. CLAVICULAR JOINTS.

The joints formed by the junction of the clavicle with the sternum and the scapula are occasionally involved in tuberculosis, but the disease is very uncommon. It is met with chiefly in young subjects, and is characterized by the usual phenomena.

When it attacks the *sterno-clavicular* articulation, the most prominent signs are a soft, puffy, and elastic swelling at the seat of the disease and a fixed pain at the same point, aggravated by pressure and motion of the scapula, and also somewhat by forced inspiration and expiration. The head of the collar bone often presents the appearance of being enlarged. In time an abscess forms, and, if its evacuation is neglected, the matter may descend into the anterior mediastinum and thus occasion fatal consequences. Luxation of the clavicle can occur only when there is complete destruction of the connecting ligaments, permitting the end of the bone to project upwards or backwards: in the latter case it may compress the trachea and œsophagus.

Tuberculosis of the *scapulo-clavicular* joint is very uncommon, and is characterized by the same symptoms as the preceding disease. Care should be taken not to confound these affections with rheumatism, to which both these joints are liable.

The treatment requires nothing peculiar. Resection of the clavicle may be performed if this bone is extensively necrosed, or otherwise diseased, or if it injuriously compresses the trachea and œsophagus.

3. OCCIPITO-ATLOID AND ATLO-AXOID JOINTS.

Tuberculosis of these articulations, first accurately described by Schupke in 1816, and since then specially investigated by Bérard, Teissier, and Schœnfeld, is met with chiefly in children and young adults, either without any assignable cause, or as a consequence of cold or injury. Although it is essentially similar to Pott's disease, it requires separate notice on account of the peculiarity of some of its effects.

The disease, whether beginning in the synovial, cartilaginous, or osseous tissue, often commits the most frightful ravages, destroying sometimes the greater part of the arch of the atlas, the whole of the odontoid process, and perhaps even the margins of the occipital bone. What is remarkable, the anterior portions of these structures generally suffer much more than the posterior.

In consequence of the destruction of these ligaments, the occipital bone may be dislocated forward, backward, or laterally, displacement by rotation being extremely rare. In whatever direction the accident may occur, the encroachment of the parts upon the spinal canal is seldom sufficient to cause any serious compression of the cord. The atlas is more frequently luxated than the occipital bone, being thrown either forward or to one side. Occasionally the displacement is by rotation. Dislocation backward is impossible on account of the obstacle offered by the odontoid process. In the more severe forms of the disease the displacement is sometimes of a mixed character.

The spinal cord is variously altered, according to the nature and extent of the osseous involvement. In some cases it retains its normal structure, while in others it is softened and broken down. The dura mater is generally thickened, engorged, fungous, ulcerated, or even perforated, and the arachnoid membrane inflamed and incrustated with lymph.

The *symptoms* of this disease are as follows: At its commencement there is a dull, aching pain, circumscribed, deep-seated, and much increased by motion and pressure. A sense of weight and fatigue is experienced in the upper part of the neck, and the patient at length finds it difficult, if not impossible, to support his head in walking. Gradually other symptoms supervene, the most distressing of which are pain and difficulty in deglutition, dependent upon inflammation of the pharynx. The neck now becomes deformed, owing to the joint agency of the displacements above alluded to, and to interstitial deposits. The posterior muscles are remarkably firm and rigid, and the head is immovably fixed, not infrequently in a very vicious position, being either bent forward toward the sternum, drawn backward, or inclined to one side. When the disease is fully developed, the pain, all along sufficiently distressing, is greatly increased in severity, and radiates about in different directions, especially up into the head and down the neck into the shoulders. If abscesses form, the patient, in addition to the dysphagia, will experience difficulty in speaking, expectorating, and breathing, in consequence of the obstruction of the fauces from the accumulating fluid, and from the same cause the tongue is sometimes partially protruded from the mouth. The matter is discharged either into the mouth or at the back of the neck; often by several apertures. Occasionally large pieces of bone come away with the pus.

When the spinal cord and its membranes are seriously involved, there will be, in addition to the symptoms here enumerated, great embarrassment of respiration, lividity of the face, and paralysis, first, of the superior, and afterwards of the inferior, extremities; together, in short, with all the phenomena of a gradual but surely fatal asphyxia. In some cases the patient perishes suddenly from an accidental twist of the neck crushing the spinal cord.

The deformity of the neck consequent upon this disease is deserving of special notice in a diagnostic point of view. The affected part is much broader than usual, and also more protuberant or irregular. When the occipital bone is thrown forward upon the atlas, the depression which naturally exists at the upper part of the neck, between the attachments of the two trapezial and the two splenial muscles, is effaced, and the finger easily recognizes the posterior arch of the atlas. If, on the contrary, the bone is forced backward, the hollow in question will be found to be increased, and the spinous process of the axis less distinguishable.

The displacements of the atlas are generally easy of recognition. Teissier, who has studied the subject with much care, states that when this bone is dislocated forward, the spinous process of the axis forms a prominence more marked and nearer to the occipital protuberance than in the natural state, at the same time that the swelling is abruptly interrupted at its upper part, where it is surmounted by an excavation. When the displacement is lateral, the spinous process of the axis will be found to be more in the direction of a vertical line, extending from the external occipital protuberance. Finally, adds this author, it may also happen that one of the articular processes of the axis may form a projection in the neck, either on the right or left side of the middle line.

It is important to remember that tuberculosis of these joints may be simulated by the effects of rheumatism and of external injury, causing pain and stiffness of the neck, with partial, if not complete, immobility of the head. When the disease is far advanced, the diagnosis is unmistakable.

When recovery takes place, the neck generally remains deformed and protuberant, with great impairment of its functions, the affected bones being completely soldered together by new osseous matter.

In the *treatment* of this affection, in addition to the employment of the usual remedies, the greatest attention must be paid to rest, and to the support of the part by means of suitable apparatus. The head should lie on a level with the

trunk, with a thin, elastic pillow under the neck, especially in the more advanced stages of the complaint, moved in any direction, lest, the ligaments having become displaced, and thus instantly and fatally recumbency must be steady and protracted. A blistered, at an early period, with the actual cautery joints, and a free discharge of matter invited. As promptly opened, in particular if they point towards they may suffocate the patient by their pressure upon, or, bursting unexpectedly, the matter may pass into fatal asphyxia. If an attempt at reposition of the deemed advisable, the operation must be performed with care and gentleness. Should recovery take place, supported for a long time by machinery, so as to afford opportunity for safe and perfect consolidation.

4. SACRO-ILIAC JOINT.

This joint is liable to a strumous affection, analogous to the white swelling of the knee, which was first accurately described by Erichsen, especially the latter. Its great rarity, founded with coxalgia and other lesions, are notwithstanding, hitherto attracted so little notice.

The disease, which is essentially very chronic, is usually of the ages of twelve and thirty. Young children seem to be free from attacks. Its causes are the same as those of sciatica. In the great majority of cases the lesion comes on without any but an instance now and then occurs in which it is caused by a blow, kick, fall, or sprain, to the effects of cutaneous perspiration. Injury done to the pelvic region, and parturition probably predisposes to its development, there is a strong strumous diathesis. Certain occupations, favor its development. Thus, Hahn has narrated several cases in tailors.

The *pathology* of the affection is not well understood. It is generally limited to the synovial and cartilaginous structures, these structures becoming eroded, and the articular surface softened, pulsatile substance, presenting a condition analogous to the so-called pulpy degeneration of strumous the knee. As the morbid action progresses, the osseous structures are evidenced by their rough and denuded appearance, and by their infiltrated, spongy, and disintegrated condition. They are, however, seldom met with, even in very chronic cases, also retain for a long time their integrity.

The most important *symptoms* are pain, swelling, and tenderness of the pelvis and limb. To these are superadded, in time, emaciation and sinuses, and the occurrence of hectic fever.

Pain is an early symptom; it is seated in the pelvic region, is increased by pressure and motion, and is accompanied by weakness in the lower part of the back and sacrum. The patient would drop apart, and finds it extremely difficult to stand, very much as in sciatica, or rheumatism, for which, it is often mistaken. As the disease advances, the pain becomes more constant and assumes a dull aching or gnawing character. In some instances, extend down the limb, nor is it aggravated by the surgeon neglects to steady the pelvis, when the gluteal region is somewhat flattened, and tender. As the finger approaches the seat of the disease.

The swelling, originally very slight, gradually increases in extent, and, in time, becomes a prominent feature. It is puffy, elongated from above downwards, and situated in the line of the affected joint; not materially involving the gluteal region, nor invading the natural hollow behind the great trochanter. When abscesses occur the form and size of the swelling are greatly changed.

Lameness is an early and prominent symptom. The patient, at first, merely limps, and is soon fatigued by exercise. In a very short time, however, his movements become much constrained, and he supports himself with great difficulty, leans forward, and employs a cane or crutch. He can put his foot on the ground, but is unable to bear his weight upon it, nor can he twist himself suddenly round without great suffering. At length his locomotive powers are completely crippled, and he is obliged to keep his bed.

The limb on the corresponding side is, from the very first, longer than the other, the increase in length varying from six lines to an inch or even an inch and a half, according to the duration and violence of the morbid action. The change, however, is not real, but, as in coxalgia, merely feigned, depending upon the alteration in the position of the pelvis, which is not only considerably depressed, or lower than on the sound side, but also tilted forward and rotated downward so as to impart an unusual degree of prominence to the anterior superior spinous process of the ilium. The limb itself is attenuated, flabby, and enfeebled. In progression, it is generally somewhat abducted, flexed at the knee, and projected a little forward, the weight of the body being thrown entirely upon the sound side. Upon taking hold of the limb it can be moved in any direction.

By and by, after months of suffering—sometimes, indeed, not until after a year or a year and a half—matter begins to form, preceded by an increase of local and constitutional disturbance, ultimately eventuating in severe hectic irritation. The swelling over the joint gradually increases in size, and the fluid, which is always of a scrofulous character, slowly burrows among the neighboring parts, spreading underneath the gluteal muscles, in the direction of the great trochanter, extending into the loin, or passing into the pelvis, by the side of the rectum or the rectum and vagina, in the former of which it occasionally finds an outlet. When this is the case, flatus may enter the cavity of the abscess, and so cause it to become tympanitic. Sometimes the matter, after having passed into the pelvis, issues at the sciatic notch, and thus gets, as has been observed by Mr. Erichsen, under the gluteal muscles.

The *diagnosis* of this disease is often difficult, and therefore requires careful study. The affections with which it is most liable to be confounded are coxalgia, neuralgia of the hip, sciatica, and caries of the spine. From coxalgia it is distinguished, 1st, by the peculiar shape and site of the swelling; 2dly, by the character and situation of the pain, which does not affect the limb or knee, as in hip-joint disease; 3dly, by the tardy progress of the morbid action; 4thly, by the rotated appearance of the pelvis and the abnormal prominence of the anterior superior spinous process of the ilium; 5thly, by the persistence of the ileo-femoral crease; and, lastly, by the preservation of the movements of the hip-joint. In both diseases there is shortening of the limb, but in the sacro-iliac it is never real at any time, while it is always so in the latter stages of coxalgia, owing to the partial destruction of the head and neck of the femur. Coxalgia is nearly always a disease of early childhood, while sacro-iliac disease is seldom observed until after the fifteenth year.

Neuralgia of the hip occurs chiefly in young females, of a nervous temperament and hysterical habits, and is, in general, easily distinguished from disease of the sacro-iliac synchondrosis: first, by the character of the pain, which is more widely diffused, as well as more superficial and irregular, than in coxalgia; secondly, by the want of intumescence in the course of the joint; thirdly, by the coexistence of neuralgia in other parts of the body; and, fourthly, by the history of the case. Another important point is the absence of abscess, which nearly always occurs in the latter stages of sacro-iliac disease.

The discrimination between sciatica and this affection is seldom difficult. The chief signs of distinction are that, in the former, the pain is confined chiefly to

the lumbar region, while in the latter it is seated more particularly in the line of the sacro-iliac joint. Besides, it is generally more easily amenable to treatment, and is very frequently connected with a gouty or rheumatico-gouty state of the system. Moreover, in sciatica, there is no deformity of the pelvis or change in the length of the limbs.

It is barely possible that sacro-iliac disease might be confounded with disease of the spine; but such an occurrence will readily be avoided if the surgeon keep clearly before his mind the distinction between the real symptoms of the two disorders. In the former, there is always more or less intumescence in the line of the sacro-iliac joint, with marked deformity of the pelvis and elongation of the limb on the affected side; in the latter, all these phenomena are wanting, and the vertebral column is stiff, tender on pressure, and excurvated. The most common site of the disease is the dorsal portion of the spine, and if an abscess form the matter never gravitates in the direction of the sacro-iliac junction.

The *prognosis* of this disease is always unfavorable. Now and then, it is true, a case recovers, but such an occurrence can be regarded only as a rare exception. In general, the patient, after having lingered for months, with an occasional intermission of suffering, is finally worn out by the profuse drain and hectic irritation, or by some intercurrent disease, as purulent infection, or tuberculosis of the lungs.

The *treatment* of sacro-iliac disease is similar to that of coxalgia. The principal remedies are rest and recumbency, with leeches and blisters in the early stage of the malady, followed, if the amelioration is not prompt and decisive, by the establishment of a long issue, with the actual cautery, in the line of the affected joint. Of course no severe counter-irritation is admissible after the parts have become seriously disorganized. If abscesses form, no time must be lost in letting out their contents by a valvular incision. The strength is supported by tonics, and the constitution improved by alterants, as iodide of iron, iodide of potassium, and bichloride of mercury, with cod-liver oil.

5. WRIST-JOINT.

The characteristic features of tuberculosis of the wrist-joint are well depicted in the annexed engraving, fig. 486, from Barwell, the disease having already made

Fig. 486.

Tuberculosis of the wrist-joint.

considerable progress. It will be observed that the greatest amount of swelling and distortion is on the dorsal surface of the hand, although there is also a good deal of fulness in front and the hollow of the palm, which is often completely effaced, especially when the matter gravitates in that direction. The thumb and fingers are tumefied, stiff, and straight, or nearly so, and have a peculiar elongated appearance. Every attempt to move them excites severe pain, or pain and spasm. A sense of fluctuation, often very faint and perplexing, is usually perceptible, being most distinct on the back of the joint, and caused either by a fungous condition of the synovial membrane, or by the presence of an unnatural quantity of synovial fluid, or both. The muscles of the limb are wasted and flabby. If matter forms, it generally experiences great difficulty in finding an outlet, and it is, therefore, very apt to travel up the forearm and down along the dorsal surface of the hand. Dislocation of the bones, in any direction, is uncommon. The

head of the ulna, however, is often abnormally prominent, but of the radius the styloid process alone is distinguishable.

The *treatment* consists in placing the limb in an easy, straight position upon a carved splint, and in employing the other measures called for in tuberculosis of other joints. If matter forms, an early outlet should be afforded, lest it diffuse itself extensively among the soft parts and the bones, and so endanger limb and life. Resection is sometimes available, though, in general, preference should be given to amputation.

6. ELBOW-JOINT.

Tuberculosis of this joint, fig. 487, from Barwell, generally begins in the structures of the humerus, from whence it may gradually spread to the ulna and radius, involving the whole articulation in ruin. Pain, stiffness, and swelling in and around the joint are the prominent symptoms of the disease. The skin is tense, glossy, and more or less red at the focus of the morbid action; the parts are intolerant of manipulation and motion, and the swelling presents itself in the form

Fig. 487.

Tuberculosis of the elbow, in its earlier stages.

of two cones, united on a level with the crease of the elbow, one apex looking upwards, the other downwards. The osseous prominences are completely effaced, except that formed by the olecranon process, on each side of which there is usually a good deal of fluctuation, caused by the presence of a large quantity of synovial fluid. The limb is wasted both above and below the joint, and the fingers are stiff, swollen, and almost useless. The biceps muscle is rigidly contracted, so as to render extension difficult, if not impossible, and the forearm is bent nearly at a right angle with the arm. When matter forms, it is usually discharged at the back part of the joint, at the side of the olecranon process, or at the lower part of the arm; seldom in the forearm or in front of the joint. The ulna, owing to the solidity of its connections, is hardly ever dislocated, but it is not uncommon for the radius to abandon its relations with the humerus when

there is much disorganization of their ligaments. In the worst forms of the disease, the bones are involved to a great extent; far, indeed, beyond their articular extremities.

In the *treatment* of this affection the same principles are to be observed as in articular tuberculosis in general. Early recourse should be had to the actual cautery, drawn linearly along each side of the joint for four or five inches, and to proper support by means of a suitable splint, extending from near the axilla down to the fingers. The forearm should be placed in a semi-flexed position; matter should be promptly evacuated, and every means should be taken to preserve the usefulness of the limb. Amputation will be necessary when the disease is very extensive, or the general health is much impaired; otherwise the affected bones may be advantageously dealt with by resection.

7. SHOULDER-JOINT.

Tuberculosis of this joint is uncommon, and is met with chiefly in young persons after the age of eighteen or twenty, beginning generally in the synovial membrane and other structures of the humerus to which it is nearly always limited, the glenoid cavity of the scapula rarely suffering.

The disease is usually announced by more or less swelling, pain and stiffness in the joint, which the patient is generally disposed to ascribe to the effects of rheumatism, cold, or some slight injury. As it progresses, the shoulder loses its natural contour, and assumes a peculiarly rounded appearance, owing to the presence of an undue quantity of synovial fluid. The deltoid muscle is gradually flattened and atrophied, and, in fact, the whole arm is wasted. The movements of the joint, at first merely restrained, are ultimately entirely lost. If the morbid action is not arrested, abscesses at length form, point and break, leaving thus a number of fistulous openings leading down to the diseased bone, which is either carious or both carious and necrosed, not infrequently to an extent of three or four inches. In the worst cases, there is sometimes serious involvement of the glenoid cavity of the scapula.

Surgeons have occasionally noticed that the pain which attends this disease, early in the attack, is most keenly felt in the elbow, just as in coxalgia it is originally seated in the knee. Such an occurrence is, however, uncommon, and therefore of little diagnostic value.

The *treatment* consists of complete repose of the joint, and of the application of leeches and blisters, or, if the attack is obstinate, the hot iron. Matter is early evacuated, and dead bone or cartilage removed as soon as it is sufficiently detached. In protracted cases, dependent upon the presence of carious or necrosed bone, the proper remedy is excision; an operation which, if carefully executed, is not only free from danger but nearly always successful, the patient regaining a good use of his limb.

8. ANKLE-JOINT.

The most common cause of tuberculosis of this joint is external injury, as a sprain, twist, blow, or contusion. Among the earlier local symptoms is a swelling just in front of each malleolus, as seen in fig. 488, from Barwell, filling up the hollow which naturally exists there; it fluctuates under the finger, and is mainly dependent upon the presence of synovial fluid, which, from the peculiar structure of the joint, always accumulates there in larger quantity than elsewhere. As the disease progresses, the grooves at the side of the tendo-Achillis disappear, and the whole joint becomes enormously enlarged, the heel and other osseous prominences losing their distinctive features. This increase of size is owing, not exclusively to morbid deposits in and around the articulation, but also, at least in part, to an expansion of the ends of the bones, as is easily ascertainable by examination. When the disease is far advanced, the fluctuation is rendered very faint in consequence of the fungous condition of the synovial membrane, the leg is excessively wasted, and the foot has a distorted or twisted appearance,

as if it were rotated upon its axis, or partially dislocated. If supuration takes place, the matter usually collects in front of the joint, diffusing itself more or less extensively in the subcutaneous cellular tissue of that region.

In the *treatment* of this disease the foot should be placed at a right angle with the leg and the parts well supported with suitable splints, so as to maintain them in an easy, relaxed and quiet position. Linear cauterization may be performed, or, what is preferable, a small issue should be established with the hot iron just above each malleolus. Prompt vent is afforded to pus; and, if the joint cannot be saved, resection or amputation is resorted to, according to the judgment of the surgeon.

Fig. 488.

Tuberculosis of the ankle.

9. KNEE-JOINT.

This joint, owing to the great size of its articular surfaces, its extensive motions, and its exposed situation, is, next to the hip, more frequently the seat of tuberculosis than any other joint in the body. While the disease is most common in young persons before the age of fifteen, it is often met with in young adults, and is generally excited under the influence of external violence, as a blow, fall, or twist, acting upon a depraved constitution.

The pain which attends this disease, and which is generally very severe, even at the commencement of the attack, is almost invariably situated in the direction of the inner condyle of the femur, at the lower part of the patella, or at the inside of the head of the tibia; seldom at the outer part of the joint. The great uniformity of this occurrence has led to various speculations as to its cause, but as yet no satisfactory explanation has been offered. As in coxalgia, the pain is liable to periodical exacerbations; in general, it is of a dull, heavy, gnawing character, and is commonly worse at night than in the day, extending up and down the limb, and destroying the patient's sleep and appetite.

The concomitant swelling, as exhibited in fig. 489, from Barwell, is usually very great, and is due, partly to interstitial deposits, partly to an inordinate increase of the synovial fluid. It is always most conspicuous, especially in the earlier stages of the complaint, in front and at the sides of the patella, owing to the laxity and yielding character of the tissues at these points. It is in consequence of this circumstance that the

Fig. 489.

Tuberculosis of the knee in its earlier stages.

depressions in this situation are generally soon completely effaced, or, what is the same thing, replaced by soft, fluctuating bags. A similar prominence, often of great size, exists just above the joint, over the lower part of the femur, bounded inferiorly by the patella, and on each side by the lateral ligament, its anterior wall being formed by the tendon of the extensor muscle. Very little tumefaction ever occurs in the popliteal region, even in the more advanced stages of the disease. The skin is tense and glossy; the subcutaneous veins are abnormally large; the knee is stiff, if not immovable; and the leg, more or less flexed, is swollen and œdematous, while the thigh is remarkably atrophied. In proportion as the ligaments yield, the deformity of the joint increases, owing chiefly to the displacement of the head of the tibia, which allows the muscles to draw the leg outwards, so as to give it a twisted or contorted appearance. Occasionally, though rarely, there is an actual enlargement of the diseased bones.

The fluctuation which constitutes so prominent a symptom in the earlier periods of this complaint, often, in great measure, if not entirely, disappears during its progress, owing to the adventitious deposits upon the synovial membrane and the absorption of the redundant synovial fluid. Whenever this is the case, the swelling, instead of being soft and yielding, will be comparatively firm and resisting, but still possess some degree of elasticity, often so deceptive as to lead to the idea that the joint contains a good deal of fluid, and which nothing but the most careful examination can dispel.

Pus does not always form in this disease, even when permitted to proceed unmolested; on the contrary, there is reason to believe that it is frequently entirely absent. When suppuration does take place, the matter may either be absorbed, or it may escape at the side of the patella, the lower part of the thigh, or over the head of the tibia; very rarely in the ham. In the worst forms of the malady, the whole surface of the joint may be riddled with fistulous apertures, leading down to the diseased bones, large portions of which are then either carious or necrosed.

The *treatment* of tuberculosis of the knee presents nothing peculiar. The same rules of practice are to be enforced here as in coxalgia. Rest of the part and system, local support by means of splints, and cauterization, either linear or circumscribed, are of primary importance, and must be thoroughly enforced from the very beginning. Resection may sometimes be advantageously employed, but, in general, amputation of the thigh will make a better and more satisfactory cure.

10. HIP-JOINT.

This affection, usually called coxalgia, femoro-coxalgia or hip-joint disease, is, according to my observation, most frequent from the third to the seventh year. Cases occasionally occur before the twelfth month, and now and then an instance is seen after puberty, or even after the age of twenty, but this is uncommon. Both sexes are liable to it; and it is sometimes witnessed in several members of the same family.

The causes of coxalgia are the same as those which provoke strumous disease in other parts of the body. The most common are external injury, as sprains, falls or blows, exposure to cold, inadequate food and clothing, and wasting maladies, as cholera, chronic diarrhœa, dysentery, scarlatina, measles, and different kinds of fevers. In very many cases it arises spontaneously, or without any obvious reason.

It is seldom that both hip-joints are involved in this affection, either simultaneously or successively. During its progress, however, it becomes occasionally complicated with other strumous maladies, as Pott's disease, psoas abscess, ophthalmitis, pulmonary phthisis, and degeneration of the lymphatic glands of the neck, mesentery, and other parts of the body.

Symptomatology.—Tuberculosis of the hip-joint may be described as consisting of three stages, each characterized by distinctive symptoms and pathological changes, as well as requiring peculiar treatment. As this division is not imaginary, but real, it is deserving of the greatest attention.

The symptoms of the disease, in its *first stage*, are usually of so obscure and stealthy a character as to render it very liable to be mistaken for other affections of the joint. The first circumstance which commonly attracts attention, especially if the patient is a child, is a feeling of fatigue after exercise, with slight pain in the knee, and a disposition to drag the limb, thus giving the gait a stiff, awkward appearance. In this manner the case may progress for several weeks, or, indeed, even for several months, with, perhaps, hardly any perceptible aggravation. The child still goes about, taking his accustomed exercise, and manifesting the same interest as formerly in his out-door amusements. Gradually, however, the pain increases; there is now a distinct limp; and the sleep is disturbed by spasmodic twitches of the extremity. The pain is usually referred to the knee, particularly to its inner side, and is either sharp and lancinating, or dull, heavy, and aching. It is sometimes felt in the very depths of the joint, but more frequently it is superficial, as if it were just beneath the integuments. Exercise, or motion of any kind, always increases it, and it is generally worse at night than in the day; damp states of the atmosphere, suppression of the cutaneous perspiration, and disorder of the digestive organs also frequently aggravate it. The knee, on inspection, is found to be free from swelling and discoloration, and commonly quite tolerant of rough manipulation, as motion, pressure, and percussion. Occasionally the pain is of a neuralgic nature, and distinctly periodical in its occurrence, very similar, in this respect, to the paroxysms of an intermittent fever; the attack, perhaps, coming on early in the evening, and, after having continued for a few hours, returning about the same time the next day. This form of pain is most frequent, as far as my observation enables me to judge, in persons living in a malarial atmosphere.

It is not often, however, that the pain, whatever may be its character, is entirely confined, at this stage of the disease, to the knee; or, if it is so at first, that it remains there exclusively for any length of time. In general, it extends also to the thigh and leg, sometimes along the front, now along the sides, especially the inner, and now along the posterior surface, in the direction, apparently, of some nervous trunk, as the crural, obturator, saphenous, or sacro-sciatic. I have known cases where the pain was felt most keenly at the tendo Achillis, just above the ankle-joint, and in one instance it was distressingly severe over the instep. Sometimes, again, it seems to shift from one of these points to another, being, perhaps, most violent at one period in the knee, and at another in the thigh, leg, or foot. It is proper also to add that the pain is generally not persistent, but that there are frequently long intervals of comparative comfort, if not of entire absence of suffering.

The occurrence of pain in the knee in this disease has been variously explained. Thus it has been imagined to be owing to irritation of some of the principal nerves of the limb, especially the obturator, but as these cords have no direct connection with this joint it is difficult to conceive how they could exert such an influence. The opinion that it is caused by disease of the long head of the femoral muscle is also far-fetched. This muscle, it is true, is intimately attached to the capsular ligament of the hip-joint; but, even supposing, what is not at all probable, that it participates in the morbid action at this early stage of the affection, how could it give rise to pain in the knee, leg, and foot? Again, it has been alleged that it is due to inflammation of the cancellated structure of the head and neck of the thigh-bone, and this certainly is the most plausible conjecture that has yet been advanced; a conjecture which derives confirmation from the fact that the disease usually begins in this structure.

After some time, varying from a few weeks to as many months, the pain shifts to the hip and its neighborhood; or, if it do not entirely forsake the knee, it is generally less constant and severe there than it was in the first instance, or soon after the commencement of the morbid action. Commonly it is most intense and persistent directly over the articulation, deep-seated, and of a dull, gnawing character. At times it is perceived most keenly in the sacro-sciatic notch, between the great trochanter and the spine of the ilium, or in the upper and outer part of the groin. Occasionally, again, it exists simultaneously at all these points,

although not in an equal degree; or, as it leaves one, it fastens itself upon another. In rare cases the pain appears in the hip before it shows itself in the knee, thigh, or leg. Pressure upon the gluteal region, motion of the affected joint, and percussion of the knee, the leg being flexed at a right angle, or of the sole of the foot, the limb being extended, always augment the pain, and lead to the detection of its seat.

As yet, there is no sensible impairment of the general health; the appetite is good, and the various tissues retain their normal development. The muscles of the affected hip and limb are, perhaps, a little thinner and softer than natural, but these changes are usually slight, and hence they often elude detection.

In the *second stage* of the complaint, the most prominent local phenomena are an increase of pain in the hip and knee, flattening of the buttock, effacement of the gluteo-femoral crease, and apparent elongation of the limb, with spasmodic twitching and wasting of its muscles.

The pain, hitherto seated chiefly in the knee, now also affects the hip, or, if it existed there previously, as, indeed, is not infrequently the case, it becomes sensibly aggravated. It is particularly violent at night, often for hours interrupting sleep, and is attended with the most distressing spasmodic twitches of the muscles of the limb, which thus greatly augment the local and general suffering by the sudden and forcible apposition of the inflamed articular surfaces. The pain at one time is fixed, deep, aching, gnawing, or boring; at another, erratic, sharp, or lancinating, darting about in different directions, now through the joint, then down the limb, and then through the groin, or back along the course of the sciatic nerve. Occasionally it is most severe in the lumbar region, in the lower part of the pelvis, in the situation of the acetabulum, or at the upper and inner part of the thigh. Sometimes, as before remarked, it is of a neuralgic character, coming, going, and recurring at particular periods. Derangement of the digestive apparatus, exposure to cold, and damp states of the atmosphere, have a tendency to aggravate and protract it. The pain in the knee, instead of disappearing, generally increases in violence, at the same time that it becomes more frequent and fixed.

The sleep is habitually disturbed by unpleasant dreams, and the patient often wakes up in great alarm, crying and screaming. Occasionally he is partially delirious from pain and fever. He sleeps by snatches, and usually feels fatigued and unrefreshed in the morning. Spasmodic twitching, jerking, or starting of the limb is a prominent symptom, and is seldom entirely absent in any case. Sometimes, indeed, it sets in at a very early period, and continues, with more or less violence, during the whole progress of the malady. It is particularly distressing in the muscles of the thigh, but often affects also those of the hip and leg.

Along with these symptoms there is frequently loss of appetite, with disorder of the secretions, and more or less fever at night. The bowels are usually inclined to be constipated, the urine is scanty and high-colored, the skin is rather arid, especially in the evening, and there is often considerable thirst. As the disease advances, the fever increases, and is frequently followed by copious sweats. The patient loses flesh and strength, he is peevish and irritable, and his countenance has a care-worn appearance. Although such is ordinarily the state of the system, in the second stage, especially after the disease has made some progress, yet there are cases in which there is hardly any constitutional disturbance whatever, except what results from the want of sleep.

The local phenomena, fig. 490, at this stage of the malady are unmistakable. The buttock of the affected side is found to be remarkably flattened, so as to be in striking contrast with the sound one. It is much broader, as well as considerably larger, than in the natural state; the gluteal muscles are soft and flabby, and the skin is preternaturally loose, from the absorption of the subcutaneous fat. The gluteo-femoral crease, so prominent in the natural state, is completely effaced, giving the thigh and hip an appearance of continuity, as if they were fused together. The muscles of the thigh and leg are also wasted, and the whole limb, in fact, is very sensibly attenuated, evidently owing to want

of exercise and perverted nervous action, leading to atrophy of their substance.

Marked elongation of the corresponding limb now exists, and is so constant an occurrence that it may, along with several of the other symptoms above described, be considered as pathognomonic. The extent of the elongation varies, on an average, from half an inch to an inch and a half. In rare cases it may amount to two inches, and even two inches and a half. It is observed both in the erect and in the recumbent posture, but is commonly more conspicuous in the former than in the latter. Various explanations have been offered of this phenomenon, all, at first sight, more or less plausible. In the first place, it has been argued that it is owing to the presence of an unusual quantity of synovial fluid, the product of inflammatory action, by which the head of the thigh-bone is partially pressed out of its socket, and the corresponding limb projected beyond the level of the sound one. No one, however, has yet verified this opinion by dissection. That there is an inordinate secretion of synovial liquor in this stage of the malady is highly probable, but that its quantity is generally so great as to cause such a result is hardly a supposable case. It is well known that there are frequently large accumulations of this kind in other joints, as the elbow and knee, without producing such an effect. In the second place, the phenomenon has been ascribed to the relaxed condition of the ligaments and muscles of the joint; but of this occurrence, if it really exist, there is no more positive proof than of the influence which has been attributed to the synovial fluid. A third opinion, and, in my judgment, the only correct one, is that the elongation in question is occasioned by the difference in the level of the two hips, that of the affected side being always lower than that of the sound side. Now, a careful examination of the body will not fail to satisfy us that this difference is real, and not imaginary, and, moreover, that it is always in direct proportion to the increase in the length of the limb. Whatever mode of examination be adopted, the result will be the same, whether the patient is recumbent or erect. In the latter case, he is necessarily obliged to support himself upon the sound limb, which, for this purpose, he maintains in a state of rigid extension, at the same time throwing the corresponding hip somewhat outward, so as to bring the axis of the trunk on a line with the sound foot, and thus take off its weight from the affected extremity. This, it will be observed, hangs loosely from the pelvis, upon which the thigh is slightly flexed, while the leg is bent on the thigh, and the foot on the leg, the knee projecting prominently forward, much beyond the level of the opposite one, and the whole member resting upon the ball of the foot and toes. If this explanation is correct, as my experience warrants me in assuming, then the elongation of the limb, so constantly witnessed in this stage of the disease, is not real but imaginary, not positive but merely apparent.

Finally, there is generally, in this stage of hip-joint disease, a marked depression, or hollow, in the lumbar region, with a slight inclination of this portion of the spine toward the sound side, and an unusual prominence of the belly. The inferior portion of the spinal groove is also more distinct than natural.

In the *third stage* the nature of the disease is no longer doubtful, whatever it may have been previously. The symptoms are characteristic of the extensive and frightful mischief that has been effected within the joint. Matter now forms, and, by its pressure upon the inflamed structures, greatly aggravates the suffering. The suppuration is indicated by an increase of pain; by a sense of throb-

Fig. 497.

Appearance of the nates and limb in hip-joint disease, in its earlier stages.

bing and tension, deep and persistent; by severe swelling of the gluteal region, generally most prominent at the centre of the articulation; by œdema of the subcutaneous cellular tissue; and by a remarkably turgid and enlarged condition of the subcutaneous veins. The affected joint is intolerant of the slightest motion or manipulation, and the patient is unable to raise himself up or turn in bed without the greatest agony. Every attempt to flex or extend the limb is attended with similar results. The constitutional disturbance is always in proportion to the local suffering, and violent rigors, followed by high fever and copious sweats, are rarely absent. Sometimes, however, the abscess forms in a quiet and insidious manner, without any of the severe symptoms that usually accompany the suppurative process in this and other varieties of inflammation. As the matter increases in quantity it gradually works its way towards the nearest surface, its approach being denoted by the occurrence of a circumscribed, erysipelatous blush. Here there is generally distinct fluctuation, and the parts, feeling soft and boggy, soon yield at one or more points, followed by the escape of the contents of the sac.

The site at which the matter, when left to itself, obtains a vent, varies in different cases. Most generally it escapes at the gluteal region, either directly over the joint, or in its immediate vicinity. The other situations at which it is most liable to discharge itself are the upper and back part of the thigh, a short distance below the great trochanter, the superior and external part of the groin, the sacro-sciatic notch, and the upper and inner surface of the thigh. Occasionally it escapes at several points, either simultaneously or successively, leaving thus a number of orifices, with a corresponding number of sinuses. These passages are sometimes very long and tortuous, and in old cases they are always lined by a false membrane. I recollect one instance in which there were nine distinct openings, and another in which there were as many as twelve; two at the upper part of the thigh, and one just below the crest of the ilium, the remainder being scattered over the gluteal region.

The matter sometimes escapes both externally and internally. When the bottom of the acetabulum is perforated, it may pass into the rectum, bladder, or

vagina, or, instead of this, it may collect in a sort of pouch, between the inner surface of the iliac bone and the soft parts of the pelvis.

The changes in the limb and hip, represented in fig. 491, in this stage of the disease, are striking and characteristic. The extremity, now actually shorter than natural, is much attenuated from the wasting of its fatty and muscular tissues, and remarkably disfigured in its appearance, the heel being considerably elevated, and the ball of the foot and toes alone touching the ground when the patient makes an effort to stand. The degree of shortening is variable, and not always by any means in proportion to the destruction of the head and neck of the thigh-bone, the acetabulum and the connecting ligaments, which forms so prominent a feature of the disease at this period. While in some instances it does not exceed an inch, or, at most, an inch and a quarter, in others it amounts to twice and even thrice that extent. One-third, and sometimes even one-half of this, as I have satisfied myself by careful examination, is generally attributable to the elevation of the pelvis on the affected side. The position of the foot is variable. Sometimes it looks directly forwards or outwards, but much more commonly it inclines inwards. These differences are due to the nature and extent of the ravages expe-

Fig. 491.

Shortening, swelling, and characteristic deformity of the advanced stage of coxalgia.

rienced by the hip-joint. When the acetabulum has suffered most severely, the foot usually turns in as in the iliac dislocation of the thigh-bone; if, on the contrary, there has been much destruction of the head and neck of the femur, and the cotyloid cavity is only slightly involved, then the limb is generally everted, as in intra-capsular fracture of that bone, the external rotary muscles tending to draw it in that direction.

The thigh, as a general rule, is bent upon the pelvis, the angle of flexion varying from the slightest perceptible change to 45° . In most cases it inclines somewhat towards the sound limb, and occasionally, though rarely, it overlaps or crosses it. Sometimes, on the other hand, it stands off widely and in a most unseemly way from its fellow, as in the case of one of my patients, a woman, aged twenty-five, in whom the two knees are habitually upwards of fifteen inches apart; the affected limb sticks out in the most grotesque manner, and the foot, in the erect posture, is at least six inches from the floor.

The thigh, moreover, is always in a painfully rigid state, depending upon the contracted condition of the muscles of the hip and limb, and the formation of adhesions between the remnants of the superior extremity of the femur and the surrounding parts. By taking hold of the knee a slight degree of flexion may, perhaps, be produced, but to abduct the thigh, or to move it backwards, is generally impracticable; besides, every effort of the kind is attended with excruciating suffering. Owing to the shortening of the hamstring muscles, the leg is commonly bent on the thigh, and, for the same reason, the flexor muscles usually draw the heel upwards towards the leg.

The great trochanter generally lies directly over the acetabulum, or in its immediate vicinity, forming a hard, firm, immovable, or nearly immovable, prominence, the nature of which cannot be mistaken. In regard to the head and neck of the femur, they are, as stated elsewhere, usually completely annihilated, or so much wasted as to exist only in a rudimentary form. It has generally been alleged that there is, in this stage of the disease, more or less displacement of this bone; but the facts collected by Dr. March, in the extensive museums of the United States and of Europe, as well as in private practice, conclusively prove that dislocation of the femur, as a consequence of this affection, in any direction, is exceedingly rare. A true luxation, such as occurs in the normal state of the parts from injury, is, in fact, impossible, from the very nature of the morbid alterations in the superior extremity of this bone. During the progress of the disease, the remnant of the neck, which is usually of a rounded conical shape, and frequently not more than three-quarters of an inch in length, ordinarily places itself over the acetabulum, to the margins of which, and to the adjacent parts, it becomes, in the event of recovery, ultimately united. That it is occasionally drawn up beyond this point, especially when there has been complete destruction of the upper border of the acetabulum, backwards towards the sciatic notch, forwards upon the pubic bone, or downwards and forwards into the thyroid foramen, is unquestionable. Dislocation, however, in most of these directions can take place only in those cases where there has been extensive suppuration with separation or destruction of the soft parts, allowing the superior extremity of the bone to move about and thus seek, as it were, a new position. The upward displacement is, undoubtedly, the most frequent, but even this is extremely rare. In one of my cases, the end of the thigh-bone projected above the acetabulum, where it had formed for itself a superficial socket in the iliac bone, admitting of very slight motion. The real cause, then, of shortening in the third stage of the disease is not dislocation, but destruction, partial or complete, of the head and neck of the thigh-bone, along with a certain degree of elevation of the corresponding hip.

Diagnosis.—Although the symptoms of this disease are usually well-marked, especially if some time has elapsed, it is extremely liable to be diagnosticated erroneously. The inexperienced practitioner, misled by the seat of the pain, too often contents himself with a most superficial examination, and, taking this as the basis of his therapeutic indications, is very apt to misapply his remedies, addressing them, perhaps, solely to the knee, which is only sympathetically in-

involved, when they ought to be directed exclusively to the hip, the actual seat of the morbid action. Numerous cases, illustrative of the truth of this remark, have fallen under my observation, and there are few surgeons in extensive practice who have not, like myself, had occasion to lament the great mischief that has thus been entailed. In a malady so grave as this an error of diagnosis may be fraught with the worst consequences both to the part and system, eventuating, as it necessarily must, in the loss of precious time ; for it but too often happens that, when the true nature of the disease is discovered, all our efforts to arrest its progress are unavailing.

The affections with which this disease is most liable to be confounded, or which may, at least for a time, obscure its diagnosis, are sprains and rheumatism of the ilco-femoral articulation, psoas abscess, purulent collections in the vicinity of the hip and in the upper part of the thigh, and inflammation of the periosteum of the great trochanter.

A *sprain*, twist, or contusion of the hip-joint is not an infrequent occurrence, and may, if followed by considerable inflammation, give rise to severe pain and stiffness, seriously weakening, if not completely disabling, the part. The consequence is that the patient, in attempting to walk, raises the hip of the affected side and relaxes the corresponding limb, by bending the knee and retracting the heel, very much as in the earlier stages of tuberculosis. The muscles, also, by degrees become flabby and attenuated, and there is a sensible diminution of the temperature of the cutaneous surface. The gluteo-femoral crease is eventually effaced, and even the general health may suffer. The signs of distinction are, the history of the case, the absence of pain in the knee, the greater latitude of motion, the absence, in general, of constitutional disturbance, and, lastly, the fact that the foot, although everted, is usually easily rotated on its axis, whereas, in strumous disease of the hip-joint, it is commonly pretty firmly fixed.

Rheumatism of the hip-joint, chronic and subacute, is generally caused by cold, or by the sudden suppression of the cutaneous perspiration. It is seated principally in the ligamentous and synovial structures, the cartilaginous and osseous being seldom involved, except in very severe and protracted cases. The pain, which runs down the front of the thigh, is dull, heavy, or aching ; the gait is limping ; the pelvis is higher on the affected side than on the sound, and the limb exhibits, in the main, the same attitude as in lameness from sprains and contusions, with this peculiarity that the foot is always strongly everted, while in the former case it is generally inclined inwards. The patient in the morning complains of stiffness in the hip, which usually diminishes very sensibly after exercise, but is sure to return in the evening if there has been much exertion or fatigue. The muscles of the thigh are attenuated, but more firm than in tuberculosis, while those of the leg often retain their normal bulk ; the gluteo-femoral fold is effaced ; the limb, owing to the obliquity of the pelvis, appears shorter, often from one to two inches, than natural ; the great trochanter is uncommonly distinct ; and a creaking noise is generally heard if the head of the thigh-bone is forcibly moved upon the acetabulum. Now, although these phenomena bear a very close resemblance to those of strumous disease of this articulation, yet the absence of severe suffering at night, and at all times at the knee, the marked relief afforded by gentle exercise, the trifling annoyance from pressure, percussion, and motion, even when rudely performed, and the rarity of rheumatism in children, together with the frequent coexistence of this disease in other parts of the body, will generally be sufficient to prove that the affection is not tubercular.

It is not often that *psoas abscess* can be mistaken for coxalgia ; for, although the matter which is formed in its latter stages occasionally points at the outside of the groin, or at the upper and inner part of the thigh, there is always the most marked difference in the character of the two swellings, not to say anything of other symptoms. In psoas abscess the tumor is usually situated above Poupart's ligament, while in hip-joint disease it is commonly below ; in the former it always sensibly diminishes and sometimes even entirely disappears under pressure, or when the patient lies down, but quickly reappears when the pressure is removed, or when the patient raises himself up ; in the latter, on the contrary,

it never changes its position, or, if it do, it is in consequence solely of the force of ulceration, absorption, and gravitation; in psoas abscess the swelling receives a distinct impulse on coughing, laughing, and crying, which is not the case in tuberculosis of the hip-joint.

Again, in psoas abscess, the principal pain is in the loins; it is fixed there, and is always greatly increased by the erect posture, as well as by every attempt to extend the corresponding limb. In coxalgia, the pain is most severe in the knee, or in the knee and hip. In psoas abscess there is at no period any change in the position of the great trochanter, nor any alteration in the length of the limb; in hip-joint disease, on the contrary, especially in its more advanced stages, these are prominent symptoms. Finally, psoas abscess occurs nearly always after puberty, whereas the other affection is most common in early childhood.

Sometimes large deposits of pus take place in the cellular tissue of the nates, or beneath the gluteal muscles, and, forming a prominent tumor in the direction of the ileo-femoral articulation, may thus simulate abscess of the hip-joint from tuberculosis. These accumulations are commonly the result of external injury, or of a phlegmonous, rheumatic, or erysipelatous state of the system, and are, therefore, in general easily distinguished by their history, by the rapidity of their progress, by the severity of the local distress, and by the comparatively prompt recovery of the parts after the evacuation of their contents. Cold abscesses of the nates, besides being exceedingly infrequent, exhibit none of the diagnostic signs of articular disease, especially such as pain in the knee, or pain in the hip-joint upon rotating the thigh, so characteristic of the latter malady. It is only when they depend upon caries of the innominate bone that the distinction would be likely to be attended with difficulty, and in this case a thorough exploration with the probe would probably furnish the requisite light.

Finally, diagnostic embarrassment, to an annoying extent, occasionally arises from *periostitis* of the great trochanter in persons of a rheumatic or gouty habit of body. The fibrous membrane of this portion of the femur becomes exquisitely painful and tender to the touch, under the slightest motion and percussion, and the disease, extending above the neck of the bone and the capsular ligament of the joint, causes distress and difficulty in walking, with elevation of the corresponding side of the pelvis, similar to what is seen in coxalgia. The soft parts around are swollen and puffy, giving the hip an increased breadth and thickness; by and by suppuration takes place, sinuses form, and small portions of the bone separate and come away. Unless the case is well managed the joint is rendered stiff, and the patient does not regain his health for a long time. The signs of distinction are the persistence of the gluteo-femoral crease, the coexistence of rheumatism or gout in other regions, and the fact that the disease usually occurs later in life than coxalgia.

But it is chiefly in the very early stages of this affection that erroneous views of its diagnosis are liable to be formed; when it is fully established, the phenomena are generally too well marked to be mistaken. It has been seen that the very first symptom, in every case, is pain in the knee; so uniform and constant, indeed, is this occurrence that it must be regarded as pathognomonic, and yet, as was previously stated, it rarely happens that it is referred to its true source. Instead of being considered as an expression of disease of the hip-joint, it is too often regarded merely as an effect of neuralgia, rheumatism, or injury of the knee, to which, accordingly, the treatment is exclusively directed. Its great value, as a diagnostic, is totally overlooked, and thus the disease is allowed to progress at the only time almost when it admits of prompt and radical cure.

In order to avoid this serious and too common mistake, a most thorough examination should be made in every case presenting the slightest suspicion of the existence of tuberculosis of the hip-joint. The very fact that there is pain in the knee, severe in degree, and of frequent recurrence, should of itself excite the alarm of the surgeon, more especially if, added to this, there is a limp in the gait, an increase of suffering after slight exercise, and disturbed sleep at night. If the diagnosis is obscure, the examination must be repeated, again and

again, until it is perfectly cleared up. To conduct the investigation properly the patient must be completely stripped, and viewed both behind and in front, as he stands on the floor. If there is any flattening of the nates, unusual prominence of the trochanter, or change in the gluteo-femoral fold, it will be sure to be detected, and so, also, if there is any alteration in the attitude, size, or length of the corresponding limb. If the patient be now requested to walk, the amount of limping will be discovered, as well as the manner in which he raises and moves the leg and foot. To complete the investigation, the patient is stretched out on the floor, or on a hard lounge, with a view of ascertaining the amount of suffering produced by rotating the head of the thigh-bone upon the acetabulum, and also by bringing these parts forcibly into contact with each other by percussing the knee, the leg being flexed, or the sole of the foot opposite the ankle, the foot being bent on the leg. The patient being next turned upon his abdomen, the hip is thoroughly examined, first, with reference to the condition of its soft parts, and, secondly, as to the amount of sensibility of the component structures of the joint; finally, if there is any obliquity of the pelvis. it may easily be observed both in the erect and in the recumbent posture; while any change in the length of the affected limb may be determined by extending a piece of tape, or other suitable band, from the anterior superior spine of the ilium to the inner side of the lower extremity of the patella. The difference in the length of the measure on the two sides will give the difference in the length of the thighs, or the distance between the hip and knee joints. The use of chloroform will often be of great service in conducting the movements of the limb while the patient is recumbent, especially when the parts are very painful and intolerant of manipulation.

Morbid Anatomy.—The anatomical changes which occur in coxalgia are essentially similar to those witnessed in strumous affections of the joints generally. They are usually more conspicuous, in every stage of the malady, in the head and neck of the femur than in the innominate bone, which, however, often suffers very severely during the progress of the morbid action.

When the disease has attained its acme, the synovial membrane, the round ligament, the articular cartilages, and the head and neck of the thigh-bone, with the margins, and frequently, also, the bottom of the acetabulum, are partially destroyed, if not completely annihilated. In the more severe cases the cotyloid, transverse, and even the capsular ligament are entirely absorbed, the surrounding parts are extensively separated by the ulcerative and suppurative processes, numerous fistulous openings exist, and the gluteal muscles are transformed into dense, firm bodies, of a pale-reddish, yellowish, or whitish color. Sometimes, especially when the disease is of long standing, these muscles undergo the fatty degeneration. Occasionally both trochanters are absorbed; or there is extensive caries of the innominate bone; or the head and neck of the thigh-bone are necrosed; or the joint contains numerous fragments of bone and cartilage; or, the bottom of the acetabulum being perforated, the matter extends into the pelvis, and passes off by the rectum. In children, prior to the completion of the ossific process, the hip-bone has been found separated, at the acetabulum, into its three primitive pieces.

When the head and neck of the femur are absorbed, the remnant of its superior extremity usually lies across the acetabulum, or in its immediate vicinity. Occasionally it is drawn up a little beyond this cavity, against the surface of the ilium, resting in a slight depression, which, however, bears only a very faint resemblance to a new socket. Instances have been observed, though very rarely, in which it was forced backward into the sciatic notch, forward upon the pubic bone, or downward into the thyroid foramen. When the disease has expended itself mainly upon the acetabulum, the head of the thigh-bone may remain in its original position, or it may even be pushed into the pelvic cavity.

The ravages produced by this disease in the acetabulum and head and neck of the femur are admirably illustrated in the annexed cut, fig. 492, from Barwell.

Prognosis.—As there are no mortuary statistics of this affection, it is impossible to state, with any degree of precision, the mean duration of fatal cases, or

the relative proportion of deaths to recoveries. My opinion, founded upon numerous observations, is, that the mortality from coxalgia is slight in almost any event, even when there has been palpable neglect in regard to its treatment.

Fig. 492.

Changes wrought in the acetabulum and head of the femur, in coxalgia.

The prognosis is generally most unfavorable in feeble, anemic children, with a tumid upper lip and a protuberant abdomen, the offspring of strumous parents, or of persons whose system is thoroughly impregnated with the syphilitic poison. Young adults seldom recover, if suppuration occur; the whole system soon becomes involved in the disease, and they rapidly sink under the profuse discharge and hectic irritation. Few children die before the eighteenth month. The case is always more likely to terminate unfavorably when the disease involves the acetabulum than when it is limited to the head and neck of the femur. Under the present improved mode of treatment many patients are saved that would formerly have perished. If the disease has been neglected, and recovery occurs, the individual will be permanently deformed and crippled, and a long time will elapse before he will be able to regain his health. The hip is sometimes completely ankylosed without the previous formation of an abscess.

Treatment.—Although the treatment of coxalgia involves the same principles as that of tuberculosis of the joints in general, there are certain points to which it is necessary to direct special attention, growing out of the peculiar structure

and situation of the articulation, the frequency with which it is assailed by this disease, and the tender age of those who are most obnoxious to its attacks.

Rest of the affected joint, as well as of the whole body, is here of primary importance, and no time should, therefore, be lost in securing it to the greatest possible advantage. The restraint must not be limited to a few days or weeks, but be continued as long as there is the slightest evidence of active disease.

In order to render the patient as comfortable as possible, and enable him to endure his protracted confinement without detriment or inconvenience, he must be furnished with a suitable bed provided with slats and a firm but elastic mattress. A common trundle-bed, about four feet in width, will answer every purpose, and is in every respect preferable to the common bed, especially if the patient is a child, as he will thus be less liable, if he should roll out, to hurt himself. The sheet should be well secured at the sides that it may not become rumped, and the pillow should be of medium size, so that, while it affords adequate support to the head and shoulders, no undue weight may be thrown upon the trunk and pelvis. The confinement, however rigid, will not prove irksome; with the aid of toys and other sources of amusement the little patient will soon—often, indeed, in a few days—become reconciled to his new mode of life.

With strict attention to this point, the disease, if in its incipency, may, in general, be easily arrested without any formal treatment, excepting, perhaps, the occasional exhibition of a laxative and a proper regulation of the diet. If the joint is stiff and painful on pressure, a few leeches may be applied, or the skin may be thoroughly painted once a day with dilute tincture of iodine, or a small blister may be raised, and the raw surface sprinkled with morphia. A diaphoretic and anodyne draught may be administered at bedtime if fever exist. The best laxative, in this stage of the disease, is calomel, in doses of two to three grains with twice that quantity of jalap. The diet must be very plain and simple, especially if the patient is, in other respects, well conditioned. General bleeding will seldom be required, unless the suffering is unusually severe and the blood decidedly thick and abundant, when the loss of a few ounces cannot fail to be highly beneficial.

To control the spasmodic action of the muscles, and thus afford more perfect repose to the diseased joint, the limb should be confined by a splint, extending from near the crest of the ilium to within a short distance of the ankle, and so

Fig. 493.

Fig. 494.

Dr. Davis's apparatus.

constructed as to cover in nearly the whole of the affected buttock. The most suitable materials are wire gauze, gutta-percha, undressed sole-leather, or trunk-maker's board, soaked in hot water, carefully moulded to the hip, thigh, and leg, and kept in place with adhesive plaster and a common roller. When dry, these substances form an admirable case, which, if properly padded, will effectually ward off pressure and prevent excoriation.

Dr. Physick, who was the first to insist upon the necessity of absolute rest in the treatment of coxalgia, was in the habit of using a splint of carved wood, very light, well padded, and carefully adapted to the size and shape of the hip and limb. At present the apparatus of Dr. H. G. Davis, of New York, is much employed, as, from its lightness and peculiar arrangement, it enables the patient to exercise, if this should be deemed proper, in the open air. It is composed of a splint, two bands, a roller, and several strips of adhesive plaster, together with a cord, pulley, and weight, to be used when the patient is confined to bed. The splint is about one inch and a half wide, very light, and long

enough to extend from near the crest of the ilium to within a short distance of the ankle. It consists, as seen in fig. 493, of two portions; an upper made of corrugated cast-steel, and a lower, which is simply a ratchet bar, worked by a key,

and so constructed as to slide within the other. To the upper end of the splint is attached, by means of a cat-gut, a perineal band, composed of two parts, one being elastic, the other inelastic. When applied, the elastic lies inside of the other, and the amount of elastic extension is regulated by the difference in their length. The inelastic, being made slightly tense, prevents the limb from receding when the weight of the body is thrown upon it. Near the inferior extremity of the splint is a buckle intended to receive a band stitched to the bottom of the adhesive strips. By this arrangement the splint may be made to take a firm hold both of the thigh and leg.

The apparatus represented in fig. 494 is intended for the thigh only. The splint is attached to a steel frame which encircles the limb, to which it is firmly secured by adhesive strips, aided, if necessary, by a roller. The leg being thus left free, the patient enjoys the unrestrained use of the knee-joint. With the assistance of a crutch, he may, with either of these contrivances, exercise during the day in the open air, while at night, as he lies in bed, the requisite degree of extension may readily be effected by means of a pulley, cord, and weight.

The apparatus of Dr. Davis has been variously modified by different surgeons, without, however, any essential change of principle. Fig. 495 represents the mode of application of the one devised by Dr. Sayre. If a perineal band of India-rubber is used great care must be taken that it does not chafe the skin.

In the *second stage* of the malady, the great topical remedy is an issue made with the actual cautery, applied to the most prominent part of the swelling, or as near as possible to the focus of the morbid action. The eschar, which should be from half an inch to an inch in diameter, usually drops off in from four to six days; the sore, besides furnishing an ample supply of thick pus, affords an excellent surface for the endermic use of morphia, now so necessary for allaying the violent pains and spasmodic twitchings of the muscles. If the discharge flag, it can easily be re-excited with some stimulating unguent. It should be maintained in full force until the severity of the disease has completely subsided. The quantity of morphia necessary to compose the parts will vary, according to the age and other circumstances of the patient, from half a grain to a grain and a half being sprinkled upon the surface of the issue once or twice a day. Should the general health suffer from want of exercise, the limb may be put up in a suitable apparatus, and the child sent into the open air.

The violent contraction of the muscles, so common in this stage of the complaint, and a source of so much pain and distortion, may generally be promptly relieved by the use of the tenotome. The muscles which are most frequently at fault are the sartorius, pectineal, and short adductors, which, if they do not yield under the influence of chloroform, should be thoroughly divided near their origin, until all resistance to the extension of the limb ceases. The nature of this operation, for the practical application of which the profession is mainly indebted to Dr. Bauer, at Brooklyn, and Dr. Sayre, of New York, has been established in numerous instances, not only of coxalgia, but of other articular affections, and cannot be too highly appreciated.

In the *third stage* of the disease, when abscesses exist in and around the

Fig. 495.

Dr. Sayre's apparatus applied.

joint, accompanied by hectic irritation, the indications plainly are to evacuate the matter and to support the system. The knife should be introduced in such a manner as to make a valvular incision, as in an ordinary strumous collection, the opening being immediately closed with adhesive plaster, and the operation repeated at intervals of six, eight, or ten days, until all tendency to reaccumulation has disappeared. The object should be to permit as little air to penetrate the joint as possible, and at the same time to afford free discharge to the pent-up fluid. In any event, however, no matter what precautions may be used, more or less hectic irritation will be sure to follow, and should claim the special attention of the surgeon. In general, the most appropriate means for relieving it will be opium and quinine, with brandy, cod-liver oil, and elixir of vitriol. If the joint contain dead bone, the incision should be free and direct, so as to afford an opportunity of getting rid of it; for, so long as it remains, it must necessarily be productive of mischief. When the pus has been evacuated, the affected parts should be supported with some sorbefacient and slightly stimulating plaster, as the soap, galbanum, or ammoniac and mercurial, the latter being the best. The sinuses about the joint may be injected with a weak solution of iodine, iodide of iron, nitrate of silver, bichloride of mercury, permanganate of potassa, or chlorinated soda. If numerous, and not too deep, they may often be advantageously laid open, but in performing such an operation care must be taken to guard against pain and loss of blood. As soon as the patient is able, he should have the benefit of exercise in the open air, and a suitable opportunity should be sought for the institution of passive motion of the affected joint.

When the parts in and around the joint are so much diseased as to render recovery by the ordinary means entirely hopeless, recourse should be had to excision. The operation, the statistics of which will be given in the chapter on excision of the joints, may be conveniently performed by making a curved incision, from five to six inches in length, perpendicularly over the joint, in a line with the great trochanter, separating the parts, and cutting off the diseased structures with the saw or pliers. If more room is required, the incision may be crucial, or in the form of a T or V. The flaps are afterwards approximated with stitches and adhesive strips, and the immobility of the limb is secured by appropriate splints, pads, and bandages, as in fracture of the thigh-bone.

When the acetabulum is implicated, it should be dealt with in the same manner as the femur, every particle of diseased bone being removed with the pliers, gouge, chisel, and scraper.

When the patient has been exhausted by protracted suffering, and life is fast ebbing away, it has been proposed, as a dernier resort, to amputate at the hip-joint; and the records of surgery contain several examples, among others, one by Dr. Duffee, of this city, in which the operation has been followed by the most gratifying results. I should, nevertheless, hesitate before undertaking so grave a procedure, the more especially as the same end may generally be more readily attained by the more simple and less dangerous operation of excision.

SECT. VII.—CHRONIC RHEUMATIC ARTHRITIS.

The joints are liable to a peculiar form of disease, known under the name of chronic articular rheumatism, or chronic rheumatic arthritis, first systematically described by Dr. R. W. Smith and Dr. R. Adams, of Dublin, the latter of whom has published an able and elaborate treatise upon it. It occurs in both sexes, chiefly in elderly and middle-aged subjects among the laboring classes, though occasionally it is also observed in the higher orders of society, especially in the indolent and habitually intemperate in eating and drinking. The joints most prone to suffer are those of the hip, knee, wrist, and fingers; one of which only may be affected, or a number may be implicated simultaneously, or in more or less rapid succession. Sometimes the disease leaves one articulation, and fastens itself upon another; but, in general, when it has once effected a firm lodgment it holds on to it pertinaciously, now and then remitting, but seldom entirely intermitting, at least not for any length of time. Ill-fed and ill-clothed

persons, living in moist, underground apartments, or in damp, confined alleys, are particularly liable to it. A gouty, rheumatic predisposition probably favors its outbreak.

The immediate *cause* of this disease is generally suppression of the cutaneous perspiration from exposure to cold, or from long-continued immersion of the feet in water, as often happens in the laboring classes. Occasionally its origin is traceable to external injury, as a blow, sprain, or concussion. In the female, it is sometimes apparently dependent upon irregularity of the menses; and in both sexes it is frequently connected with disorder of the digestive apparatus, as dyspepsia, constipation, or derangement of the biliary secretion.

The disease often, if not ordinarily, approaches in a slow and stealthy manner, the first *symptoms* being usually merely a sense of soreness and stiffness of the affected joint, with slight derangement of the general health. As it progresses, the local distress assumes a more marked and open character; what was before only a feeling of uneasiness now becomes a source of real pain and distress. The joint gradually growing rigid, moves with great difficulty, and a careful examination seldom fails to detect fluctuation, dependent upon the presence of synovial fluid, an early product, and generally the principal one, of inflammation in its milder forms. When the effusion is considerable, it will necessarily seriously change the contour of the affected joint, the synovial membrane bagging across the ligaments, as is so apt to happen when the disease is seated in the knee, wrist, or elbow. It is seldom that pus forms in any case, even if unusually severe and protracted; but plastic matter is often poured out in large quantity, and it is the presence of this substance that causes the remarkable rigidity which so constantly attends the complaint in its more severe grades. Spasmodic twitchings of the muscles in the neighborhood of the affected joint commonly set in at an early period of the inflammation, and constitute a source of great distress, effectually interrupting sleep, and requiring large doses of anodynes for their relief.

The pain in chronic rheumatic arthritis is often excessive; it is always increased by motion and pressure, and is usually materially aggravated at night. It is of a dull, heavy, aching character, and frequently extends in different directions, but especially along the course of the larger nerves, which it sometimes follows to their very extremities. The general health suffers severely; the patient is feverish, and deprived of appetite and sleep; the bowels are constipated; and the skin is hot and arid. The urine, however, although commonly scanty and high-colored, does not deposit any lithic acid, a circumstance which remarkably distinguishes this disease from gout and rheumatism, properly so called.

In old cases of this disease, or in the strictly chronic form of it, the general health, although perhaps somewhat impaired, is comparatively good, and the patient may even grow fleshy and ruddy. His locomotive powers, however, are greatly deranged, and he is, in consequence, often obliged to use crutches. The affected joints are habitually tender, sore, and distorted, perhaps frequently presenting an appearance of being partially dislocated. Such a change is particularly liable to occur in the fingers, but is also occasionally noticed in the hip, shoulder, and other large articulations. Exostoses sometimes spring from the sides of the affected joints and serve to add to the deformity, already sufficiently great. The synovial bursae are also apt to suffer, becoming inflamed, enlarged, and distended with fluid. The muscles, in consequence of their perpetual inactivity, become atrophied and powerless. What strikes the observer as very peculiar, amidst these changes, is the entire absence of cretaceous deposits in and around the disabled joints.

Chronic rheumatic arthritis is essentially an inflammatory malady. If the affected structures be examined in the earlier stages of the disease, they will be found to exhibit indubitable evidence of vascular injection of the synovial membrane, and of the presence of synovial fluid, with here and there, perhaps, a patch of lymph, or more or less of this substance intermingled with the other secretion. Pus, as already stated, is seldom seen. When the disease is permitted to go on unchecked, great structural changes gradually take place, con-

sisting in the removal, either partial or entire, of the synovial membrane and articular cartilages, and the conversion of the extremities of the bones into a hard, ivory, or porcellaneous substance, totally destitute of its normal qualities. In many cases the ends of the bones have a beautiful polished aspect, being perfectly smooth and glistening; while in others they are remarkably rough and tuberculated, or beset with exostotic incrustations. The interarticular fibro-cartilages are generally completely destroyed, and the funicular ligaments often undergo partial absorption, while the capsular are liable to become stretched and relaxed, thus allowing the bones to slip away from each other, and produce an appearance of being partially dislocated. Finally, fibroid, fibro-cartilaginous, and osseous growths of various shapes and sizes, are extremely prone to form in the interior of joints thus affected.

What is the *pathology* of this disease? That it is of an inflammatory nature is unquestionable; but how it is produced, or what the peculiar condition of the system is which predisposes to its development, or which keeps the affection in play after it has been fairly established, are circumstances in its history of which we are totally ignorant.

The *diagnosis* is commonly very easy, especially in its more chronic forms. The history of the case, the excessive obstinacy of the disease, and the gradual failure of the functions of the affected joint, together with its distorted appearance, and the absence of cretaceous deposits in the structures around the articulation, and of lithic acid in the urine, always readily distinguish it from ordinary gout and rheumatism, the only maladies with which it is at all liable to be confounded.

The *prognosis* of chronic rheumatic arthritis is generally most unfavorable. In the milder forms of the disease, and in its earlier stages, a cure is certainly occasionally practicable, but under opposite circumstances the patient almost invariably remains a cripple for life, as it is impossible by any mode of treatment at present known to effect restoration of the disorganized structures of the affected joints.

Treatment.—In the treatment of this affection, everything depends upon the efficiency with which the case is met in its earliest stages; for after the morbid action has made serious inroads, all that can, in general, be expected from our remedial interference is a mitigation of suffering, seldom anything like a complete, permanent cure. Unfortunately it but too often happens that the disease has occasioned great disorganization of the affected structures before the practitioner is afforded an opportunity of taking it in hand. Considering its inflammatory character, the course of treatment to be adopted is indisputably the antiphlogistic, directed not to the part merely, but also, and in an especial manner, to the state of the general system, which, whatever may be the real pathology of the disorder, is always more or less extensively implicated. In this country there are few cases of chronic rheumatic arthritis which will not, in their earlier stages, bear active depletion by the lancet, purgatives, diaphoretics, and antimonials. The quantity of blood taken from the arm must of course depend strictly upon the condition of the constitution, as to the existence or absence of plethora, anorexia, and other evidence of vascular disturbance. Mercurial purgatives, administered in efficient doses, in union with jalap or rhubarb, and compound extract of colocynth, are among the most reliable means that can be employed for arresting the morbid action; and it would be difficult to conceive of any case in which they can altogether be dispensed with. At the same time, however, they must be used with caution. The improvement of the secretions always forms an important indication, and there is no class of remedies so likely to do this promptly and effectually as purgatives. After the violence of the disease has been moderated by these means the most efficient prescription, according to my observation, is a combination of morphia, antimony, and veratrum, given in full and sustained doses, until it makes its specific impression upon the heart and nervous system. Half a grain of morphia, with one-sixth of a grain of tartar emetic, and ten drops of tincture of veratrum, is a fair average dose for an adult, to be repeated once or twice in the twenty-four hours, accord-

ing to the severity of the suffering, or the effects of the remedy, which should, of course, always be carefully watched. Administered in this way, it promptly subdues pain, produces perspiration, and reduces vascular excitement. When this result has been brought about, the medicines are given in smaller or less frequently repeated doses, until the necessity for their exhibition entirely ceases.

Colchicum is seldom of any material benefit in this disease in any of its stages; for, although the disorder unquestionably generally partakes of a rheumatic or gouty nature, yet, as already stated, there is rarely any lithic acid deposit in the urine, or cretaceous formation within the joints, and this is probably one, if not the principal, reason of the inefficiency of the medicine. Dover's powder, so highly extolled by some practitioners in the treatment of chronic rheumatic arthritis, is both bulky and nauseous, and in every respect inferior to the articles mentioned in the preceding paragraph.

Among the more important topical remedies are leeches and fomentations, medicated with acetate of lead, opium, and aconite. Local steam baths are sometimes highly beneficial, the vapor being conducted by means of a tube directly to the inflamed parts. Cold applications are rarely admissible in any case, from their tendency to shock the system and cause metastasis. As the disease declines, recourse is had to the dilute tincture of iodine and to steady compression with the bandage. At a still later period, passive motion is instituted, and the parts around the joint are well douched and shampooed twice a day, in order to promote the absorption of effused fluids and the restoration of impaired function.

In the more advanced chronic forms of the affection the main reliance of the practitioner must be upon a proper regulation of the diet, which must be chiefly of a mild, farinaceous character, with a little white meat or fish at dinner; the preservation of the secretions by the occasional exhibition of a few grains of blue mass, or calomel; the steady, persistent use of iodide of iron, either alone or in union with iodide of potassium, and a residence in a dry, genial climate, exempt from sudden and severe vicissitudes. A sojourn of from three to six months at the Hot Springs of Arkansas, with the daily use of the warm baths obtainable at that place, will often prove serviceable. If the general health is much broken, cod-liver oil with iron and quinine may be required. In all cases the body should be incased in flannel, and gentle exercise should be frequently taken in the open air; a precaution of paramount importance in regard to the prevention of ankylosis, which is always so much favored by inactivity in all articular affections, whatever may be their character.

CHRONIC RHEUMATIC ARTHRITIS OF PARTICULAR JOINTS.

Although this disease may, as already stated, occur in any of the joints, it is by far most frequent in those of the carpus and fingers, where it is always readily recognized by the pain, stiffness, and permanent distortion which it occasions. The elbow, wrist, and ankle joints rarely suffer from it. When the malady is constitutional, the sterno-clavicular and acromio-clavicular articulations are liable to be invaded, and it then often requires more than ordinary care and skill to determine the diagnosis, especially if the parts have recently been subjected to local injury, as a blow or fall, thus exciting doubt as to whether the affection is one of rheumatism, dislocation, or fracture. In a practical point of view, however, it is chiefly in the lower jaw, spine, elbow, hip, and knee that the disease is of much interest.

Chronic Rheumatic Arthritis of the Lower Jaw.—In the lower jaw the disease is frequently symmetrical, although it rarely exists in an equal degree on both sides. The subjects are usually elderly men, after the fiftieth year, who have been exposed to all kinds of hardships. Among the earlier symptoms is a slight degree of stiffness in the joint, which is soon succeeded by pain and by a creaking, crackling, or grating sensation, particularly annoying during eating, and often so loud as to be heard at some distance. The cause of this sensation is evidently an absence of synovial fluid. The condyloid process increases in size, and forms

a distinct knob in front of the ear. The mouth is opened with difficulty, mastication is greatly restricted, and the chin and face are distorted from the destruction of the articular eminences, allowing the external pterygoid muscles to drag the bone out of its natural position. When both joints are affected the chin is elongated, but if only one suffers the jaw is thrown towards the opposite side, very much as in a traumatic unilocular dislocation. The pain is generally worse at night than in the day, as well as in damp than in dry weather, and there is often considerable enlargement of the lymphatic ganglions of the upper part of the neck.

The *diagnosis* is determined principally by the age of the patient, the gradual changes in the joint, face, and chin, and the symmetrical character of the attack.

The fibro-cartilage is destroyed, the surfaces of the joint, divested of their natural coverings, are of a porcellaneous hardness, the articular eminences are flattened, if not entirely wasted, and the condyles are enlarged and disfigured.

Chronic Rheumatic Arthritis of the Spine.—This disease occasionally attacks the spine, especially the cervical and dorsal divisions; the subjects are generally elderly persons, and the attack is commonly associated with the same affection in other regions of the body. The most distressing forms of the disease are met with in the lower part of the neck and the upper part of the back, where it often causes great deformity, the curvature being a combination of the posterior and lateral varieties. The trunk, in time, becomes greatly arched, and the patient is unable to stand erect, or to turn his head from side to side. The earlier symptoms are gradually increasing pain and stiffness, and a crackling noise heard on motion of the affected joints.

The *diagnosis* rests upon the history of the case, as the age of the patient, the absence of local tenderness, or, what is tantamount to this, the tolerance of the parts under rough manipulation, and the fact that the patient does not experience any marked pain if the spine is forcibly concussed through the skull as he sits upon his chair.

Chronic Rheumatic Arthritis of the Shoulder.—When this disease attacks the shoulder it may come on either as an independent affection, as when it is caused by external violence, or, as is more generally the case, it coexists with chronic arthritis of some of the other articulations. The earlier symptoms are, stiffness of the joint, with a crackling sensation on moving the arm, an increased deposit of synovial fluid, more or less pain, especially at night, and in damp states of the atmosphere, and gradual wasting of the deltoid muscle. As the disease proceeds, the joint becomes more and more rigid, from the dryness of its surfaces, and the effects of plastic deposits, the shoulder presents a wasted appearance, the acromion and coracoid processes stand out in bold relief, and the movements of the arm are restricted within the most narrow limits. The patient can still abduct the limb slightly, but he finds it impossible to elevate it to a horizontal level, or to carry it behind the trunk. The head of the humerus is generally a little raised, as well as somewhat nearer the middle line than natural, the scapula is unusually mobile, and a remarkable depression exists at the posterior part of the joint.

The *diagnosis* is established by the history of the case. When the disease is constitutional, its coexistence with similar attacks in other joints is sufficiently denotive of its character. When it is caused by injury it may be confounded with tuberculosis, from which, however, it may readily be distinguished by the crackling sound that attends the movements of the arm, and by the fact that the parts are much more tolerant of pressure and rude manipulation. In caries of the joint the slightest motion is productive of intense pain, there is more swelling, with greater constitutional disturbance, and the affected structures ultimately run into suppuration, an effect which is never witnessed in chronic rheumatic arthritis.

When a person, affected with this disease, is so unfortunate as to meet with a fall or blow upon the hip, the surgeon may find it very difficult, if not impossible, unless he is fully acquainted with the previous history of the case, to determine whether the affection is one merely of sprain, of fracture, or dislocation.

The head of the humerus, partially absorbed, flattened, and tuberculated, is

denuded of cartilage at one place, porous at another, and eburnized at a third. In very old cases, it generally rests against the under surface of the acromion and coracoid processes, in a kind of socket formed for its accommodation. These processes themselves are often greatly changed; sometimes they are much enlarged and roughened, at other times completely wasted. The glenoid cavity is expanded and excavated, while its margin is elevated into a sharp, irregular ridge. Sometimes all these parts are soldered together by osseous matter.

The soft structures around the joint are materially altered, the muscles are pale, wasted, and flabby, the long head of the biceps is destroyed, the tendons have a macerated appearance, as if their fibres were separated into their original elements, and the capsular ligament is thickened and perforated, or hypertrophied at one point and atrophied at another.

Chronic Rheumatic Arthritis of the Hip.—This affection is nearly always met with in elderly persons laboring under the rheumatic diathesis. For this reason it frequently coexists with the same disease in other parts of the body. Sometimes, however, it is limited to one of the hip-joints, and is then generally caused either by external violence, or by suppression of the cutaneous perspiration. Falls and blows upon the great trochanter occasionally give rise to it. Males are by far its most common subjects.

The earliest evidence of the disease is a stiffness in the joint, which is generally most annoying in the morning when the patient gets out of bed, but which gradually diminishes after exercise, provided this is not carried to severe fatigue, which always produces an opposite effect. At first, there is little or no pain, but after a while this becomes a prominent and distressing symptom. It is either dull and aching or of a gnawing or boring character, and is most severe in the joint and in the great trochanter, from which, however, it radiates in different directions, as up into the gluteal region and down along the thigh, often as far as the knee and even the leg. It is increased by motion and exercise, is worse at night than in the daytime, and is influenced by the state of the atmosphere. The patient walks very lame, and as he supports the weight of his body upon the sound limb, the affected one is drawn up in such a manner as to give it a shortened appearance. The foot is strongly everted, the power of rotation is lost, the buttock is flattened, the gluteo-femoral crease is effaced, the muscles of the thigh are attenuated, and a crackling sensation is perceived on moving the joint. The patient cannot stoop when he stands, and when he sits he is compelled to stretch out his leg. The trochanter is unusually prominent, and progression is painful and restricted. Great shortening of the limb at length takes place, often amounting, apparently, to two and a half or even to three inches, but, in reality, seldom exceeding one-third of that amount, and depending mainly upon the wasted condition of the head and neck of the thigh-bone.

The *diagnosis* of this disease is generally sufficiently easy. The principal affections with which it is liable to be confounded are tuberculosis and sciatica. From the former it may usually be readily distinguished by the fact that the malady nearly always occurs in elderly subjects, by its frequent coexistence with similar attacks in other parts of the body, by the peculiar crackling sensation produced on moving the joint, by the absence of heat, swelling, and tendency to suppuration, by the greater tolerance of the parts under rude manipulation, by the flattening of the nates, by the remarkable prominence of the trochanter, and by the natural appearance of the calf of the leg. In sciatica, the pain is seated in the sacro-lumbar region; it is generally of a neuralgic character, is often very severe at night, and always extends along the outer and posterior part of the thigh. The motions of the hip-joint are unimpaired, and the limb retains its natural length and direction.

The joint, in the confirmed stage of the disease, is greatly changed in its structure. Its surfaces, completely denuded of cartilage, are remarkably altered in their shape, and exhibit a rough porcellaneous appearance. The head of the femur, especially its tip, is reduced in size, and often worn down to a mere stump. Sometimes it is quite conical. The neck of the bone is shortened, unusually horizontal, and eburnized. The acetabulum is deformed, scooped out,

and scabrous at its margin. The round ligament is annihilated, while the osseous is thickened and perforated, partially destroyed, or hypertrophied and inlaid with bony matter. The muscles around the joint are thin, pale, and flabby. In any old cases, the articular surfaces are frequently connected together by stalactites and osseous bridges.

The changes wrought in this disease are beautifully illustrated in the annexed cuts, from Druitt. Fig. 496 represents the head of the thigh-bone, and fig. 497 the corresponding acetabulum, in an advanced state of rheumatic arthritis.

Fig. 496.

Appearance of the head of the femur in chronic
rheumatic arthritis.

Fig. 497.

Changes of the acetabulum in chronic rheumatic
arthritis.

Chronic Rheumatic Arthritis of the Knee.—This disease usually begins as an ordinary attack of synovitis. The pain, at first very slight, gradually increases and is generally most severe at the inner part of the joint, particularly over the inner condyle. The stiffness progresses until, at length, it amounts almost to complete ankylosis; the knee is deformed, and crackles when moved; the hamstring muscles are rigidly contracted; the leg is strongly everted; and the tibia is partially dislocated from the femur. The patella is often considerably displaced, and foreign bodies, or cartilaginous concretions, may occasionally be detected in the joint.

The *diagnosis* is based upon the chronicity of the disease, the absence of tendency to suppuration, the marked eversion of the leg, the dislocated appearance of the knee, the singular condition of the ligament of the patella, which forms a distinct band in front of the joint, and the tuberculated state of the margins of the patella and of the condyles of the femur.

The disease not infrequently appears at a very early age. I have repeatedly witnessed it in children, especially in boys, before the fifteenth year, and in some instances as early as the twelfth.

Treatment.—To the treatment of this affection, as it occurs in these different articulations, little is to be added to what has already been said in regard to the subject in general. The most important internal remedies, especially in the earlier stages of the attack, after venesection, are mercurial purgatives and a dry diaphoretics, followed, in due time, by a regular course of alterants, especially the iodide of potassium. In chronic arthritis of the lower jaw the local means are leeches and a series of small blisters in front of the ears. When the disease attacks the spine, dorsal recumbency will be necessary, and should

be observed for a long time, otherwise horrible deformity may be the result. A similar plan of treatment, in addition to the use of splints, will be required when the disease involves the hip, knee, or ankle. The elbow and forearm should be well supported in a sling, when it affects the shoulder. Passive motion, friction, shampooing, douching, and electricity come in play at a later period of the disease, and sometimes afford marked relief. Contracted tendons, muscles, and aponeuroses are divided with the tenotome. When the case is of long standing, all that can be done is to mitigate suffering.

SECT. VIII.—ANCHYLOSIS.

Several varieties of this complaint are met with, as the complete and incomplete, in the former of which all motion is annihilated, while in the latter motion still exists, although in a very limited degree. There is another form of stiffness, in which the structures of the joint retain their normal characters, but are prevented from being exercised by disease in the neighboring tissues; and this circumstance has induced the division of ankylosis into true and false, or into intra-articular and extra-articular. This classification is not only more philosophical than the other, but is of paramount importance in a practical point of view, as it leads to a just appreciation of the etiology of the disorder, and also, as a necessary consequence, to proper therapeutic indications. The terms complete and incomplete refer, in fact, merely to different degrees of the same complaint, and might be very well replaced by the words fibrous and osseous, as more expressive of the true nature of the ankylosis.

1. *Intra-articular Ankylosis*.—Intra-articular ankylosis may be produced by whatever has a tendency to excite inflammation in the synovial membrane of a joint, with a deposit of plastic matter upon its free surface. Hence it may arise from all kinds of external injury, as wounds, sprains, blows, and contusions; the presence of interarticular bodies; luxations, especially neglected ones; and fractures which involve the joints, or are situated in their immediate neighborhood. Gout, rheumatism, syphilis, and struma also act as exciting causes; but of all these causes, as well as others that might be referred to, there are none which so frequently occasion ankylosis, permanent and irremediable, as fractures and dislocations. Long disuse powerfully disposes to the occurrence of stiffness of certain articulations, especially those of the fingers, wrist, and elbow. I am aware that the force of this influence has been denied, but certainly not upon just grounds; for experience has shown, and my own observation has repeatedly verified the fact, that this circumstance alone is often capable of producing ankylosis of a very obstinate and intractable character. Such an event need not surprise us if we remember that motion is the appropriate stimulus of an articulation, and that more or less of this is just as necessary to its healthy action as food is to the stomach, light to the eye, or sound to the ear. When motion is suspended for any length of time, the synovial membrane becomes dry and stiff, and, eventually taking on inflammation, pours out plastic matter, which effectually obliterates its cavity and so induces permanent ankylosis, on the principle that when the function of a part is destroyed its structure is essentially changed in its character, if not completely annihilated.

All joints are liable to this variety of ankylosis, but it takes place much more easily in the ginglymoid than in the orbicular, and among the former it is more frequently witnessed in the knee, elbow, and wrist, than in any others. Several joints are sometimes involved in the occurrence, especially when it arises from gout, rheumatism, or syphilis; and instances have been noticed in which nearly every articulation in the body was completely ankylosed, the skeleton forming almost one rigid piece.

In every case of intra-articular ankylosis a series of changes is obliged to take place before the loss of function can be complete. Hence if we examine a joint which is about to become thus affected, it will be found that the first step consists in the effusion and organization of plastic matter, and the second in the

gradual conversion of this matter, first, into fibrous, or cellulo-fibrous tissue, then into cartilage, and finally into bone, the latter forming the ultimate link in the morbid chain. A fibrous or fibro-cellular ankylosis generally terminates, at no distant period, in osseous ankylosis, the change from one to the other being regularly progressive until the process is completed, this being the method which nature adopts to effect a cure when any serious accident befalls a movable articulation.

These adhesions and transformations vary in extent, not less than in structure and consistence. Sometimes they are very limited, a considerable portion of the synovial membrane remaining sound, or being only slightly affected by disease, and then the connection between the opposing surfaces is generally easily broken, so that ultimately the joint may regain its original functions. In a second series of cases, again, the fibrous or fibro-ligamentous bands are not only more numerous, but they extend from different points of one articular cartilage to the other, and thus either obliterate the synovial cavity, or, at all events, completely destroy its usefulness. Finally, in a third class of cases, the new tissue becomes the recipient of osseous deposits, which, gradually increasing in quantity, in time usurp the place of the synovial membrane and cartilage, and ultimately solder the ends of the two bones firmly together. Hence, if a section be made of what was once the joint, the areolar and solid structures will be found to be inseparably blended, their junction being no longer indicated by the thin layer of compact

Fig. 498.

Osseous ankylosis of the knee-joint.

substance which originally invested their heads. These changes are well seen in fig. 498, from a specimen in my cabinet. The femur and tibia are firmly united to each other and to the patella, the three forming one solid piece.

The *treatment* of this variety of ankylosis must vary according to the nature and extent of the tissues upon which it depends, and also, in no inconsiderable degree, upon the character of the articulation. When the case is of recent standing, when the adhesions are weak and of limited extent, and when the joint is not too complicated in its structure, a reasonable hope may be entertained that the new tissues may be broken up, and brought fully under the action of the absorbents, so that, in due time, and with proper diligence, the functions of the joint may be measurably, if not completely, re-established. Under opposite circumstances, however, a cure will not only be difficult, but generally impracticable.

Much may be done in most cases of intra-articular ankylosis, in the way of prevention, by the steady and persistent use of sorbefacients and passive motion. The attendant inflammation having been divested of its violence, the plastic deposits must be disposed of before they have an opportunity of becoming firmly organized, and the only way in which this can be effected is by frictions with stimulating lotions, aided by the cold or hot douche, and by rubbing the articular surfaces gently against each other, at first once every forty-eight hours, and then once or twice a day, until all the matter has been absorbed, and the synovial membrane has regained its primitive characters. Much more skill and attention are required in these cases than the surgeon is usually willing to bestow, and it unfortunately too frequently happens that their entire management is confided to persons who are wholly ignorant of the manner in which it should be conducted. The consequence is that a great deal of harm is commonly done, which it is impossible subsequently to rectify by any mode of treatment, however carefully carried out. For the

most part, indeed, the time for successful interposition has gone by when the case falls into judicious hands.

When, through neglect, mismanagement, or unavoidable circumstances, the movements of the joint have become greatly impaired, or when the case has already attained a certain degree of chronicity, instead of abandoning the patient to his fate, an attempt should be made to break up the adhesions by forcible means, not forgetting, however, that they must, nevertheless, be conducted with a certain degree of gentleness in order to prevent mischief. The patient being thoroughly anæsthetized, the distal portion of the limb is moved with one hand, while the proximal, or that nearest to the trunk, is firmly steadied with the other, at the same time that it rests upon a smooth, solid surface, so as to afford a better fulcrum for the other part to move upon. Thus, when we wish to break up the adhesions in ankylosis of the knee, the thigh is firmly pressed upon the table, while the leg, drawn away from its edge, is alternately flexed and extended to as great a degree as may be compatible with safety. In operating on the elbow a similar procedure is adopted, the arm being the fixed, and the forearm the movable, point. Much muscular power is frequently required to conduct these movements, and yet the greatest care must be taken so to distribute this power as not to produce any mischief. Not long ago, in one of my cases at the Jefferson College Clinic, I was so unfortunate, in attempting to remedy an ankylosed elbow, as to fracture the humerus just above the joint, the accident being announced by a loud snap, very different from the crackling noise which attends the severance of fibrous, or cellulo-fibrous bands. The patient, a female, aged sixty-five, had dislocated her elbow nearly three months previously, and it is highly probable that the bone had become softened and brittle from an extension of the inflammation. Such an occurrence is not always avoidable; for I am quite sure that in the case in question much less force was used than I had often employed before on similar occasions without any such mishap.

The amount of force and the length of time during which it should be continued must vary according to the circumstances of the case, especially the strength and extent of the adhesions. The efforts should always be very gentle at first, and gradually increased as the parts are found to yield. If the joint is tender, it may be necessary to spend a few days in preliminary treatment, dieting, purging, and perhaps even bleeding the patient, to prepare him for the approaching ordeal. The subsequent management must be of a strictly antiphlogistic character, and the repetition of the operation must depend upon the effects of the first trial; at all events, it should now be conducted with great gentleness, and rather with a view to a passive than an active result. In many cases it will be found advantageous, after the first efforts, to extend the joint by an angular splint, worked by a screw, and worn steadily until the object is attained, the degree of tension being regulated at will by the patient himself. Apparatus for fulfilling these indications is delineated in the accompanying sketches. Fig. 499 represents Kolbe's contrivance for straightening the knee; and fig. 500 that of Stromeyer for rectifying ankylosis of the elbow.

These attempts at curing ankylosis may not only eventuate in fracture of the bones, either of the joint itself, or of those in their immediate vicinity, but they may give rise to consequences still more disastrous, as violent inflammation, erysipelas, gangrene, and even loss of life. All such operations then should be conducted with the utmost caution, especially when performed with the aid of machinery.

Finally, when it is found that there is no possible chance of effecting a cure, but that ankylosis is inevitable, every effort, compatible with safety, should be made to place the affected limb in a situation most conducive to its future usefulness. Thus, the wrist should be straight; the elbow bent at a right angle with the arm; and the arm brought close to the side of the body, and as far forwards as possible, to enable the patient to put his hand to his mouth. In ankylosis of the hip, the thigh is flexed slightly upon the pelvis; when the knee is concerned, the leg is inclined somewhat backwards; and in ankylosis of the ankle, the foot

is placed at a right angle to the leg; the parts being found to be most servicable when held in these several positions.

Fig. 499.

Fig. 500.

Particular occupations may, however, render it proper to deviate from the above rules. Thus, Mr. Bryant, of London, had under his charge a painter who desired that his arm might be ankylosed in the straight position; and a turner, whose leg, at his own request, was allowed to remain at a right angle with the thigh, as he was thus the better enabled to move his wheel.

Oseous ankylosis is incurable, except by an operation, which consists in cutting out a V-shaped portion of bone, as originally proposed and successfully executed by Dr. John Rhea Barton, in 1826. His patient was a sailor, twenty-one years of age, who had lost the use of his hip-joint, by an injury from a severe fall on shipboard. The thigh was drawn up nearly at a right angle with the axis of the pelvis, the knee projecting inwards across the sound limb, and the foot presenting forwards. All attempts at correcting the malposition having failed, a crucial incision was carried through the integuments, over the most prominent part of the great trochanter, when, raising the flaps thus defined, the operator next detached the muscles connected with this portion of the bone, making a passage both in front and behind the femur for the easy introduction of the finger. With a saw constructed for the purpose, he now divided the bone through the great trochanter and a part of its neck in a transverse direction. The wound being lightly dressed, the limb was placed in Desault's fracture-apparatus, as modified by Physick, and the case managed upon strictly antiphlogistic principles.

Twenty days after the operation the limb was gently and cautiously moved, in different directions, but neither so long, nor so violently, as to produce severe irritation. At first the motion was repeated only every other day, but afterwards every twenty-four hours, for four months, at which time the artificial joint had acquired such a degree of freedom as to enable the patient to walk about with the aid merely of a cane. The wound had healed, and he could not only rotate the foot, but abduct it twenty inches, and carry it forwards and backwards to a still greater extent. The case is reported in full, with an illustrative plate, in the third volume of the *North American Medical and Surgical Journal*.

The operation of Dr. Barton, or, more correctly speaking, an operation conducted upon similar principles, is particularly applicable to the relief of deformity of the lower extremity, dependent upon ankylosis of the knee-joint. The proceeding was first executed by Professor Gibson, in 1838, in the case of a boy, seventeen years of age, who made an excellent recovery, the limb being only half an inch shorter than the sound one. It is divided into four distinct stages. In the first, a triangular flap is formed of the soft parts in front of the

limb, consisting of the integuments and the extensor muscles, by making two horizontal incisions, one just above the superior border of the patella, and the other two inches and a half higher up, down to the bone. This flap, which has a broad base on the inside of the thigh, is then dissected up, and held out of the way. The next step is to remove a V-shaped portion of the femur, which is easily done with a narrow saw, care being taken not to divide the bone completely, for fear of injuring the popliteal artery. In the third stage the bone is fractured, by gently flexing the limb; and, lastly, the flap is replaced and secured by suture. The dressing is completed by putting the limb upon a double inclined plane, where it is retained for the next ten days, or until the ends of the broken bone have become enveloped in plastic matter, when it is placed in the straight position, in a suitable apparatus for insuring quietude. The patient is usually able to rise, and walk about on crutches, in six weeks.

The sawing of the bone constitutes one of the leading objects of interest in this operation; if the wedge-shaped piece is too large, there is a possibility of non-union, whereas, if it is too small, it may be impracticable to straighten the limb sufficiently. In order to avoid these contingencies, all that is necessary is to measure the angle of deformity, and then to saw out a portion of bone equal to the complement of that angle. The adjoining cut, fig. 501, will afford a better idea of the nature of the operation than any description of it, however elaborate.

Dr. J. Kearney Rodgers modified this operation by connecting the ends of the bone with silver wire, on the supposition that the proceeding would tend to expedite their reunion. Such a measure, however, is hardly required if proper care is taken to keep the limb well secured during the after-treatment.

Of 10 cases of this operation, of which the results have transpired, 8 recovered and 2 perished, death in one having been caused by an attack of intercurrent pneumonia from accidental exposure. The success would thus seem to be eminently flattering. When the operation is done at the knee, the risk is always greater when the joint retains a portion of its natural structures than when these structures are completely annihilated.

The amount of shortening after this operation is variable. In general, it ranges from half an inch to an inch and a quarter. In a case by Dr. Buck, of New York, in which the excision was performed through the patella, the patient recovered with a shortening of four inches.

An operation for the relief of bony ankylosis of the knee, based upon the same principles as that of Dr. Barton, but differing from it in some essential particulars, was performed by Professor Pancoast at the Clinic of the Jefferson Medical College in the winter of 1859, the patient being a youth on whom extension had previously been tried in vain. It consisted in perforating with a stout gimlet the femur subcutaneously, through a single opening, at half a dozen points, just above the knee, and then forcibly breaking the bone. The limb was placed in appropriate apparatus, the upper end of the inferior fragment forming an angle with the apex projecting into the ham. A large abscess formed at the seat of fracture, but, with this exception, the case progressed favorably, and the boy made a good recovery, the foot coming down well, and the limb being nearly as straight as could be desired in such a condition of the knee-joint.

An operation similar to the above was performed by Professor Brainard, in 1860, upon a man twenty-three years of age; but in this case the femur was divided through its condyles by means of a perforator. The patient recovered with a good limb. In another case of ankylosis of the knee, the patella was

Fig. 501.

Barton's operation.

detached subcutaneously from the femur and tibia, and excellent motion of the joint obtained.

The trifling suffering which sometimes follows this operation is well exemplified in a case that was under my charge at the College Clinic in 1861, in a man twenty-two years of age. The knee, injured several years previously, was completely ankylosed, and the leg flexed nearly at a right angle with the thigh. After much difficulty, I finally succeeded by means of perforators and levers, constructed for the purpose, in severing the connections between the femur and tibia, on the one hand, and the femur and patella, on the other, and had the satisfaction of effecting an excellent cure, without the slightest untoward symptom after the operation. The leg was placed at a proper angle, in suitable apparatus, and the treatment, during the first few days, was rigidly antiphlogistic. The immunity from suffering in this case was doubtless due to the fact that the natural structures of the joint had been completely destroyed.

2. *Extra-articular Ankylosis*.—In extra-articular ankylosis, the spurious ankylosis of some authors, the articular structures retain, at least for a time, their normal characters, but their functions are impaired or suspended by the diseased condition of the surrounding parts. Several distinct causes may induce such a result, of which muscular contraction, vicious cicatrices, osseous deposits, and the pressure of new growths, or aneurismal tumors, and paralysis of the articular muscles, are the most common and efficient.

a. Of the several causes here enumerated as capable of producing rigidity of a joint, permanent contraction of the muscles and tendons, which naturally influence and control its movements, is the most frequent. Examples of this are constantly met with in gout, rheumatism, fractures, and dislocations, where, from an extension of the inflammation which attends these diseases and accidents, motion is greatly impeded, if not completely destroyed, by this occurrence. The influence exerted by permanent contraction of the muscles is well illustrated in club-foot and analogous distortions, where the joints are not only crippled in their functions, but greatly changed in their form and relations, giving the limb that peculiar aspect, from the resemblance to which it derives its name. Similar effects may be caused by the contraction of the aponeuroses.

b. Secondly, a joint may become stiff from a vicious cicatrice, as, for instance, one caused by a burn or scald. The tendency of the new substance is to go on contracting until it produces hideous deformity, stretching the soft parts to their utmost capacity, and drawing the neighboring articular surfaces completely out of their natural position. The morbid adhesions formed after ulcerative pyalism generally give rise to distressing and often irremediable ankylosis of the temporo-maxillary articulation.

c. In gout, rheumatism, and other affections, as well as in certain accidents, the motions of the joints are occasionally destroyed by the formation of osseous bridges, extending across the articulation, from one bone to the other. Such an occurrence is most frequently met with in the sacro-iliac symphyses, and in the joints of the vertebræ; it sometimes occurs also in the more perfect joints, especially the ginglymoid. In fractures, followed by exuberant callus, the muscles and tendons, in the vicinity of the neighboring joint, may be so completely imprisoned by the new matter, as to cause ankylosis of the worst kind.

d. Ankylosis may be produced, in greater or less degree, by the development of various kinds of tumors, or morbid growths, in the neighborhood of an articulation, or in direct contact with it, interfering with its functions, and ultimately, if not removed, perhaps annihilating them. Thus, an aneurism of the popliteal region may cause stiffness of the knee, and an osteo-sarcoma of the jaw, partial ankylosis of the temporo-maxillary joint.

e. Finally, paralysis of the muscles of a joint may induce a certain degree of ankylosis; we constantly observe cases where, from long disuse of an articulation from this cause, its functions are permanently lost. The shoulder-joint frequently becomes stiff and useless, from palsy of the deltoid interfering with its natural movements.

It is extremely probable that the most of the causes here enumerated may, if

long continued, induce permanent ankylosis, in consequence of the operation of the general pathological law, that, when a part ceases to perform its functions, it gradually degenerates, and is ultimately completely deprived of its characteristic attributes. Nature abhors everything that is useless, and when a joint is once rendered passive, the synovial membrane, losing its secreting faculty, becomes dry, and is at length converted into fibrous, or fibro-cellular tissue.

The *treatment* of extra-articular ankylosis must be regulated by our knowledge of the nature of the exciting cause, which should, therefore, always be clearly ascertained before we attempt to interpose any curative agents. Thus, if it be found to depend upon contraction of the muscles, tendons, or aponeuroses, whether singly or unitedly, the only remedy, in confirmed cases, is their subcutaneous division; whereas, in recent cases, it may often be relieved by a course of friction, douching, and passive motion, aided by gentle exercise on the part of the patient. Vicious cicatrices must be cut out, and, if possible, replaced by new substance; such a procedure, however, is not always practicable, and, therefore, most cases of this description go on from bad to worse until they are rendered wholly irremediable. Osseous bridges, circles, or bands may occasionally be removed with the saw and pliers; morbid growths are excised, or, as in aneurism, the artery leading to it is tied; and paralysis of the muscles is relieved by stimulating frictions, the cold douche, shampooing, and electricity, the general health being at the same time improved by tonics, alterants, and exercise in the open air.

SECT. IX.—NEURALGIC AND HYSTERICAL AFFECTIONS.

The joints are occasionally the seat of neuralgia, although not nearly as often as is generally imagined, especially if it be regarded as an independent lesion. As a complication of coxalgia and other articular affections it is sufficiently frequent. It is not improbable that in many of the cases in which it is referred to the joints it is in reality situated altogether exterior to them, in the structures immediately around, and not in those directly concerned in their composition. Its most common sites by far are the knee and hip. As an independent affection, neuralgia is most frequent in young, delicate, nervous females, soon after the appearance of the menses, of the derangement of which it is occasionally an exponent. No period of life, temperament, habit, or occupation, however, is exempt from it. The attacks are sometimes strictly periodical, precisely like those of an intermittent fever, coming and going regularly once a day, or every forty-eight hours; but more frequently they are irregular, the patient being tormented nearly incessantly, the pain being now slight, now severe, and then perhaps again entirely absent, though never very long at one time. The paroxysms are often coincident with neuralgia in other parts of the body, alternating with it, usurping its place, or going on with it simultaneously. The pain is either of a dull, heavy, aching character, or sharp, lancinating, and darting, flying about in fits and starts, in different directions, almost with the rapidity of lightning. It is usually attended with more or less soreness and tenderness on pressure, motion, and percussion, and sometimes with a slight degree of tumefaction or puffiness of the parts around the affected joint, which often entirely disappears in the intervals of the attacks. Motion also is usually somewhat impeded, and, when the hip is involved, there may even be considerable deformity of the lower part of the spine and of the pelvis. In the more aggravated cases the whole limb may be swollen, tender, and disabled; and under such circumstances there is commonly also a sense of numbness, extending to the very extremity of the member. The general health is not always appreciably affected; often, however, there is marked disorder of the digestive organs, with a sallow state of the skin, headache, constipation, and derangement of the renal secretion. In the female the symptoms are often of an hysterical character, and are liable to frequent exacerbations in consequence of the peculiar state of the mind, which is generally morbidly sensitive, and absorbed in selfishness and disagreeable forebodings.

It is of great moment to discriminate carefully between neuralgic and other affections of the joints, inasmuch as a wrong diagnosis may lead to serious errors in practice, inducing perhaps the employment of harsh measures where gentle alone are required; or, on the other hand, allowing the patient to move about and exercise the joint when he ought to observe the most perfect quietude. In general the history of the case, the peculiar nature of the pain, the suddenness of the attack, the absence of constitutional disturbance, and the perfect freedom of motion of the affected joint, when the surgeon takes hold of the limb and attempts to carry it about in different directions, especially when the patient is under the influence of chloroform, will serve to distinguish it from organic disease of the articulations. When, however, there is any doubt respecting the real nature of the complaint, the examination should be repeated again and again, and varied in every possible manner, so as to elicit the true state of the case. In many instances the best diagnostic is the success or failure of anti-neuralgic remedies.

The *hysterical* form of this affection appears to be much more common in England than in America, where, judging from personal observation, it is quite infrequent both in town and country. Sir B. C. Brodie, who was the first to call attention to it, declares that among the higher classes of society in London, at least four-fifths of the female patients, supposed to labor under disease of the articulations, suffer under hysteria, and nothing else. The pain is generally excessively severe; it is aggravated by the slightest motion and pressure, and is usually confined to one particular spot, from which, however, it is liable to shift to other points. It is frequently associated with excessive morbid sensibility of the surface, and is commonly located, not in the joints, but in the parts around them; often, indeed, apparently in the skin, or in the skin and muscles. Spinal irritation often exists, the extremities are cold, the pulse is small and feeble, the countenance is pale, the breathing is, at times, much embarrassed, the bowels are irregular, and the stomach is oppressed with flatulence. The disease is most common in young girls soon after the age of puberty.

In the *treatment* of articular neuralgia the first object should be to ascertain, if possible, the nature of the exciting cause, and then to direct our remedies accordingly. Attention to the diet, bowels, and secretions should, throughout, be kept prominently in view. The malady very often has its origin in a vitiated state of the alimentary canal, or in the suppression of some important habitual discharge, by correcting or restoring which the symptoms frequently disappear without any further effort. In general, however, anti-neuralgic remedies, properly so called, will be needed, and of these unquestionably the best are quinine, strychnia, and arsenious acid, in doses varying from three to five grains of the first, with the twenty-fifth of a grain of the second, and the tenth of a grain of the last, three times daily. When there is marked evidence of anemia, iron may be advantageously combined with these articles. If, on the other hand, the patient is plethoric, I usually add to each dose from the sixth to the eighth of a grain of tartar emetic, with a view to its relaxing and diaphoretic effects. Morphia also forms a valuable adjuvant, and can rarely be dispensed with. Colchicum often proves very serviceable, affording prompt relief when everything else fails. It is particularly valuable when the disease partakes of a rheumatic or gouty character.

As topical remedies the most valuable are, soap liniment, with a liberal addition of laudanum and chloroform, kept constantly upon the part with a piece of flannel; the steam of hot water, conveyed to the joint from a tube connected with a boiler near the bed; frictions with atropia, veratria, or aconite ointment; and the employment of electro-magnetism. Leeches may be used when the articulation exhibits evidence of being inflamed, but, as a general rule, they will be found to afford only very transient relief. Motion of the affected limb, especially in protracted cases, is usually highly beneficial, and should never be neglected.

In the hysterical variety of the disease assafoetida and valerian often prove highly beneficial, especially if combined with chalybeate tonics. When the dis-

ease is associated with disorder of the menstrual function, great advantage will generally accrue from an occasional aloetic purge and the steady use of the compound iron mixture. The cold bath, change of air, residence at the sea-shore, and exercise on horseback will sometimes effect relief when everything else fails. Brodie relates a number of cases in which the disease was almost instantaneously cured by an accident, as a fall or blow upon the suffering joint.

END OF VOL. I.

BLANCHARD & LEA'S MEDICAL AND SURGICAL PUBLICATIONS.

TO THE MEDICAL PROFESSION.

The greatly enhanced cost of materials and labor has obliged us to make a rather increase in the price of some of our books, and we have been forced in a few instances to change the style of binding from leather to cloth, in consequence of the increased difficulty of procuring a full supply of the superior quality leather which we require for our publications. We have made these changes with reluctance, and can only hope that we may not be forced to further modifications by a continued increase of cost.

For the present, therefore, the prices on this Catalogue are those at which our books can generally be furnished by booksellers, who can readily procure for their customers any which they may not have on hand. Where access to bookstores is not convenient, we will forward them at these prices, *free by mail*, to any post office in the United States. In all cases the amount must accompany the order, as we open accounts only with dealers; we assume no risks of the mail, either on the money or the books, and we can supply nothing but our own publications. Gentlemen desirous of purchasing will, therefore, find it more advantageous to deal with the nearest bookseller whenever practicable, or to send orders through their merchants visiting the larger cities.

BLANCHARD & LEA.

PHILADELPHIA, September, 1864.

* * We have recently issued an ILLUSTRATED CATALOGUE of Medical and Scientific Publications, forming an octavo pamphlet of 80 large pages, containing specimens of illustrations, notices of the medical press, &c. &c. It has been prepared without regard to expense, and will be found one of the handsomest specimens of typographical execution as yet presented in this country. Copies will be sent to any address, by mail, free of postage, on receipt of nine cents in stamps.

Catalogues of our numerous publications in miscellaneous and educational literature are forwarded on application.

☞ The attention of physicians is especially solicited to the following important new works and new editions, just issued or nearly ready:—

Bowman's Medical Chemistry, a new edition,	See page	4
Bowman's Practical Chemistry, a new edition,	"	4
Bennett on the Uterus, sixth edition,	"	4

NO INCREASE OF PRICE.

TWO MEDICAL PERIODICALS, FREE OF POSTAGE,
Containing about Fifteen Hundred large octavo pages,
FOR FIVE DOLLARS PER ANNUM.

THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, subject to postage, when not paid for in advance, \$5 00
THE MEDICAL NEWS AND LIBRARY, invariably in advance, 1 00
OR, BOTH PERIODICALS mailed, FREE OF POSTAGE (as long as the existing rates are maintained), to any post-office in the United States, for Five Dollars remitted in advance.

It will be observed that notwithstanding the great increase in the cost of production, the subscription price has been maintained at the former very moderate rate, which has long rendered it among the

CHEAPEST OF AMERICAN MEDICAL PERIODICALS

The publishers trust that this course will be responded to by the profession in a liberal manner to the subscription list.

THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES

EDITED BY ISAAC HAYS, M. D.,

is published Quarterly, on the first of January, April, July, and October. Each number contains about two hundred and seventy large octavo pages, handsomely and appropriately illustrated wherever necessary. It has now been issued regularly for more than FORTY years, and has been under the control of the present editor for more than a quarter of a century. For so long a period, it has maintained its position in the highest rank of medical periodicals in this country and abroad, and has received the cordial support of the entire profession in this country. Its Collaborators will be found to contain a large number of the most distinguished names of the profession in every section of the United States, rendering the department devoted to

ORIGINAL COMMUNICATIONS

full of varied and important matter, of great interest to all practitioners.

As the aim of the Journal, however, is to combine the advantages presented by all the varieties of periodicals, in its

REVIEW DEPARTMENT

will be found extended and impartial reviews of all important new works, presenting with novelty and interest, together with very numerous

BIBLIOGRAPHICAL NOTICES.

including nearly all the medical publications of the day, both in this country and Great Britain, and a choice selection of the more important continental works. This is followed by the

QUARTERLY SUMMARY,

being a very full and complete abstract, methodically arranged, of the

IMPROVEMENTS AND DISCOVERIES IN THE MEDICAL SCIENCES.

This department of the Journal, so important to the practising physician, is the object of special care on the part of the editor. It is classified and arranged under different heads, thus affording the researcher of the reader in pursuit of particular subjects, and will be found to present a full and accurate digest of all observations, discoveries and inventions recorded in every branch of medical science. The very extensive arrangements of the publishers are such as to afford the editor complete materials for this purpose, as he not only regularly receives

ALL THE AMERICAN MEDICAL AND SCIENTIFIC PERIODICALS

but also twenty or thirty of the more important Journals issued in Great Britain and on the Continent, thus enabling him to present in a convenient compass a thorough and complete abstract of everything interesting or important to the physician occurring in any part of the civilized world.

To their old subscribers, many of whom have been on their list for twenty or thirty years, the publishers feel that no promises for the future are necessary, but those who may desire for the first time to subscribe, can rest assured that no exertion will be spared to maintain the Journal in the high position which it has occupied for so long a period.

By reference to the terms it will be seen that, in addition to this large amount of valuable practical information on every branch of medical science, the subscriber, by paying in advance, becomes entitled, without further charge, to

THE MEDICAL NEWS AND LIBRARY.

a monthly periodical of thirty-two large octavo pages. Its "NEWS DEPARTMENT" presents current information of the day, while the "LIBRARY DEPARTMENT" is devoted to presenting and works on various branches of medicine. Within a few years, subscribers have thus received, without expense, many works of the highest character and practical value, such as "Walters' Practice," "Todd and Bowman's Physiology," "Magaigue's Surgery," "West on Children," "West on Females, Part I," "Haber-shon on the A. Mentary Canal," "Simps on Females," &c.

The work selected for the year 1874, commencing in the number for January, is

CONSUMPTION; ITS EARLY AND REMEDIAL STAGES.

BY EDWARD SMITH, M. D.,

Assistant Physician to the Dispensary for Consumption Hospital, &c.

The special experience of the author in the treatment of this disease invests his work with practical authority which cannot but render it satisfactory to subscribers.

It will thus be seen that for the small sum of FIVE DOLLARS, paid in advance, the subscriber will obtain a Quarterly and a Monthly periodical,

EMBRACING ABOUT FIFTEEN HUNDRED LARGE OCTAVO PAGES.

Those subscribers who do not pay in advance will bear in mind that their subscription of Five Dollars will entitle them to the Journal, only, without the News and that they will be at the expense of their own postage on the receipt of each number. The advantage of a remittance when obtaining the Journal will thus be apparent.

Remittances of subscriptions can be mailed at our risk, when a certificate is taken from the Postmaster that the money is duly inclosed and forwarded.

Address **BLANCHARD & LEA, Philadelphia.**

ASHTON (T. J.),

Surgeon to the Blenheim Dispensary, &c.

ON THE DISEASES, INJURIES, AND MALFORMATIONS OF THE RECTUM AND ANUS; with remarks on Habitual Constipation. From the third and enlarged London edition. With handsome illustrations. In one very beautifully printed octavo volume, of about 300 pages, extra cloth. \$3 00.

The most complete one we possess on the subject. *Medico-Chirurgical Review*.

We are satisfied, after a careful examination of the volume, and a comparison of its contents with those of its leading predecessors and contemporaries, that the best way for the reader to avail himself of

the excellent advice given in the concluding paragraph above, would be to provide himself with a copy of the book from which it has been taken, and diligently to read its instructive pages. They may secure to him many a triumph and fervent blessing.—*Am. Journal Med. Sciences*.

ALLEN (J. M.), M. D.,

Professor of Anatomy in the Pennsylvania Medical College, &c.

THE PRACTICAL ANATOMIST; or, The Student's Guide in the Dissecting-ROOM. With 266 illustrations. In one handsome royal 12mo. volume, of over 600 pages, extra cloth. \$2 00.

We believe it to be one of the most useful works upon the subject ever written. It is handsomely illustrated, well printed, and will be found of convenient size for use in the dissecting-room.—*Med. Examiner*.

However valuable may be the "Dissector's Guides" which we, of late, have had occasion to

notice, we feel confident that the work of Dr. Allen is superior to any of them. We believe with the author, that none is so fully illustrated as this, and the arrangement of the work is such as to facilitate the labors of the student. We most cordially recommend it to their attention.—*Western Lancet*.

ANATOMICAL ATLAS.

By Professors H. H. SMITH and W. E. HORNER, of the University of Pennsylvania. 1 vol. 8vo., extra cloth, with nearly 650 illustrations. See SMITH, p. 26.

ABEL (F. A.), F. C. S. AND C. L. BLOXAM.

HANDBOOK OF CHEMISTRY, Theoretical, Practical, and Technical; with a Recommendatory Preface by Dr. HOFMANN. In one large octavo volume, extra cloth, of 662 pages, with illustrations. \$1 25.

ASHWELL (SAMUEL), M. D.,

Obstetric Physician and Lecturer to Guy's Hospital, London.

A PRACTICAL TREATISE ON THE DISEASES PECULIAR TO WOMEN.

Illustrated by Cases derived from Hospital and Private Practice. Third American, from the Third and revised London edition. In one octavo volume, extra cloth, of 528 pages. \$3 50.

The most useful practical work on the subject in the English language.—*Boston Med. and Surg. Journal*.

The most able, and certainly the most standard and practical, work on female diseases that we have yet seen.—*Medico-Chirurgical Review*.

ARNOTT (NEILL), M. D.

ELEMENTS OF PHYSICS; or Natural Philosophy, General and Medical. Written for universal use, in plain or non-technical language. A new edition, by ISAAC HAYS, M. D. Complete in one octavo volume, leather, of 484 pages, with about two hundred illustrations. \$2 25.

BIRD (GOLDING), A. M., M. D., &c.

URINARY DEPOSITS: THEIR DIAGNOSIS, PATHOLOGY, AND THERAPEUTICAL INDICATIONS. Edited by EDMUND LLOYD BIRKETT, M. D. A new American, from the last and enlarged London edition. With eighty illustrations on wood. In one handsome octavo volume, of about 400 pages, extra cloth. \$3 00.

It can scarcely be necessary for us to say anything of the merits of this well-known Treatise, which so admirably brings into practical application the results of those microscopical and chemical researches regarding the physiology and pathology of the urinary secretion, which have contributed so much to the increase of our diagnostic powers, and

to the extension and satisfactory employment of our therapeutic resources. In the preparation of this new edition of his work, it is obvious that Dr. Golding Bird has spared no pains to render it a faithful representation of the present state of scientific knowledge on the subject it embraces.—*British and Foreign Med.-Chir. Review*.

BARLOW (GEORGE H.), M. D.

Physician to Guy's Hospital, London, &c.

A MANUAL OF THE PRACTICE OF MEDICINE. With Additions by D. F. CONNIX, M. D., author of "A Practical Treatise on Diseases of Children," &c. In one handsome octavo volume, extra cloth, of over 600 pages. \$2 50.

We recommend Dr. Barlow's Manual in the warmest manner as a most valuable vade-mecum. We have had frequent occasion to consult it, and have

found it clear, concise, practical, and sound.—*Boston Med. and Surg. Journal*.

BUCKLER ON THE ETIOLOGY, PATHOLOGY, AND TREATMENT OF FIBRO-BRONCHITIS AND RHEUMATIC PNEUMONIA. In one 8vo. volume, extra cloth. pp. 150. \$1 25.

BRODIE'S CLINICAL LECTURES ON SURGERY. 1 vol. 8vo. cloth. 350 pp. \$1 25.

BLOOD AND URINE (MANUALS ON). BY JOHN WILLIAM GRIFFITH, G. OWEN REESE, AND ALFRED MARKWICK. One thick volume, royal 12mo., extra cloth, with plates. pp. 400. \$1 25.

BUDD (GEORGE), M. D.

Professor of Medicine in King's Co

ON DISEASES OF THE LIVER. Third

enlarged London edition. In one very handsome octavo fully colored plates, and numerous wood-cuts. pp. 500.

Has fairly established for itself a place among the classical medical literature of England.—*British and Foreign Medico-Chir. Review.*Dr. Budd's Treatise on Diseases of the Liver is now a standard work in Medical literature, and during the intervals which have elapsed between the successive editions, the author has incorporated into the text t

BUMSTEAD (FREEMAN J.) M. D.,

Lecturer on Venereal Diseases at the College of Physicians and Surgeons, New York, &c.

THE PATHOLOGY AND TREATMENT OF VENEREAL DISEASES,
including the results of recent investigations upon the subject. Second edition, thoroughly revised and much improved. With illustrations on wood. In one very handsome octavo volume, of about 700 pages. \$4 75 (*Now Ready.*)

By far the most valuable contribution to this particular branch of practice that has seen the light within the last score of years. His clear and accurate descriptions of the various forms of venereal disease, and especially the methods of treatment he proposes, are worthy of the highest encomium. In these respects it is better adapted for the assistance of the every-day practitioner than any other with which we are acquainted. In variety of methods proposed, in minuteness of direction, guided by careful discrimination of varying forms and complications, we write down the book as unsurpassed. It is a work which should be in the possession of every practitioner.—*Chicago Med. Journal*, Nov. 1861.

The foregoing admirable volume comes to us, embracing the whole subject of syphilology, resolving many a doubt, correcting and confirming many an entertained opinion, and in our estimation the best, completest, fullest monograph on this subject in our language. As far as the author's labors themselves are concerned, we feel it a duty to say that he has not only exhausted his subject, but he has presented to us, without the slightest hyperbole, the best digested treatise on these diseases in our language. He has carried its literature down to the present moment, and has achieved his task in a manner which cannot but redound to his credit.—*British American Journal*, Oct. 1861.

We believe this treatise will come to be regarded as high authority in this branch of medical practice, and we cordially commend it to the favorable notice of our brethren in the profession. For our own part, we candidly confess that we have received many new ideas from its perusal, as well as modified many views which we have long, and, as we now think, erroneously entertained on the subject of syphilis.

To sum up all in a few words, this book is one which no practising physician or medical student can very well afford to do without.—*American Med. Times*, Nov. 2, 1861.

The whole work presents a complete history of venereal diseases, comprising much interesting and valuable material that has been spread through medical journals within the last twenty years—the period of many experiments and investigations on the subject—the whole carefully digested by the aid of the author's extensive personal experience, and offered to the profession in an admirable form. Its completeness is secured by good plates, which are especially full in the anatomy of the genital organs. We have examined it with great satisfaction, and congratulate the medical profession in America on the nationality of a work that may fairly be called original.—*Berkshire Med. Journal*, Dec. 1861.

One thing, however, we are impelled to say, that we have met with no other book on syphilis, in the English language, which gave so full, clear and impartial views of the important subjects on which it treats. We cannot, however, refrain from expressing our satisfaction with the full and perspicuous manner in which the subject has been presented, and the careful attention to minute details, so useful—not to say indispensable—in a practical treatise. In conclusion, if we may be pardoned the use of a phrase now become stereotyped, but which we here employ in all seriousness and sincerity, we do not hesitate to express the opinion that Dr. Bumstead's Treatise on Venereal Diseases is a "work without which no medical library will hereafter be considered complete."—*Boston Med. and Surg. Journal*, Sept. 5, 1861.

BARCLAY (A. W.), M. D.,

Assistant Physician to St. George's Hospital, &c.

A MANUAL OF MEDICAL DIAGNOSIS; being an Analysis of the Signs and Symptoms of Disease. Third American from the second and revised London edition. In one neat octavo volume, extra cloth, of 451 pages. \$3 50. (*Just Ready.*)

The demand for a second edition of this work shows that the vacancy which it attempts to supply has been recognized by the profession, and that the efforts of the author to meet the want have been successful. The revision which it has enjoyed will render it better adapted than before to afford assistance to the learner in the prosecution of his studies, and to the practitioner who requires a convenient and accessible manual for speedy reference in the exigencies of his daily duties. For this latter purpose its complete and extensive Index renders it especially valuable, offering facilities for immediately turning to any class of symptoms, or any variety of disease.

The task of composing such a work is neither an easy nor a light one; but Dr. Barclay has performed it in a manner which meets our most unqualified approbation. He is no mere theorist; he knows his work thoroughly, and in attempting to perform it, has not exceeded his powers.—*British Med. Journal*.

We venture to predict that the work will be deservedly popular, and soon become, like Watson's Practice, an indispensable necessity to the practitioner.—*N. A. Med. Journal*.

An inestimable work of reference for the young practitioner and student.—*Nashville Med. Journal*.

We hope the volume will have an extensive circulation, not among students of medicine only, but practitioners also. They will never regret a faithful study of its pages.—*Cincinnati Lancet*.

An important acquisition to medical literature. It is a work of high merit, both from the vast importance of the subject upon which it treats, and also from the real ability displayed in its elaboration. In conclusion, let us bespeak for this volume that attention of every student of our art which it so richly deserves—that place in every medical library which it can so well adorn.—*Pennsylvan Medical Journal*.

BARTLETT (ELISHA), M. D.**THE HISTORY, DIAGNOSIS, AND TREATMENT OF THE FEVERS OF THE UNITED STATES.** A new and revised edition. By ALONZO CLARK M. D., Prof. of Pathology and Practical Medicine in the N. Y. College of Physicians and Surgeons, &c. In one octavo volume, of six hundred pages, extra cloth. Price \$4 00.

It is a work of great practical value and interest, containing much that is new relative to the several diseases of which it treats, and, with the additions of the editor, is fully up to the times. The distinctive features of the different forms of fever are plainly and forcibly portrayed, and the lines of demarcation carefully and accurately drawn, and to the American practitioner is a more valuable and safe guide than any work on fever extant.—*Ohio Med. and Surg. Journal*.

This excellent monograph on febrile disease, has

stood deservedly high since its first publication. It will be seen that it has now reached its fourth edition under the supervision of Prof. A. Clark, a gentleman who, from the nature of his studies and pursuits, is well calculated to appreciate and discuss the many intricate and difficult questions in pathology. His annotations add much to the interest of the work, and have brought it well up to the condition of the science as it exists at the present day in regard to this class of diseases.—*Southern Med. and Surg. Journal*.

BRANDE (WM. T.) D. C. L., AND ALFRED I
Of her Majesty's Mint, &c. Professor of

CHEMISTRY. In one handsome 8vo. volume of
(Now Ready, May, 1863)

"Having been engaged in teaching Chemistry in this M and the other for a period of thirty years, it has appeared to already existing, there was room for an additional volume, the use of students. In preparing such a volume for the mind, that the student in the present day has much to learn, the acquisition of this learning."—AUTHORS' PREFACE.

In reprinting this volume, its passage through the press by chemist, who has sedulously endeavored to secure the ac ture. No notes or additions have been introduced, but the authors with some corrections and revisions of the first two inserted.

In so progressive a science as Chemistry, the latest work the subject as modified by the results of the latest investigati age has been made the most of, and that the work possesses clearness, simplicity of style, and lucid arrangement, are m of the English medical press.

It needs no great sagacity to foretell that this book will be, literally, the Handbook in Chemistry of the student and practitioner. For clearness of language, accuracy of description, extent of information, and freedom from pedantry and mysticism of modern chemistry, no other text-book comes into competition with it. The result is a work which for fulness of matter, for lucidity of arrangement, for clearness of style, is as yet without a rival. And long will it be without a rival. For, although with the necessary advance of chemical knowledge addenda will be required, there will be little to take away. The fundamental excellences of the book will remain, preserv ing it for years to come, what it now is, the best guide to the study of Chemistry yet given to the world.—*London Lancet*, Dec. 30, 1862.

Most assuredly, time has not abated one whit of the fluency, the vigor, and the clearness with which they not only have composed the work before us, but have, so to say, cleared the ground for it, by hitting right

Assistant Surgeon Charing Cross H

A TREATISE ON DISEASES OF THE JOI
ings on wood. In one very handsome octavo volume, of

At the outset we may state that the work is worthy of much praise, and bears evidence of much thoughtful and careful inquiry, and here and there of no slight originality. We have already carried this notice further than we intended to do, but not to the extent the work deserves. We can only add, that the perusal of it has afforded us great pleasure. The author has evidently worked very hard at his subject, and his investigations into the Physiology and Pathology of Joints have been carried on in a manner which entitles him to be listened to with attention and respect. We must not omit to mention the very admirable plates with which the volume is enriched. We seldom meet with such striking and fa *Med. Time*

CARPENTER (WILLIAM B.), M. D., F. R. S.,

Examiner in Physiology and Comparative Anatomy in the University of London.

PRINCIPLES OF HUMAN PHYSIOLOGY; with their chief applications to Psychology, Pathology, Therapeutics, Hygiene, and Forensic Medicine. A new American, from the last and revised London edition. With nearly three hundred illustrations. Edited, with additions, by FRANCIS GURNEY SMITH, M. D., Professor of the Institutes of Medicine in the Pennsylvania Medical College, &c. In one very large and beautiful octavo volume, of about nine hundred large pages, handsomely printed, extra cloth, \$5 25.

For upwards of thirteen years Dr. Carpenter's work has been considered by the profession generally, both in this country and England, as the most valuable compendium on the subject of physiology in our language. This distinction it owes to the high attainments and unwearied industry of its accomplished author. The present edition (which, like the last American one, was prepared by the author himself), is the result of such extensive revision, that it may almost be considered a new work. We need hardly say, in concluding this brief notice, that while the work is indispensable to every student of medicine in this country, it will amply repay the practitioner for its perusal by the interest and value of its contents.—*Boston Med. and Surg. Journal*.

This is a standard work—the text-book used by all medical students who read the English language. It has passed through several editions in order to keep pace with the rapidly growing science of Physiology. Nothing need be said in its praise, for its merits are universally known; we have nothing to say of its defects, for they only appear where the science of which it treats is incomplete.—*Western Lancet*.

The most complete exposition of physiology which any language can at present give.—*Brit. and For. Med.-Chirurg. Review*.

The greatest, the most reliable, and the best book on the subject which we know of in the English language.—*Stethoscope*.

To eulogize this great work would be superfluous. We should observe, however, that in this edition the author has remodelled a large portion of the former, and the editor has added much matter of interest, especially in the form of illustrations. We may confidently recommend it as the most complete work on Human Physiology in our language.—*Southern Med. and Surg. Journal*.

The most complete work on the science in our language.—*Am. Med. Journal*.

The most complete work now extant in our language.—*N. O. Med. Register*.

The best text-book in the language on this extensive subject.—*London Med. Times*.

A complete cyclopædia of this branch of science.—*N. Y. Med. Times*.

The profession of this country, and perhaps also of Europe, have anxiously and for sometime awaited the announcement of this new edition of Carpenter's Human Physiology. His former editions have for many years been almost the only text-book on Physiology in all our medical schools, and its circulation among the profession has been unsurpassed by any work in any department of medical science.

It is quite unnecessary for us to speak of this work as its merits would justify. The mere announcement of its appearance will afford the highest pleasure to every student of Physiology, while its perusal will be of infinite service in advancing physiological science.—*Ohio Med. and Surg. Journ.*

BY THE SAME AUTHOR.

ELEMENTS (OR MANUAL) OF PHYSIOLOGY, INCLUDING PHYSIOLOGICAL ANATOMY. Second American, from a new and revised London edition. With one hundred and ninety illustrations. In one very handsome octavo volume, leather. pp. 566. \$4 00.

In publishing the first edition of this work, its title was altered from that of the London volume, by the substitution of the word "Elements" for that of "Manual," and with the author's sanction the title of "Elements" is still retained as being more expressive of the scope of the treatise.

BY THE SAME AUTHOR.

PRINCIPLES OF COMPARATIVE PHYSIOLOGY. New American, from the Fourth and Revised London edition. In one large and handsome octavo volume, with over three hundred beautiful illustrations. pp. 752. Extra cloth, \$5 00.

This book should not only be read but thoroughly studied by every member of the profession. None are too wise or old, to be benefited thereby. But especially to the younger class would we cordially commend it as best fitted of any work in the English language to qualify them for the reception and comprehension of those truths which are daily being developed in physiology.—*Medical Counsellor*.

Without pretending to it, it is an encyclopedia of the subject, accurate and complete in all respects—a truthful reflection of the advanced state at which the science has now arrived.—*Dublin Quarterly Journal of Medical Science*.

A truly magnificent work—in itself a perfect physiological study.—*Ranking's Abstract*.

This work stands without its fellow. It is one few men in Europe could have undertaken; it is one

no man, we believe, could have brought to so successful an issue as Dr. Carpenter. It required for its production a physiologist at once deeply read in the labors of others, capable of taking a general, critical, and unprejudiced view of those labors, and of combining the varied, heterogeneous materials at his disposal, so as to form an harmonious whole. We feel that this abstract can give the reader a very imperfect idea of the fulness of this work, and no idea of its unity, of the admirable manner in which material has been brought, from the most various sources, to conduce to its completeness, of the lucidity of the reasoning it contains, or of the clearness of language in which the whole is clothed. Not the profession only, but the scientific world at large, must feel deeply indebted to Dr. Carpenter for this great work. It must, indeed, add largely even to his high reputation.—*Medical Times*.

CHURCHILL (FLEETWOOD), M. D., M. R. I. A.
ON THE THEORY AND PRACTICE OF MIDWIFERY. A new American
 from the fourth revised and enlarged London edition. With Notes and Additions, by D. FRANKS
 COMBES, M. D., author of a "Practical Treatise on the Diseases of Children," &c. With 104
 illustrations. In one very handsome octavo volume, of nearly 700 large pages, extra cloth, \$4 00.

This work has been so long an established favorite, both as a text-book for the learner and as a
 reliable aid to consultation for the practitioner, that in presenting a new edition it is only necessary
 to call attention to the very extended improvements which it has received. Having had the benefit
 of two revisions by the author since the last American reprint, it has been materially enlarged, and
 Dr. Churchill's well-known conscientious industry is a guarantee that every portion has been thor-
 oughly brought up with the latest results of European investigation in all departments of the sci-
 ence and art of obstetrics. The recent date of the last Dublin edition has not left much of novelty
 for the American editor to introduce, but he has endeavored to insert whatever has since appeared,
 together with such matters as his experience has shown him would be desirable for the American
 student, including a large number of illustrations. With the exception of the author he has added
 in the form of an appendix, some chapters from a little "Manual for Midwives and Nurses," re-
 cently issued by Dr. Churchill, believing that the details there presented can hardly fail to prove of
 advantage to the junior practitioner. The result of all these additions is that the work now em-
 braces fully one-half more matter than the last American edition, with nearly one-half more illus-
 trations, so that a 4thwithstanding the use of a smaller type, the volume contains almost two hundred
 pages more than before.

No effort has been spared to secure an improvement in the mechanical execution of the work
 equal to that which the text has received, and the volume is confidently presented as one of the
 hand-sonest that has thus far been laid before the American profession; while the very low price
 at which it is offered should secure for it a place in every lecture-room and on every office table.

A better book in which to learn these important
 points we have not met than Dr. Churchill's. Every
 page of it is full of instruction, the opinion of all
 writers of authority is given on questions of diffi-
 culty, as well as the directions and advice of the
 learned author himself, to which he adds the result
 of statistical inquiry, putting statistics in their pro-
 per place and giving them their due weight, and no
 more. We have never read a book more free from
 professional jealousy than Dr. Churchill's. It ap-
 pears to be written with the free design of a book on
 medicine, viz: to give all that is known on the sub-
 ject of which he treats, both theoretically and prac-
 tically, and to advance such opinions of his own as
 he believes will benefit the dual science, and insure
 the safety of the patient. We have said enough to
 convey to the profession that this book of Dr. Church-
 ill's is admirably suited for a book of reference
 for the practitioner, as well as a text-book for the
 student, and we hope it may be extensively per-
 ceived amongst our readers. To them we most
 strongly recommend it.—*Dublin Medical Press*

To bestow praise on a book that has received such
 marked approbation would be superfluous. We need
 only say, therefore, that if the first edition was
 thought worthy of a favorable reception by the
 medical public, we can confidently affirm that this
 will be found much more so. The lecturer, the
 practitioner, and the student, may all have recourse
 to its pages, and derive from their perusal much in-
 struction and instruction in everything relating to the-
 oretical and practical midwifery.—*Dublin Quarterly*
Journal of Medical Science

A work of very great merit, and such as we can
 confidently recommend to the study of every obste-
 trician practitioner.—*London Medical Gazette*

Few treatises will be found better adapted as a
 text-book for the student, or as a manual for the
 frequent consultation of the young practitioner.—
American Medical Journal

Were we reduced to the necessity of having but
 one work on midwifery, and permitted to choose,
 we would unhesitatingly select Churchill.—*Western*
Med and Surg Journal

It is impossible to conceive a more useful and
 elegant manual than Dr. Churchill's Practice of
 Midwifery.—*Provincial Medical Journal*

Certainly, in our opinion, the very best work on
 the subject which exists.—*N. Y. Eclectic*

No work holds a higher position, or is more de-
 serving of being placed in the hands of the tyro,
 the advanced student, or the practitioner.—*Medical*
Examiner

Previous editions have been received with mark-
 ed favor, and they deserved it; but this, reprinted
 from a very late Dublin edition, carefully revised
 and brought up by the author to the present time,
 does present an unusually accurate and able ex-
 position of every important particular embraced in
 the department of midwifery. The clearness,
 directness, and precision of its teachings, together
 with the great amount of statistical research which
 its text exhibits, have served to place it already in
 the foremost rank of works in this department of re-
 medical science.—*N. O. Med and Surg Journal*

In our opinion, it forms one of the best if not the
 very best text-book and epitome of obstetric science
 which we at present possess in the English lan-
 guage.—*Monthly Journal of Medical Science*

The clearness and precision of style in which it is
 written, and the great amount of statistical research
 which it contains, have served to place it in the first
 rank of works in this department of medical science.
 —*N. Y. Journal of Medicine*

This is certainly the most perfect system extant.
 It is the best adapted for the purposes of a text-
 book, and that which the whole community could
 find in one book, should select in preference to all
 others.—*Southern Medical and Surgical Journal*

BY THE SAME AUTHOR. (Lately Published.)

ON THE DISEASES OF INFANTS AND CHILDREN. Second American
 Edition, revised and enlarged by the author. Edited, with Notes, by W. V. KEATING, M. D. In
 one large and handsome volume, extra cloth, of over 700 pages. \$4 00.

In preparing this work a second time for the American profession, the author has spared no
 labor in giving it a very thorough revision, introducing several new chapters, and rewriting others,
 while every portion of the volume has been subjected to a severe scrutiny. The efforts of the
 American editor have been directed to supplying such information relative to matters peculiar
 to this country as might have escaped the attention of the author, and the whole may, there-
 fore, be safely pronounced one of the most complete works on the subject accessible to the Ameri-
 can Profession. By an alteration in the size of the page, these very extensive additions have
 been accommodated without unduly increasing the size of the work.

BY THE SAME AUTHOR.

DICKSON (S. H.), M
 Professor of Practice of Medicine in the Jefferson Med
ELEMENTS OF MEDICINE; a Compendious V
 penetics, or the History and Treatment of Diseases. Second
 handsome octavo volume, of 750 pages, extra cloth. \$3 75

The steady demand which has so soon exhausted the first e
 that the author was not mistaken in supposing that a volum
 elementary manual of practice, which should present the les
 practical results, in a condensed and perspicuous manner. I
 and fruitless speculations, it embodies what is most requisite
 some time what the active practitioner wants when obliged, u
 refresh his memory on special points. The clear and attrac
 whole easy of comprehension, while his long experience give
 where acknowledged. Few physicians, indeed, have had wit
 experience, and few, perhaps, have used them to better purpo
 posed to study and practice, the present edition, revised and b
 will doubtless maintain the reputation already acquired as a
 text-book on the Practice of Medicine.

DRUITT (ROBERT), M. R.
THE PRINCIPLES AND PRACTICE OF MO
 and revised American from the eighth enlarged and improv
 four hundred and thirty-two wood-engravings. In one vol
 of nearly 700 large pages, extra cloth, \$4 00.

A work which like DRUITT'S SURGERY has for so many ye
 ing favorite with all classes of the profession, needs no specia
 to a revised edition. It is only necessary to state that the au
 work up to its well earned reputation of presenting in a su
 condition of every department of surgery, considered both as
 services of a competent American editor have been employed
 have escaped the author's attention, or may prove of servic
 several editions have appeared in London since the issue of it
 has had the benefit of repeated revisions by the author, result
 improvement. The extent of these additions may be estimat
 about one-third more matter than the previous American e
 adoption of a smaller type, the pages have been increased by
 hundred and fifty wood-cuts have been added to the former six

A marked improvement will also be perceived in the mech
 work, which, printed in the best style, on new type, and fine
 regards external finish; while at the very low price affixed
 volumes accessible to the profession.

This popular volume, now a most comprehensive
 work on surgery, has undergone many corrections,
 improvements, and additions, and the principles and
 the practice of the art have been brought down to
 the latest record and observation. Of the operations
 in surgery it is impossible to speak too highly. The
 descriptions are so clear and concise, and the illus-
 trations so accurate and numerous, that the student
 can have no difficulty, with instrument in hand, and
 book by his side, over the dead body, in obtaining
 a proper knowledge and sufficient tact in this much
 neglected department of medical education.—*British*
and Foreign Medico-Chirurg. Review, Jan 1860

In the present edition the author has entirely re-
 written many of the chapters, and has incorporated
 the various improvements and additions in modern
 surgery. On carefully going over it, we find that

 of

DALTON, JR. (J. C.), M. D.

Professor of Physiology in the College of Physicians, New York.

A TREATISE ON HUMAN PHYSIOLOGY, designed for the use of Students and Practitioners of Medicine. Third edition, revised, with nearly three hundred illustrations on wood. In one very beautiful octavo volume, of 700 pages, extra cloth, \$5 00. (*Just Ready, 1861.*)

The rapid demand for another edition of this work sufficiently shows that the author has succeeded in his efforts to produce a text-book of standard and permanent value, embodying within a moderate compass all that is definitely and positively known within the domain of Human Physiology. His high reputation as an original observer and investigator, is a guarantee that in again revising it he has introduced whatever is necessary to render it thoroughly on a level with the advanced science of the day, and this has been accomplished without unduly increasing the size of the volume.

No exertion has been spared to maintain the high standard of typographical execution which has rendered this work admittedly one of the handsomest volumes as yet produced in this country.

It will be seen, therefore, that Dr. Dalton's best efforts have been directed towards perfecting his work. The additions are marked by the same features which characterize the remainder of the volume, and render it by far the most desirable text-book on physiology to place in the hands of the student which, so far as we are aware, exists in the English language, or perhaps in any other. We therefore have no hesitation in recommending Dr. Dalton's book for the classes for which it is intended, satisfied as we are that it is better adapted to their use than any other work of the kind to which they have access.—*American Journal of the Med. Sciences*, April, 1861.

It is, therefore, no disparagement to the many books upon physiology, most excellent in their day, to say that Dalton's is the only one that gives us the science as it was known to the best philosophers throughout the world, at the beginning of the current year. It states in comprehensive but concise diction, the facts established by experiment, or other method of demonstration, and details, in an understandable manner, how it is done, but abstains from the discussion of unsettled or theoretical points. Herein it is unique; and these characteristics render it a text-book without a rival, for those who desire to study physiological science as it is known to its most successful cultivators. And it is physiology thus presented that lies at the foundation of correct pathological knowledge; and this in turn is the basis of rational therapeutics; so that pathology, in fact, becomes of prime importance in the proper discharge of our every-day practical duties.—*Cincinnati Lancet*, May, 1861.

Dr. Dalton needs no word of praise from us. He is universally recognized as among the first, if not the very first, of American physiologists now living. The first edition of his admirable work appeared but two years since, and the advance of science, his

own original views and experiments, together with a desire to supply what he considered some deficiencies in the first edition, have already made the present one a necessity, and it will no doubt be even more eagerly sought for than the first. That it is not merely a reprint, will be seen from the author's statement of the following principal additions and alterations which he has made. The present, like the first edition, is printed in the highest style of the printer's art, and the illustrations are truly admirable for their clearness in expressing exactly what their author intended.—*Boston Medical and Surgical Journal*, March 28, 1861.

It is unnecessary to give a detail of the additions; suffice it to say, that they are numerous and important, and such as will render the work still more valuable and acceptable to the profession as a learned and original treatise on this all-important branch of medicine. All that was said in commendation of the getting up of the first edition, and the superior style of the illustrations, apply with equal force to this. No better work on physiology can be placed in the hand of the student.—*St. Louis Medical and Surgical Journal*, May, 1861.

These additions, while testifying to the learning and industry of the author, render the book exceedingly useful, as the most complete exposé of a science, of which Dr. Dalton is doubtless the ablest representative on this side of the Atlantic.—*New Orleans Med Times*, May, 1861.

A second edition of this deservedly popular work having been called for in the short space of two years, the author has supplied deficiencies, which existed in the former volume, and has thus more completely fulfilled his design of presenting to the profession a reliable and precise text-book, and one which we consider the best outline on the subject of which it treats, in any language.—*N. American Medico-Chirurg. Review*, May, 1861.

DUNGLISON, FORBES, TWEEDIE, AND CONOLLY.

THE CYCLOPÆDIA OF PRACTICAL MEDICINE: comprising Treatises on the Nature and Treatment of Diseases, Materia Medica, and Therapeutics, Diseases of Women and Children, Medical Jurisprudence, &c. &c. In four large super-royal octavo volumes, of 3254 double-columned pages, strongly and handsomely bound, with raised bands. \$14 00.

* * * This work contains no less than four hundred and eighteen distinct treatises, contributed by sixty-eight distinguished physicians, rendering it a complete library of reference for the country practitioner.

The most complete work on Practical Medicine extant; or, at least, in our language.—*Buffalo Medical and Surgical Journal*.

For reference, it is above all price to every practitioner.—*Western Lancet*.

One of the most valuable medical publications of the day—as a work of reference it is invaluable.—*Western Journal of Medicine and Surgery*.

It has been to us, both as learner and teacher, a work for ready and frequent reference, one in which modern English medicine is exhibited in the most advantageous light.—*Medical Examiner*.

The editors are practitioners of established reputation, and the list of contributors embraces many of the most eminent professors and teachers of London, Edinburgh, Dublin, and Glasgow. It is, indeed, the great merit of this work that the principal articles have been furnished by practitioners who have not only devoted especial attention to the diseases about which they have written, but have also enjoyed opportunities for an extensive practical acquaintance with them and whose reputation carries the assurance of their competency justly to appreciate the opinions of others, while it stamps their own doctrines with high and just authority.—*American Medical Journal*.

DEWEES'S COMPREHENSIVE SYSTEM OF MIDWIFERY. Illustrated by occasional cases and many engravings. Twelfth edition, with the author's last improvements and corrections. In one octavo volume, extra cloth, of 600 pages \$3 50.

DEWEES'S TREATISE ON THE PHYSICAL

AND MEDICAL TREATMENT OF CHILDREN. The last edition. In one volume, octavo, extra cloth, 542 pages. \$2 80

DEWEES'S TREATISE ON THE DISEASES OF FEMALES. Tenth edition. In one volume, octavo extra cloth, 532 pages, with plates. \$3 00.

NEW AND ENLARGED

MEDICAL LEXICON; a Dictionary of Medic

Explanation of the various Subjects and Terms of Anat. Therapeutics Pharmacology, Pharmacy, Surgery, Obstet &c. Notices of Climate and of Mineral Waters; Formulae Preparations, &c. With French and other Synonyms. In one very large and handsome octavo volume, of 992 (strongly bound in leather. Price \$4 00.

Especial care has been devoted in the preparation of it worthy a continuance of the very remarkable favor while sale of FIFTYTHREE large editions, and the constantly increasing profession as the standard authority. Stimulated by this present revision to introduce whatever might be necessary to—if not indispensable—lexicon, in which the student in every term that has been legitimated in the nomenclature large additions have been found requisite, and the extent of from the fact that about SIX THOUSAND subjects and terms dering the whole number of definitions about SIXTY THOUSAND of pages has been increased by nearly a hundred, notwithstanding the whole number of definitions about SIXTY THOUSAND of the page. The medical press, both in this country and in dispensable to all medical students and practitioners, and the that enviable reputation.

The publishers have endeavored to render the mechanical universal use in daily reference. The greatest care has been accuracy so necessary in a work of the kind. By the small an immense amount of matter is condensed in its thousand found strong and durable. With all these improvements and at the former very moderate rate, placing it within the reach

This work, the appearance of the fifteenth edition of which, it has become our duty and pleasure to announce, is perhaps the most stupendous monument of labor and erudition in medical literature. One would hardly suppose after constant use of the preceding editions, where we have never failed to find a sufficiently full explanation of every medical term, that in this edition "about six thousand subjects and terms have been added," with a careful revision and correction of the entire work. It is only necessary to announce the advent of this edition to make it occupy the place of the preceding one on the table of every medical man, as it is without doubt the best and most comprehensive work of the kind which has ever appeared.—*Buffalo Med. Journ.*, Jan. 1858.

The work is a monument of patient research, skilful judgment, and vast physical labor, that will perpetuate the name of the author more effectually than any possible device of stone or metal. Dr. Dunglison deserves the thanks not only of the American profession, but of the whole medical world.—*Norfolk Am. Medical-Chir. Review*, Jan. 1858.

A Medical Dictionary better adapted for the wants of the profession than any other with which we are acquainted, and of a character which places it far above comparison and competition.—*Am. Journ. Med. Sciences*, Jan. 1858.

We need only say, that the addition of 6,000 new terms, with their accompanying definitions, may be said to constitute a new work, by itself. We have examined the Dictionary attentively, and are most happy to pronounce it unrivalled of its kind. The erudition displayed, and the extraordinary industry which must have been demanded, in its preparation and perfection, redound to the lasting credit of its author, and have furnished us with a volume indispensable at the present day, to all who would find themselves as well as with the highest standards of medical information.—*Boston Medical and Surgical Journal*, Dec. 31, 1857.

Good lexicons and encyclopedic works generally, are the most labor-saving contrivances which literary men enjoy; and the labor which is required to produce them in the perfect manner of this example is something appalling to contemplate. The author

BY THE SAME AUTHO

THE PRACTICE OF MEDICINE. A Treati

reputation. Third Edition. In two large octavo volumes

DUNGLISON (ROBLEY), M. D.,

Professor of Institutes of Medicine in the Jefferson Medical College, Philadelphia.

HUMAN PHYSIOLOGY. Eighth edition. Thoroughly revised and extensively modified and enlarged, with five hundred and thirty-two illustrations. In two large and handsomely printed octavo volumes, extra cloth, of about 1500 pages. \$7 00.

In revising this work for its eighth appearance, the author has spared no labor to render it worthy a continuance of the very great favor which has been extended to it by the profession. The whole contents have been rearranged, and to a great extent remodelled; the investigations which of late years have been so numerous and so important, have been carefully examined and incorporated, and the work in every respect has been brought up to a level with the present state of the subject. The object of the author has been to render it a concise but comprehensive treatise, containing the whole body of physiological science, to which the student and man of science can at all times refer with the certainty of finding whatever they are in search of, fully presented in all its aspects; and on no former edition has the author bestowed more labor to secure this result.

We believe that it can truly be said, no more complete repertory of facts upon the subject treated, can anywhere be found. The author has, moreover, that enviable tact at description and that facility and ease of expression which render him peculiarly acceptable to the casual, or the studious reader. This facility, so requisite in setting forth many graver and less attractive subjects, lends additional charms to one always fascinating.—*Boston Med. and Surg. Journal*.

The most complete and satisfactory system of Physiology in the English language.—*Amer. Med. Journal*.

The best work of the kind in the English language.—*Silliman's Journal*.

The present edition the author has made a perfect mirror of the science as it is at the present hour. As a work upon physiology proper, the science of the functions performed by the body, the student will find it all he wishes.—*Nashville Journ. of Med.*

That he has succeeded, most admirably succeeded in his purpose, is apparent from the appearance of an eighth edition. It is now the great encyclopædia on the subject, and worthy of a place in every physician's library.—*Western Lancet*.

BY THE SAME AUTHOR. (A new edition.)

GENERAL THERAPEUTICS AND MATERIA MEDICA; adapted for a Medical Text-book. With Indexes of Remedies and of Diseases and their Remedies. SIXTH EDITION, revised and improved. With one hundred and ninety-three illustrations. In two large and handsomely printed octavo vols., extra cloth, of about 1100 pages. \$6 50.

In announcing a new edition of Dr. Dunglison's General Therapeutics and Materia Medica, we have no words of commendation to bestow upon a work whose merits have been heretofore so often and so justly extolled. It must not be supposed, however, that the present is a mere reprint of the previous edition; the character of the author for laborious research, judicious analysis, and clearness of expression, is fully sustained by the numerous additions he has made to the work, and the careful revision to which he has subjected the whole.—*N. A. Medico-Chir. Review*, Jan. 1858.

The work will, we have little doubt, be bought and read by the majority of medical students; its size, arrangement, and reliability recommend it to all; no one, we venture to predict, will study it without profit, and there are few to whom it will not be in some measure useful as a work of reference. The young practitioner, more especially, will find the copious indexes appended to this edition of great assistance in the selection and preparation of suitable formulas.—*Charleston Med. Journ. and Review*, Jan. 1858.

BY THE SAME AUTHOR. (A new Edition.)

NEW REMEDIES, WITH FORMULÆ FOR THEIR PREPARATION AND ADMINISTRATION. Seventh edition, with extensive Additions. In one very large octavo volume, extra cloth, of 770 pages. \$4 00.

One of the most useful of the author's works.—*Southern Medical and Surgical Journal*.

This elaborate and useful volume should be found in every medical library, for as a book of reference, for physicians, it is unsurpassed by any other work in existence, and the double index for diseases and for remedies, will be found greatly to enhance its value.—*New York Med. Gazette*.

The great learning of the author, and his remarkable industry in pushing his researches into every source whence information is derivable, have enabled him to throw together an extensive mass of facts and statements, accompanied by full reference to authorities; which last feature renders the work practically valuable to investigators who desire to examine the original papers.—*The American Journal of Pharmacy*.

ELLIS (BENJAMIN), M. D.

THE MEDICAL FORMULARY: being a Collection of Prescriptions, derived from the writings and practice of many of the most eminent physicians of America and Europe. Together with the usual Dietetic Preparations and Antidotes for Poisons. To which is added an Appendix, on the Endermic use of Medicines, and on the use of Ether and Chloroform. The whole accompanied with a few brief Pharmacœutic and Medical Observations. Eleventh edition, carefully revised and much extended by ROBERT P. THOMAS, M. D., Professor of Materia Medica in the Philadelphia College of Pharmacy. In one volume, 8vo., of about 350 pages. \$2 75. (Just Ready.)

On no previous edition of this work has there been so complete and thorough a revision. The extensive changes in the new United States Pharmacopœia have necessitated corresponding alterations in the Formulary, to conform to that national standard, while the progress made in the materia medica and the arts of prescribing and dispensing during the last ten years have been carefully noted and incorporated throughout. It is therefore presented as not only worthy a continuance of the favor so long enjoyed, but as more valuable than ever to the practitioner and pharmacist. Those who possess previous editions will find the additional matter of sufficient importance to warrant their adding the present to their libraries.

GROSS (SAMUEL D.),

Professor of Surgery in the Jefferson Medical Coll.

Enlarged Edition. Preparing for ear

A SYSTEM OF SURGERY: Pathological, Diagnostic. Illustrated by over TWELVE HUNDRED ENGRAVINGS. Carefully revised. In two large and beautifully printed royal

The exhaustion within five years of two large editions a work as this is the best evidence that the author was a man which existed of a complete American System of Surgery necessary details and in all its branches. That he has succeeded is shown not only by the rapid sale of the work, but also by the fact that it has been received by the organs of the profession in this country a translation is now preparing in Holland—a mark of appreciative work so extended in size.

The author has not been insensible to the kindness thus bestowed on the work for a third edition he has spared no pains to render it more complete. Every portion has been subjected to close scrutiny; deficiencies apparent have been supplied, and the results of recent surgery have been everywhere introduced; while the series enlarged, rendering it one of the most thoroughly illustrated. To accommodate these very extensive additions, the form is changed to octavo, so that notwithstanding the increase in the matter and more convenient than before. Every care will be taken in the execution unexceptionable, and it is confidently expected to find a place in even the most limited library of the practitioner of

Has Dr. Gross satisfactorily fulfilled this object? A careful perusal of his volumes enables us to give an answer in the affirmative. Not only has he given to the reader an elaborate and well-written account of his own vast experience, but he has not failed to embody in his pages the opinions and practice of surgeons in this and other countries of Europe. The result has been a work of such completeness, that it has no superior in the systematic treatises on surgery which have emanated from English or Continental authors. It has been justly objected that these have been far from complete in many essential particulars, many of them having been deficient in some of the most important points which should characterize such works. Some of them have been elaborate—too elaborate—with respect to certain diseases, while they have merely glanced at, or given an unsatisfactory account of, others equally important to the surgeon. Dr. Gross has avoided this error, and has produced the most complete work that has yet issued from the press on the science and practice of surgery. It is not, strictly speaking, a Dictionary of Surgery, but it gives to the reader all the information that he may require for his treatment of surgical diseases. Having said so much, it might appear superfluous to add another word; but it is only due to Dr. Gross to state that he has embraced the opportunity of transferring to his pages a vast number of engravings from English and other authors, illustrative of the pathology and treatment of surgical diseases. To these are added several hundred original woodcuts. The work altogether commends itself to the attention of British surgeons, from whom it cannot fail to meet with extensive patronage.—*London Lancet*, Sept. 1, 1860.

Of Dr. G. no more than a complete work has ever been written, but, did on some extent of the classical way in *Quarterly J*

Second Edition, revised and much enlarged, with one hundred and eighty-four illustrations. In one large and very handsome octavo volume, of over nine hundred pages, extra cloth, \$4 00.

Philosophical in its design, methodical in its arrangement, ample and sound in its practical details, it may in truth be said to leave scarcely anything to be desired on so important a subject.—*Boston Med. and Surg. Journal*.

Whoever will peruse the vast amount of valuable practical information it contains, will, we think,

agree with us, that there is no work in the English language which can make any just pretensions to be its equal.—*N. Y. Journal of Medicine*

A volume replete with truths and principles of the utmost value in the investigation of these diseases.—*American Medical Journal*.

GRAY (HENRY), F. R. S.,

Lecturer on Anatomy at St. George's Hospital, London, &c.

ANATOMY, DESCRIPTIVE AND SURGICAL. The Drawings by H. V. CARTER, M. D., late Demonstrator on Anatomy at St. George's Hospital; the Dissections jointly by the AUTHOR and Dr. CARTER. Second American, from the second revised and improved London edition. In one magnificent imperial octavo volume, of over 800 pages, with 388 large and elaborate engravings on wood. Price in extra cloth, \$7 00.

The speedy exhaustion of a large edition of this work is sufficient evidence that its plan and execution have been found to present superior practical advantages in facilitating the study of Anatomy. In presenting it to the profession a second time, the author has availed himself of the opportunity to supply any deficiencies which experience in its use had shown to exist, and to correct any errors of detail, to which the first edition of a scientific work on so extensive and complicated a science is liable. These improvements have resulted in some increase in the size of the volume, while twenty-six new wood-cuts have been added to the beautiful series of illustrations which form so distinctive a feature of the work. The American edition has been passed through the press under the supervision of a competent professional man, who has taken every care to render it in all respects accurate, and it is now presented, without any increase of price, as fitted to maintain and extend the popularity which it has everywhere acquired.

With little trouble, the busy practitioner whose knowledge of anatomy may have become obscured by want of practice, may now resuscitate his former anatomical lore, and be ready for any emergency. It is to this class of individuals, and not to the student alone, that this work will ultimately tend to be of most invaluable advantage, and we feel satisfied that the library of the medical man will soon be considered incomplete in which a copy of this work does not exist.—*Madras Quarterly Journal of Med. Science*, July, 1861.

This edition is much improved and enlarged, and contains several new illustrations by Dr. Westmacott. The volume is a complete companion to the dissecting-room, and saves the necessity of the student possessing a variety of "Manuals."—*The London Lancet*, Feb. 9, 1861.

The work before us is one entitled to the highest praise, and we accordingly welcome it as a valuable addition to medical literature. Intermediate in fulness of detail between the treatises of Sharpey and of Wilson, its characteristic merit lies in the number and excellence of the engravings it contains. Most of these are original, of much larger than ordinary size, and admirably executed. The various parts are also lettered after the plan adopted in Holden's Osteology. It would be difficult to over-estimate the advantages offered by this mode of pictorial illustration. Bones, ligaments, muscles, bloodvessels, and nerves are each in turn figured, and marked with their appropriate names; thus enabling the student to comprehend, at a glance, what would otherwise often be ignored, or at any rate, acquired only by prolonged and irksome application. In conclusion, we heartily commend the

work of Mr. Gray to the attention of the medical profession, feeling certain that it should be regarded as one of the most valuable contributions ever made to educational literature.—*N. Y. Monthly Review*, Dec. 1859.

In this view, we regard the work of Mr. Gray as far better adapted to the wants of the profession, and especially of the student, than any treatise on anatomy yet published in this country. It is destined, we believe, to supersede all others, both as a manual of dissections, and a standard of reference to the student of general or relative anatomy.—*N. Y. Journal of Medicine*, Nov. 1859.

In our judgment, the mode of illustration adopted in the present volume cannot but present many advantages to the student of anatomy. To the zealous disciple of Vesalius, earnestly desirous of real improvement, the book will certainly be of immense value; but, at the same time, we must also confess that to those simply desirous of "cramping" it will be an undoubted godsend. The peculiar value of Mr. Gray's mode of illustration is nowhere more markedly evident than in the chapter on osteology, and especially in those portions which treat of the bones of the head and of their development. The study of these parts is thus made one of comparative ease, if not of positive pleasure; and those bugbears of the student, the temporal and sphenoid bones, are shorn of half their terrors. It is, in our estimation, an admirable and complete text-book for the student, and a useful work of reference for the practitioner; its pictorial character forming a novel element, to which we have already sufficiently alluded.—*Am. Jour. Med. Sci.*, July, 1859.

GIBSON'S INSTITUTES AND PRACTICE OF SURGERY. Eighth edition, improved and altered. With thirty-four plates. In two handsome octavo volumes, containing about 1,000 pages, leather, raised bands. \$6 50.

NEILL (JOHN), M. D.,

Surgeon to the Pennsylvania Hospital, &c.; and

FRANCIS GURNEY SMITH, M. D.,

Professor of Institutes of Medicine in the Pennsylvania Medical College.

AN ANALYTICAL COMPENDIUM OF THE VARIOUS BRANCHES OF MEDICAL SCIENCE; for the Use and Examination of Students. A new edition, revised and improved. In one very large and handsomely printed royal 12mo. volume, of about one thousand pages, with 374 wood-cuts, extra cloth, \$3 50. Strongly bound in leather, with raised bands. \$4 50.

This work is again presented as eminently worthy of the favor with which it has hitherto been received. As a book for daily reference by the student requiring a guide to his more elaborate text-books, as a manual for preceptors desiring to stimulate their students by frequent and accurate examination, or as a source from which the practitioners of older date may easily and cheaply acquire a knowledge of the changes and improvement in professional science, its reputation is permanently established.

The best work of the kind with which we are acquainted.—*Med. Examiner.*

Having made free use of this volume in our examinations of pupils, we can speak from experience in recommending it as an admirable compend for students, and as especially useful to preceptors who examine their pupils. It will save the teacher much labor by enabling him readily to recall all of the points upon which his pupils should be examined. A work of this sort should be in the hands of every one who takes pupils into his office with a view of examining them; and this is unquestionably the best of its class.—*Pennsylvania Med. Journal.*

In the rapid course of lectures, where work for

the students is heavy, and review necessary for examination, a compend is not only valuable, but it is almost a *sine qua non*. The one before us is, in most of the divisions, the most unexceptionable of all books of the kind that we know of. The newest and soundest doctrines and the latest improvements and discoveries are explicitly, though concisely, laid before the student. There is a claim to whom we very sincerely commend this cheap book as worth its weight in silver—that class is the graduates in medicine of more than ten years' standing, who have not studied medicine since. They will perhaps find out from it that the science is not exactly now what it was when they left it off.—*The Stethoscope.*

NELIGAN (J. MOORE), M. D., M. R. I. A., &c.

ATLAS OF CUTANEOUS DISEASES. In one beautiful quarto volume, extra cloth, with splendid colored plates, presenting nearly one hundred elaborate representations of disease. \$5 50.

This beautiful volume is intended as a complete and accurate representation of all the varieties of Diseases of the Skin. While it can be consulted in conjunction with any work on Practice, it has especial reference to the author's "Treatise on Diseases of the Skin," so favorably received by the profession some years since. The publishers feel justified in saying that few more beautifully executed plates have ever been presented to the profession of this country.

Neligan's Atlas of Cutaneous Diseases supplies a long existent desideratum much felt by the largest class of our profession. It presents, in quarto size, 16 plates, each containing from 3 to 6 figures, and forming in all a total of 90 distinct representations of the different species of skin affections, grouped together in genera or families. The illustrations have been taken from nature, and have been copied with such fidelity that they present a striking picture of life; in which the reduced scale aptly serves to

give, at a coup d'œil, the remarkable peculiarities of each individual variety. And while thus the disease is rendered more definable, there is yet no loss of proportion incurred by the necessary concentration. Each figure is highly colored, and so truthful has the artist been that the most fastidious observer could not justly take exception to the correctness of the execution of the pictures under his scrutiny.—*Montreal Med. Chronicle.*

With numerous Cases, Formulæ, and Clinical Observations. From the Third and entirely rewritten London edition. In one neat octavo volume, extra cloth, of 316 pages. \$2 50.

PARRISH (EDWARD).

Professor of Materia Medica in the Philadelphia College of Pharmacy.

A TREATISE ON PHARMACY. Designed as a Text-book for the Student, and as a Guide for the Physician and Pharmaceutist. With many Formulas and Prescriptions. Third edition, greatly improved. In one handsome octavo volume, of 850 pages, with several hundred illustrations, extra cloth. \$5 00. (*Just Ready.*)

Though for some time out of print, the appearance of a new edition of this work has been delayed for the purpose of embodying in it the results of the new U. S. Pharmacopœia. The publication of this latter has enabled the author to complete his revision in the most thorough manner. Those who have been waiting for the work may therefore rely on obtaining a volume completely on a level with the most advanced condition of pharmaceutical science.

The favor with which the work has thus far been received shows that the author was not mistaken in his estimate of the want of a treatise which should serve as a practical text-book for all engaged in preparing and dispensing medicines. Such a guide was indispensable not only to the educated pharmacist, but also to that large class of practitioners throughout the country who are obliged to compound their own prescriptions, and who during their collegiate course have no opportunity of obtaining a practical familiarity with the necessary processes and manipulations. The rapid exhaustion of two large editions is evidence that the author has succeeded in thoroughly carrying out his object. Since the appearance of the first edition, much has been done to perfect the science; the new Pharmacopœia has introduced many changes to which the profession must conform; and the author has labored assiduously to embody in his work all that physicians and pharmacutists can ask for in such a volume. The new matter alone will thus be found worth more than the very moderate cost of the work to those who have been using the previous editions.

All that we can say of it is that to the practising physician, and especially the country physician, who is generally his own apothecary, there is hardly any book that might not better be dispensed with. It is at the same time a dispensatory and a pharmacy.—*Louisville Review.*

A careful examination of this work enables us to speak of it in the highest terms, as being the best treatise on practical pharmacy with which we are acquainted, and an invaluable *vide-mecum*, not only to the apothecary and to those practitioners who are accustomed to prepare their own medicines, but to every medical man and medical student.—*Boston Med. and Surg. Journal.*

This is altogether one of the most useful books we have seen. It is just what we have long felt to be needed by apothecaries, students, and practitioners of medicine, most of whom in this country have to put up their own prescriptions. It bears, upon every page, the impress of practical knowledge, conveyed in a plain common sense manner, and adapted to the comprehension of all who may read it.—*Southern Med. and Surg. Journal.*

That Edward Parrish, in writing a book upon practical Pharmacy some few years ago—one eminently original and unique—did the medical and pharmaceutical professions a great and valuable service, no one, we think, who has had access to its pages will deny; doubly welcome, then, is this new

edition, containing the added results of his recent and rich experience as an observer, teacher, and practical operator in the pharmaceutical laboratory. The excellent plan of the first is more thoroughly,—*Peninsular Med. Journal*, Jan. 1860.

Of course, all apothecaries who have not already a copy of the first edition will procure one of this; it is, therefore, to physicians residing in the country and in small towns, who cannot avail themselves of the skill of an educated pharmacist, that we would especially commend this work. In it they will find all that they desire to know, and should know, but very little of which they do really know in reference to this important collateral branch of their profession; for it is a well established fact, that, in the education of physicians, while the science of medicine is generally well taught, very little attention is paid to the art of preparing them for use, and we know not how this defect can be so well remedied as by procuring and consulting Dr. Parrish's excellent work.—*St. Louis Med. Journal*, Jan. 1860.

We know of no work on the subject which would be more indispensable to the physician or student desiring information on the subject of which it treats. With Griffith's "Medical Formulary" and this, the practising physician would be supplied with nearly or quite all the most useful information on the subject.—*Charleston Med. Jour. and Review*, Jan. 1860.

PEASLEE (E. R.), M. D.,

Professor of Physiology and General Pathology in the New York Medical College.

HUMAN HISTOLOGY, in its relations to Anatomy, Physiology, and Pathology; for the use of Medical Students. With four hundred and thirty-four illustrations. In one handsome octavo volume, extra cloth, of over 600 pages. \$3 75.

It embraces a library upon the topics discussed within itself, and is just what the teacher and learner need. We have not only the whole subject of Histology, interesting in itself, ably and fully discussed, but what is of infinitely greater interest to the student, because of greater practical value, are its relations to Anatomy, Physiology, and Pathology, which are here fully and satisfactorily set forth.—*Nashville Journ. of Med. and Surgery.*

We would recommend it as containing a summary of all that is known of the important subjects which it treats; of all that is in the great works of Simon and Lehmann, and the organic chemists in general. Master this one volume, and you know all that is known of the great fundamental principles of medicine, and we have no hesitation in saying that it is an honor to the American medical profession.—*St. Louis Med. and Surg. Journal.*

ROKITANSKY (CARL), M. D.,

Curator of the Imperial Pathological Museum, and Professor at the University of Vienna, &c.

A MANUAL OF PATHOLOGICAL ANATOMY. Four volumes, octavo, bound in two, extra cloth, of about 1200 pages. Translated by W. E. SWAIN, EDWARD SIVERKING, C. H. MOORE, and G. E. DAY. \$7 00.

The profession is too well acquainted with the reputation of Rokitansky's work to need our assurance that this is one of the most profound, thorough, and valuable books ever issued from the medical press. It is *sui generis*, and has no standard of comparison. It is only necessary to announce that it is issued in a form as cheap as is compatible with its size and preservation, and its sale follows as a matter of course. No library can be called complete without it.—*Buffalo Med. Journal.*

An attempt to give our readers any adequate idea of the vast amount of instruction accumulated in

these volumes, would be feeble and hopeless. The effort of the distinguished author to concentrate in a small space his great fund of knowledge, has so charged his text with valuable truths, that any attempt of a reviewer to epitomize is at once paralyzed, and must end in a failure.—*Western Lancet.*

As this is the highest source of knowledge upon the important subject of which it treats, no real student can afford to be without it. The American publishers have entitled themselves to the thanks of the profession of their country, for this timeous and beautiful edition.—*Nashville Journal of Medicine.*

WINSLOW (FORBES), M. D.,

ON OBSCURE DISEASES OF THE BRAIN

MIND; their incipient Symptoms, Pathology, Diagnosis, handsome octavo volume, of nearly 600 pages, extra cloth

We close this brief and necessarily very imperfect notice of Dr. Winslow's great and classical work, by expressing our conviction that it is long since so important and beautifully written a volume has issued from the British medical press.—*Dublin Med. Press*, July 26, 1869.

We honestly believe this to be the best book of the season.—*Rankin's Abstract*, July, 1869.

The latter portion of Dr. Winslow's work is exclusively devoted to the consideration of Cerebral Pathology the same relating to unnoticed monitory overrate perusal of interesting

WEST (CHARLES),

Accoucher to and Lecturer on Midwifery at St. Bartholomew's Sick Children, &c.

LECTURES ON THE DISEASES OF WOMEN

second London edition. In one handsome octavo volume price \$3 25.

* * * Gentlemen who received the first portion, as issued in 1860, now complete their copies by procuring Part II, being pages 80-160, 8vo., cloth, price \$1 25.

We must now conclude this hastily written sketch with the confident assurance to our readers that the work will well repay perusal. The conscientious, painstaking, practical physician is apparent on every page.—*N. Y. Journal of Medicine*.

We know of no treatise of the kind so complete and yet so compact.—*Chicago Med. Jour.*

A fairer, more honest, more earnest, and more reliable investigator of the many diseases of women and children is not to be found in any country.—*Southern Med. and Surg. Journal*.

We have to say of it, briefly and decidedly, that it is the best work on the subject in any language; and that it stamps Dr. West as the *facile princeps* of British obstetric authors.—*Edinb. Med. Jour.*

BY THE SAME AUTHOR

LECTURES ON THE DISEASES OF INFANTS

Third American, from the fourth enlarged and improved octavo volume, extra cloth, of about six hundred and fifty

The three former editions of the work now before us have placed the author in the foremost rank of those physicians who have devoted special attention to the diseases of early life. We attempt no analysis of this edition, but may refer the reader to some of the chapters to which the largest additions have been made—those on Diphtheria, Disorders of the Mind, and Idiocy, for instance—as a proof that the work is really a new edition; not a mere reprint. In its present shape it will be found of the greatest possible service in the every-day practice of nine-tenths of the profession.—*Med. Times and Gazette*, London, Dec. 10, 1869.

All things considered, this book of Dr. West is by far the best treatise in our language upon such modifications of morbid action and disease as are witnessed when we have to deal with infancy and childhood. It is true that it confines itself to such disorders as come within the province of the physician, and even with respect to these it is unequal as regards minuteness of consideration, and some
